

2024 ANNUAL CONGRESS

of the Schizophrenia
International Research Society

Responding to Challenges in a Changing World

ABSTRACT BOOK

3-7 April 2024

Florence, Italy

schizophreniaresearchsociety.org

Concurrent Workshops

3:15 p.m. - 5:15 p.m.

1. GLOBAL GUIDELINES FOR THE TREATMENT OF SCHIZOPHRENIA

Dan Siskind, *Metro South Addiction and Mental Health Service*

Overall Abstract: There are numerous treatment guidelines for schizophrenia and related psychotic disorders. However, these guidelines tend to be lengthy, and rarely provide precise recommendations for common clinical scenarios. As such, there is a risk that guidelines are not routinely useful in everyday practice. This is in direct contrast to physical health guidelines, which often distil recommendations into simple stepwise algorithms. Furthermore, the views of people with lived experience are rarely incorporated, meaning that recommendations may not be acceptable to patients. Finally, guidelines often lack global perspective, meaning that recommendations may not be universally feasible.

To address this, we have formed an international consortium to produce 'global guidelines' for the management of schizophrenia, including a treatment algorithm designed for day-to-day use. As part of the process, the consortium is working closely with people with lived experience of schizophrenia and incorporating a global view by engaging with international colleagues. A step-wise process has been followed, including use of umbrella literature reviews, patient focus groups, and a survey/Delphi Consensus of the Treatment Response and Resistance in Psychosis (TRRIP) working group, comprising GREATER THAN 80 clinical and academic experts from 29 countries.

The workshop will present the results of the project to date and involve the audience in the discussion of how to incorporate these into a global guideline. Prof Siskind will chair the workshop, Drs Pillinger and Varvari will present a summary of the umbrella review, Dr Kabir will report results of lived experience focus groups, Drs McCutcheon and Hahn will present the result of the Delphi Survey. Prof Chen will provide a perspective regarding barriers in low and middle income countries.

The workshop will be fully interactive with comment and debate encouraged. Attendees will:

- Gain understanding of the development of clinical guidelines, as per international Appraisal of Guidelines, Research and Evaluation (AGREE) principles.
- Gain insight into the views of patients regarding treatment of schizophrenia, and how these relate to those of clinicians.
- Gain access to the key outcomes of the guidelines, learning about state-of-the-art management approaches through interactive discussion.

1.1. GLOBAL GUIDELINES FOR SCHIZOPHRENIA- RESULTS OF DELPHI SURVEY

Margaret Hahn, *Center for Addiction and Mental Health*

1.2. GOLD-STANDARD MANAGEMENT OF SCHIZOPHRENIA: AN UMBRELLA REVIEW

Toby Pillinger, *Institute of Psychiatry, King's College London*

1.3. DEVELOPING A CONSENSUS FOR THE PHARMACOLOGICAL MANAGEMENT OF SCHIZOPHRENIA

Rob McCutcheon, *University of Oxford*

1.4. PATIENT PERSPECTIVES ON THE PROPOSED 'GLOBAL GUIDELINES' FOR THE MANAGEMENT OF SCHIZOPHRENIA

Thomas Kabir, *University of Oxford*

1.5. A CONCISE OVERVIEW FROM THE UMBRELLA REVIEW IN SCHIZOPHRENIA TREATMENT

Ioana Varvari, *University of Oxford, Oxford Health NHS Foundation Trust*

2. RESEARCH HARMONIZATION AWARD WORKSHOP

Sohee Park, *Vanderbilt University*

Overall Abstract: The past decade has seen rapid development, worldwide, of digital health interventions (DHIs) for people with serious mental health problems, including schizophrenia-spectrum psychosis. When evaluating any health intervention, it is vital to measure and collect empirical data on potential harms as well as potential benefits. Patients, healthcare professionals, policy makers, regulators and funding bodies need this information when deciding whether to use, recommend, certify, prescribe and/or fund a specific health intervention. Despite accumulating evidence of feasibility and acceptability of DHIs for serious mental health problems, and emerging evidence of efficacy, information about their safety is not always systematically collected. Reporting of harms remains generally poor in DHI trials and there is a lack of consistency across trials and countries.

We were awarded the SIRS 2021-2023 Research Harmonisation Award, Digital Health to convene an international network to address the need for greater harmonisation for adverse events reporting in digital psychosis research. A service user researcher in our network emphasised this issue's relevance as follows: "It is important for us to know if technology is safe, and that researchers will value our worldview and actually listen and take note of adverse experiences and formally consider if they should be recorded as an adverse event."

We are a group comprising members from seven countries and include individuals with lived experience of psychosis, early career and senior researchers. To meet our objectives, we drew on existing datasets and members' international expertise, taking particular care to consider lived experience perspectives, cross-cultural issues and international differences. This workshop will consist of the following presentations, delivered by members of our multi-disciplinary iCharts network:

1. iCharts network aims, objectives and methods.
2. Phase 1 findings on the nature and range of adverse events reports.
3. Phase 2 findings from an in-depth analysis of adverse events SOPs.
4. Practical recommendations arising from the programme of work.

2.1. TRANSDIAGNOSTIC AND CROSS-CULTURAL ASSESSMENT OF SOCIAL COGNITION – INITIAL FINDINGS FROM THE SIRS HARMONIZATION AWARD

Amy Pinkham, *The University of Texas at Dallas*

2.2. MINDSET. MINIMUM DATA STANDARDS FOR SCHIZOPHRENIA AND THE ENVIRONMENT

Nicolas Crossley, *Facultad de Medicina, P. Universidad Catolica de Chile*

Sinan Guloksuz, *Maastricht University*

2.3. POOLING AND HARMONIZATION OF PSYCHOSIS COHORT DATA - THE IPEC GUIDE AND VIRTUAL DATABANK

Wim Veling, *University Medical Center Groningen*

3. FINDINGS FROM THE SIRS-FUNDED ICHARTS NETWORK: INTERNATIONAL COLLABORATION FOR HARMONISING ADVERSE EVENTS REPORTING IN TECHNOLOGY FOR SERIOUS MENTAL HEALTH PROBLEMS

Sandra Bucci, *The University of Manchester*

Overall Symposia Abstract: The past decade has seen rapid development, worldwide, of digital health interventions (DHIs) for people with serious mental health problems, including schizophrenia-spectrum psychosis. When evaluating any health intervention, it is vital to measure and collect empirical data on potential harms as well as potential benefits. Patients, healthcare professionals, policy makers, regulators and funding bodies need this information when deciding whether to use, recommend, certify, prescribe and/or fund a specific health intervention. Despite accumulating evidence of feasibility and acceptability of DHIs for serious mental health problems, and emerging evidence of efficacy, information about their safety is not always systematically collected. Reporting of harms remains generally poor in DHI trials and there is a lack of consistency across trials and countries.

We were awarded the SIRS 2021-2023 Research Harmonisation Award, Digital Health. Our objective was to convene an international network to address the need for greater harmonisation for adverse events reporting in digital psychosis research. There is currently no internationally recognised guidance on how to measure, monitor and record adverse events associated with DHIs specifically, with existing guidelines focusing largely on how to monitor and report harms in pharmacological trials. As the field of digital health for psychosis moves beyond feasibility studies into larger trials testing the efficacy and effectiveness of DHIs, and ultimately their implementation, it is an optimum time to harmonise measurement and reporting practices, ensuring future studies systematically monitor and record important safety information. A service user researcher in our network emphasised this issue's relevance as follows: "It is important for us to know if technology is safe, and that researchers will value our worldview and actually listen and take note of adverse experiences and formally consider if they should be recorded as an adverse event."

Convened by Professor Sandra Bucci, our iCharts network (International Collaboration for Harmonising Adverse Event Reporting in Technology for Serious Mental Health Problems) is a group of international experts comprising members from seven countries (UK, Belgium, Germany, Pakistan, Australia, USA, China), including two Low- or Middle-Income Countries (Pakistan, China). Network members include individuals with lived experience of psychosis, and an equal number of early career and senior researchers. To meet our objectives, we drew on existing datasets and members' international expertise, taking particular care to consider

lived experience perspectives, cross-cultural issues and international differences. We carried out the work in two phases to address different aspects of our harmonisation aim. In Phase 1, we collected raw adverse events data from existing digital psychosis studies to catalogue the nature and range of adverse events reported in this context. In Phase 2, we collated and analysed adverse events Standard Operating Procedures (SOPs) to develop best-practice recommendations and a practical resource to support adverse event measurement, monitoring, recording and safety reporting in DHI studies for people with psychosis.

This symposium will consist of the following presentations, delivered by members of our multi-disciplinary iCharts network:

1. iCharts network aims, objectives and methods.
2. Phase 1 findings on the nature and range of adverse events reports.
3. Phase 2 findings from an in-depth analysis of adverse events SOPs.
4. Practical recommendations arising from the programme of work.

3.1. ICHARTS NETWORK AIMS, OBJECTIVES, METHODS AND COMPOSITION

Sandra Bucci^{*1}, Emily Eisner², Stephanie Allan³, Mario Alvarez-Jimenez⁴, Imogen Bell⁵, Matteo Cella⁶, Imran Chaudhry², Joseph Firth², Philippa Garety⁷, John Gleeson⁸, Eric Granholm⁹, Andrew Gumley³, Amy Hardy¹⁰, Thomas Kabir¹¹, Tayyeba Kiran¹², Inez Myin-Germeys¹³, Ulrich Reininghaus¹⁴, Cara Richardson², Mar Rus-Calafell¹⁵, Anita Schick¹⁶, Matthias Schwannauer¹⁷, Suzie Syrett³, Neil Thomas¹⁸, John Torous¹⁹, Evelyne van Aubel²⁰, Thomas Ward²¹, Xiaolong Zhang²²

¹The University of Manchester, ²University of Manchester, ³University of Glasgow, ⁴Orygen, The University of Melbourne, ⁵Orygen, ⁶Institute of Psychiatry, Psychology and Neuroscience King's College London, ⁷Kings College London, ⁸Australian Catholic University, ⁹UCSD, ¹⁰Institute of Psychiatry, Psychology and Neuroscience, King's College London, ¹¹The McPin Foundation, ¹²Pakistan Institute of Living and Learning, ¹³KU Leuven, Center for Contextual Psychiatry, ¹⁴Central Institute of Mental Health, University of Heidelberg, ¹⁵Ruhr University Bochum, ¹⁶Central Institute of Mental Health, ¹⁷University of Edinburgh, ¹⁸Swinburne University of Technology, ¹⁹BIDMC / Harvard Medical School, ²⁰Center for Contextual Psychiatry, KU Leuven, ²¹King's College London, ²²Beijing Anding Hospital

Background: The Good Clinical Practice guidelines of the International Council for Harmonization (GCP-ICH) foreground the importance of monitoring adverse events, defined as “any untoward medical occurrence in a patient or clinical investigation subject administered a pharmaceutical product and which does not necessarily have a causal relationship with this treatment”. Concerns have been expressed regarding the conceptualization and reporting of adverse events within trials of psychosocial interventions more generally, and in psychosis specifically, because standard definitions were developed for pharmacological trials. While monitoring adverse events is standard practice in clinical trials of DHIs, a recent review highlighted significant issues with respect to transparency of reporting, in particular regarding relatedness of an adverse event to a specific DHI. To address this gap, we convened an international network and, in this symposium, present the findings from our two-year programme of work on this focused topic.

Methods: In this symposium, we present the findings from two key aims of the iCharts network: i) collate and analyse individual level records of adverse events from published international digital health trials for psychosis using content analysis alongside a coding framework approach; and ii) systematic literature search alongside a framework analysis approach to develop a practical, open-source adverse events reporting procedure/tool specific to digital mental health, freely available for the research community.

Results: iCharts comprises international experts working on developing and evaluating DHIs for psychosis and includes experts by experience and clinical/academic researcher from seven countries (UK, Belgium, Germany, Pakistan, Australia, USA, China), including two Low- or Middle-Income Countries (LMIC; Pakistan, China). Carried out across two phases, two 'writing groups' were formed to address different aspects of our harmonization aim. Writing Group 1 collated 593 raw adverse events data from 18 digital psychosis studies to catalogue the nature and range of adverse events reported in digital psychosis trials. Writing Group 2 collated and analyzed 32 adverse events Standard Operating Procedures (SOPs)/guidelines to develop the open-source reporting resource.

Conclusions: Our successful international network of multi-disciplinary researchers has identified putative adverse events researchers can expect to record when conducting digital psychosis studies and has developed best-practice guidelines and a practical resource for adverse event monitoring. The importance of adverse events monitoring, the procedure we followed to establish this successful multi-disciplinary network and to derive our outputs, will be described in this presentation.

3.2. ADVERSE EVENTS REPORTING IN DIGITAL INTERVENTIONS EVALUATIONS FOR PSYCHOSIS: A SYSTEMATIC LITERATURE SEARCH AND INDIVIDUAL LEVEL CONTENT ANALYSIS OF ADVERSE EVENT REPORTS

Stephanie Allan^{*1}, Thomas Ward², Emily Eisner³, John Torous⁴, Ulrich Reininghaus⁵, Imogen Bell⁶, Matteo Cella⁷, Imran Chaudhry³, Thomas Kabir⁸, Matthias Schwannauer⁹, Xiaolong Zhang³, Suzanne Syrett¹, Tayyeba Kiran¹⁰, Aansha Priya³, Cara Richardson³, Anita Schick¹¹, Sandra Bucci¹²

Background: Many people with psychosis do not get access to evidence-based care. Digital health interventions (DHIs) have significant potential to upscale treatment access to people experiencing psychosis. However, these interventions raise specific concerns around patient safety because many can be used by patients at home without a clinician available to monitor for negative consequences of intervention usage. Adverse Event monitoring and reporting is the gold standard used to identify, record, and manage safety issues in clinical trials. However, little is known about the specific content and context contained within extant Adverse Event reports in trials of DHIs and how these are reported. Additionally, different studies and countries use different reporting standards and may not agree on whether what a participant experiences are an Adverse Event. To address this gap, this study had two aims: 1) to work as

an international team to assess current Adverse Event reporting within DHIs for psychosis by analysing individual-level Adverse Event reports to identify what types of adverse experiences have been reported in DHIs, and 2) To identify areas for improvement in Adverse Event reporting.

Methods: A systematic literature search was conducted to identify evaluations of DHIs in psychosis populations. Study authors were approached via email, by the iCharts network convener and asked to provide anonymised Adverse Events reports. A content analysis was then conducted on the individual level Adverse Event reports shared by DHI trialists working in this field.

Results: Of 169 study authors approached, 20% agreed to share AE reports. A total of 593 anonymized Adverse Event reports were shared from 18 DHI evaluations across six countries. The content analysis identified 19 codes linked to adverse consequences of DHI usage. Psychiatric admission (23%) and psychosis exacerbation (22%) were the two most frequently coded categories. Only 29 Adverse Events (4.9% of total) were reported to be related to the interventions or study procedures. While overall results support the safety of DHIs, in a minority of cases, in a minority of cases DHIs were linked to mood problems and psychosis such as an increase in paranoia. Importantly, 27% of studies did not report information on relatedness for all or at least some Adverse Events. Additionally, 9.6% of Adverse Event reports were unclear because it could not clearly be determined what had happened to the participant.

Conclusions: The results from the studies that shared data support the safety of DHIs, but it is important that Adverse Events are routinely monitored, and intervention evaluated according to best practice. This may be achieved by a change of adverse event reporting culture where adverse events are viewed not as a negative outcome of a research trial, but as a valuable outcome measurement that can enable both clinicians and patients to make informed decisions when offering individual patients a DHI. To help achieve this, the iCharts group have provided recommendations for reporting in future studies including guidance for optimising the collection and sharing of anonymised adverse event reports.

3.3. PHASE 2 FINDINGS FROM AN IN-DEPTH ANALYSIS OF ADVERSE EVENTS SOPS

Xiaolong Zhang^{*1}, Emily Eisner², Cara Richardson², Neil Thomas³, Mar Rus-Calafell⁴, Suzy Syrett⁵, Joseph Firth², Andrew Gumley⁵, Amy Hardy⁶, Stephanie Allan⁵, Thomas Kabir⁷, Aansha Priyam², Sandra Bucci²

¹Beijing Anding Hospital, Capital Medical University, ²University of Manchester, Manchester, ³Swinburne University of Technology, Melbourne, ⁴Ruhr-Universitat Bochum, ⁵University of Glasgow, Glasgow, ⁶King's College London, London, ⁷The McPin Foundation, London

Background: Given the rapid expansion of research into digital health interventions (DHIs) for serious mental health problems, robust and consistent monitoring of their potential harms is crucial. However, reviews suggest that measurement and reporting of adverse events are currently inconsistent across DHI studies. Existing international guidelines focus largely on how to monitor and report harms in pharmacological trials; guidelines specific to DHIs for people with psychosis are lacking. We aimed to examine how existing international guidelines have been operationalised, to date, in the context of DHI studies for psychosis, in order to describe and build on current methods, identify best practice, make recommendations for ideal adverse events monitoring procedures and develop a practical resource to aid future researchers.

Methods: A systematic literature search identified relevant studies testing DHIs in samples with schizophrenia-spectrum psychosis. The iCharts convener approached authors of eligible studies, via email, and asked them to provide a document outlining their Standard Operating Procedure (SOP) for monitoring and reporting adverse events. Additional grey literature searches were used to identify publicly available adverse events SOPs from funders and relevant national regulators, agencies or governmental departments. All retrieved SOPs were analysed using framework analysis. Following an initial round of coding, it was evident that the study SOPs did not fully document the details of all procedures of relevance to adverse events monitoring and recording; additional information was obtained from study authors (n=11).

Results: SOPs were obtained from DHI studies (n=15), funders or regulators (n=12), and health services or universities (n=5). Study SOPs came from studies testing a variety of DHIs and levels of blending, across seven countries and various study designs (full-scale RCT, feasibility RCT, cohort study, pilot study). Framework analysis of SOPs identified commonalities for best practice for certain domains, but also revealed some inconsistencies, challenges and methodological gaps. We found the core adverse event definitions were largely consistent across SOPs and in line with existing pharmacological guidelines, albeit with “investigational medicinal product” replaced by more relevant terms (e.g. “digital health tool”, “investigational psychological therapy”). However, our analysis suggested certain inherent difficulties of applying existing definitions and guidelines from the pharmacological literature to non-pharmacological trials in relation to defining seriousness, relatedness and expectedness of adverse events. Our analysis also revealed substantial gaps in adverse event SOPs regarding how adverse events should be elicited and regarding research staff training/supervision. We found a reliance on implicit knowledge about these processes rather than explicit documentation in SOPs. Our analysis and additional information provided by study authors allowed us to make explicit recommendations for the benefit of future researchers.

Conclusions: Based on this detailed analysis of 32 adverse events SOPs, we developed best-practice guidelines and a practical resource for adverse event monitoring in DHI studies for psychosis, details of which will be discussed in Presentation 4 of the symposium.

3.4. PRACTICAL RECOMMENDATIONS ARISING FROM THE PROGRAMME OF WORK

Emily Eisner^{*1}, Cara Richardson¹, Neil Thomas², Mar Rus-Calafell³, Suzanne Syrett⁴, Joseph Firth¹, Andrew Gumley⁴, Amy Hardy⁵, Stephanie Allan⁴, Thomas Kabir⁶, Aansha Priyam⁷, Sandra Bucci⁸

¹University of Manchester, ²Swinburne University of Technology, ³Ruhr-Universität Bochum, ⁴University of Glasgow, ⁵Institute of Psychiatry, Psychology and Neuroscience, King's College London, ⁶The McPin Foundation, ⁷University of Manchester, Manchester, ⁸The University of Manchester

Background: In undertaking the work described in presentations 1-3, the iCharts network sought to develop best-practice recommendations and practical resources to support adverse event measurement, monitoring, recording and safety reporting in DHI studies for people with psychosis.

Methods: The final presentation of the symposium will pull together core recommendations from across the iCharts programme of work, provide details of a practical resource that will be made publicly available to other researchers in the field, and outline future considerations regarding adverse events monitoring in this area.

Results: Recommendations: We will discuss recommendations regarding: responsibilities of individuals and committees in relation to managing adverse events; definitions of terms; how adverse events may be elicited; avoiding unblinding researchers while managing adverse events; training and supervising research workers in adverse events procedures; meeting adverse events safety reporting requirements; reporting adverse events in publications and reports. Practical resource: We will provide details of a template adverse events SOP, collating our findings from across the framework analysis of SOPs, which will be made publicly available under a Creative Commons Attribution (CC BY). This resource is intended to provide a starting point from which researchers can create an adverse event SOP for use in studies that include a DHI or other digital health tool. Adverse event measurement in this field is likely to evolve over time as DHI studies for psychosis become widespread, and as common adverse events are better documented and known. Our intention is for the publicly available template SOP to be a live document, updated at intervals as needed.

Conclusions: Future considerations: As the empirical evidence supporting the efficacy of DHIs for psychosis accumulates, it will become increasingly important to develop adverse event monitoring procedures in relation to wider implementation of DHIs in health services, outside of a clinical research context. Such procedures will likely depend on local and national governance processes. Nevertheless, stakeholders would benefit from international consistency regarding how adverse event monitoring is managed and reported in the context of implementation, and extended international guidelines would be welcomed. Ultimately, it is essential that data on potential harms of DHIs is collected and made public, whether in a research context or during implementation, so that stakeholders (e.g. patients, health professionals, policy makers, regulators, funding bodies) can access this information when deciding whether to use, recommend, certify, prescribe and/or fund a specific DHI.

Our findings contribute towards international efforts to standardise the measurement and reporting of adverse events in the emerging field of digital mental health to ensure that the safety aspects of DHIs for SMI are well-studied in research and well-understood by those ultimately implementing such interventions.

Keynote: Dr. German Berrios - Psychopathology in a Historical and Cultural Context
6:15 p.m. - 7:15 p.m.

4. PSYCHOPATHOLOGY AND TIME: AN UNEXPLORED RELATIONSHIP

Eric YH Chen, *Nanyang Technical University LKC School of Medicine, Singapore*

4.1. “PSYCHOPATHOLOGY AND TIME: AN UNEXPLORED RELATIONSHIP”

German Berrios, *University of Cambridge*

Individual Abstract: The discipline now called ‘Psychopathology’ was constructed early in the 19th century. An ancillary discipline of Alienism (Psychiatry), it created a set of objects or units of analysis meant to stand alone (diagnosis) and be relatable to the brain (aetiology). Borrowing from medical semiology, ‘mental symptoms’ were configured as existing in the ‘here and now’ (i.e. cross-sectionally, synchronically).

Ab initio, Psychopathology included the Newtonian definition of time as an eternal container. The need to organize serially their objects of interest and create interpretative frames (this is the origin of the theory of evolution) led neighbouring disciplines such as biology and geology to search for a view of time as interactional duration. Psychopathology opted for a compromise: mental diseases became 'temporalized' leading to redefinitions of acuteness and chronicity; but mental symptoms continued being considered as mere atemporal tokens of a prototype. This view remains popular today.

In this lecture it will be hypothesized that a temporalization of at least some mental symptoms should throw additional light onto their structure. It is a common clinical observation that in the acute state of a psychosis some symptoms (e.g. hallucinations and delusions) are oscillatory, that is, come in and out of awareness. This begs the question of whether for each new appearance the symptoms are generated anew or whether they remain extant at some level and their oscillations are caused by masking variables such as distraction, emotional valence, etc.

Equally interesting is the issue of whether chronicity causes a change in symptom structure. It will be further hypothesized that symptoms present in the first episode and in later episodes (although still called by the same name) are in fact different phenomena. In other words, hallucinations seen in a first episode can be considered as prototypical whilst those seen in later episodes are just overlearned behavioural phenocopies.

Lastly, there is the intriguing proposal by Von Monakow and Mourgue suggesting that "chronogenic brain localization" should replace conventional 'geometric localization'. The main implication of this claim concerns the relevance of time to the definition of mental symptoms and psychopathologists need to express a view in this regard.

In summary, it is the purpose of this lecture to show that:

- 1) to remain relevant to psychiatry and neurobiology psychopathology needs to keep reconstructing/updating its conceptual structure; and,
- 2) one of the roles of the epistemological analysis of psychopathology is to generate questions of direct empirical import, relevant to both diagnosis and treatment. This point has been illustrated in this lecture by showing how the addition of time frames illuminates our understanding of mental symptoms.

Plenary Session I: Robin Emsley - Psychopharmacological Developments and the Quest for Optimal Outcomes in Schizophrenia

9:00 a.m. - 10:00 a.m.

5. PSYCHOPHARMACOLOGICAL DEVELOPMENTS AND THE QUEST FOR OPTIMAL OUTCOMES IN SCHIZOPHRENIA

Gemma Modinos, *King's College London*

5.1. PSYCHOPHARMACOLOGICAL DEVELOPMENTS AND THE QUEST FOR OPTIMAL OUTCOMES IN SCHIZOPHRENIA

Robin Emsley, *Faculty of Medicine and Health Sciences, Stellenbosch University*

Individual Abstract: Antipsychotics have been the mainstay of treatment for schizophrenia since the 1950s, and their beneficial effects are extensively documented. Despite their efficacy in alleviating symptoms of acute psychosis, the real-world outcome for afflicted individuals is frequently poor. The course of illness is typically characterised by multiple relapses, accruing morbidity and enduring cognitive and functional deficits. The limitations of currently available antipsychotics have been clearly demarcated and include their relative lack of efficacy against symptoms other than those of psychosis, as well as their very significant side effect burden. Nevertheless, even within the context of these limitations, the judicious and correct use of antipsychotics in clinical practice may provide critical opportunities for clinicians to facilitate a favourable treatment outcome. Masses of data from drug development clinical trials together with real world outcome studies have improved our understanding of the way the illness responds to treatment and have enabled us to focus on those aspects that are malleable to treatment. Key aspects include early effective intervention; using the lowest effective dose to minimise the exquisite sensitivity of individuals to adverse effects in the early stages of treatment; adopting a person-centred approach to promote treatment engagement and focussing psychosocial and pharmacological interventions on medication adherence. While exciting alternatives to dopamine blocking antipsychotics are in an advanced stage of development, the basic treatment principles will remain the same.

Concurrent Symposia

10:00 a.m. - 12:00 p.m.

6. PREDICTING OUTCOME IN UHR: A PERSPECTIVE FROM DATA ANALYSIS AND STUDY COORDINATION

René Kahn, *Icahn School of Medicine at Mount Sinai*

Overall Symposia Abstract: The Accelerated Medicine Partnership- Schizophrenia (AMP-SCZ) was launched in 2020 to “address the critical need for more effective treatments for people with schizophrenia and related mental health conditions” (ampscz.org). AMP-SCZ is a large international longitudinal study of individuals at clinical high risk (CHR) for psychosis who have repeated multimodal assessments, including cognition, MRI, EEG, fluid biomarkers, digital markers, communication behavior and symptoms. It includes multiple languages and spans 42 sites. The project involves collecting data from approximately 2000 CHR individuals and 640 matched healthy controls. This data includes a wide range of longitudinal assessments, such as clinical, environmental, cognitive, biobehavioral, neuroimaging, electrophysiology, and fluid biospecimens markers. Additionally, AMP SCZ collects speech and facial expression samples, as well as measures from novel digital health technologies, passive sensing and actigraphy.

Modern research management assumes a data governance model in which grantees are considered stewards rather than owners of important data sets, and thus there is an expectation that samples are shared with the widest possible community of researchers who can collaborate to gain insights. This presents challenges in the study of complex, heterogeneous conditions involving sensitive health information, which require balancing privacy and autonomy of individuals with the needs of the research community.

This symposium will present data from the 4 cores of the AMP-SCZ, Data Processing, Analysis, and Coordination Center (DPACC) overseeing the data collection, analysis, and dissemination of AMP-SCZ.

The first core will be presented by Cheryl Corcoran from the Icahn School of Medicine at Mount Sinai in New York. The AMP-SCZ DPACC Core 1 has overseen coordination and monitoring for the ongoing AMP-SCZ consortium, with key deliverables including the development and standardization of SOP's across data domains or modalities, to be available to the broader research community, and the use of dashboards and automated programs with high utility for visualization and monitoring of recruitment, data completeness, demographics, and importantly QA/QC that includes ethical, human subjects and safety issues.

The second core will be presented by Sylvain Bouix, from the École de technologie supérieure in Montreal, Canada, reporting on the data operation ecosystem crafted for the AMP SCZ project, a complex, international multisite observational study of young individuals who are at clinical high risk (CHR) for developing a psychotic condition, such as schizophrenia.

The third core, presented by Ofer Pasternak from Harvard University, plays a crucial role in defining and parametrizing the clinical endpoints of the observational study highlighting the significant advantages of intermediate data fusion techniques, like multi-kernel learning (MKL), compared to single modality predictors. He will also present the utility of Dynamic Time Warping approaches, demonstrating the predictive advantage of using longitudinal data as opposed to relying solely on single time point predictors.

The dissemination of program resources developed by the AMP SCZ program is performed by the Dissemination core (Core 4) which will be presented by Tina Kapur from Harvard University which has overseen the dissemination of resources from the AMP SCZ program to the broader community using the program website and has promoted the voices of people with lived experience to enhance the work, resulting in better science and greater community partnership.

6.1. DPACC CORE 1: COORDINATION AND MONITORING ACTIVITIES KEY TO SUCCESSFUL DATA COLLECTION IN THE ACCELERATING MEDICINES PARTNERSHIP IN SCHIZOPHRENIA

Cheryl Corcoran^{*1}, Michael Coleman², Inge Winter-van Rossum³, Owen Borders⁴, Kathryn Lewandowski⁵, Alessia McGowan⁶, Suzanne Garcia⁷, Marek Kubicki⁴, Grace Jacobs⁸, Anastasia Haidar⁴, Nora Penzel⁹, Sylvain Bouix¹⁰, Justin Baker⁵, Rene Kahn¹, Martha Shenton⁴

¹Icahn School of Medicine at Mount Sinai, ²McLean Hospital, ³UMC Utrecht, ⁴Brigham and Women's Hospital, Harvard Medical School, ⁵Harvard Medical School/McLean Hospital, ⁶Icahn School of Medicine At Mount Sinai, ⁷NIMH, ⁸Brigham and Womens Hospital, ⁹Massachusetts General Hospital, Harvard Medical School, ¹⁰École de Technologie Supérieure,

Background: AMP-SCZ was launched in 2020 to “address the critical need for more effective treatments for people with schizophrenia and related mental health conditions” (ampscz.org). AMP-SCZ is a large international longitudinal study of individuals at clinical high risk (CHR) for psychosis who have repeated multimodal assessments, including cognition, MRI, EEG, fluid biomarkers, digital markers, communication behavior and symptoms. It includes multiple languages and spans 42 sites. Together, these features raise challenges for effective coordination, and standardized collection and monitoring of multimodal data over time.

Methods: AMP-SCZ DPACC Core 1 has been tasked with consortium coordination, standardization and monitoring of data collection. For coordination, this has entailed

scheduling, recording and note-taking for meetings, including for the expertise teams for each data modality; the development and monitoring of all Standard Operating Procedures (SOPs), including training, and the building out of complex RedCAP data entry forms and databases for all study measures and variables (data and metadata), including the new PSYCHS (Positive SYmptoms and Diagnostic Criteria for the CAARMS Harmonized with the SIPS) clinical assessment instrument, key for CHR case ascertainment, measures of symptom severity and occurrence of primary outcomes (e.g., psychosis transition).

For monitoring, AMP-SCZ DPACC Core 1 has overseen measurement fidelity and performance tracking (quality assurance/quality control or QA/QC), ensuring human subject protections and ethical practices (review of IRB documentation, eligibility, informed consent procedures), and oversight and reporting of recruitment and retention rates, demographics, and trends in data collection.

Results: AMP-SCZ Core 1 has created key tools and deliverables, in collaboration with other Cores, that will be available broadly to investigators. In collaboration with Core 2, SOPs were iteratively developed for each data modality (domain), with detailed descriptions of data collection from recruitment to data acquisition, QA/QC, storage and transfer, including training, specific to each domain. In collaboration with Core 4, these SOPs will be disseminated through the ampscz.org website. Further, each Data Domain Team will publish a protocol paper to be included in a special issue of *Nature Schizophrenia* dedicated to AMP-SCZ.

For monitoring, in collaboration with Core 2, automated tools were developed to assess data quality, reliability and other QA/QC metrics for frequent monitoring and rapid feedback to data collection sites and NIMH. A sophisticated dashboard was developed for visualization and to track recruitment/retention, demographics and trends in data collection. The AMPSCZ Data Dashboard has 18 figures that provide information on recruitment, data completeness, demographics, and more.; its purpose is to visualize information that can assist in recruiting the correct demographics for the study, identify unforeseen systemic issues, and make important general information easily accessible. Features include filters for the two networks, individual sites, forms, timepoints, and more. There is also a subject search function that allows information for individual subjects to be viewed.

Specific to QA/QC, manual monitoring by a clinical trialist of 21% of subjects (143 of 686), identifying mostly minor and correctable issues with forms, with immediate feedback provided. In 2023, extensive scripts were set up for automatic checks on most assessments entered into electronic data capture. This extensive data completeness check now allows QA/QC on the full sample, with checks available to data collection networks continuously.

Conclusions: The AMP-SCZ DPACC Core 1 has overseen coordination and monitoring for the ongoing AMP-SCZ consortium, with key deliverables including the development and standardization of SOP's across data domains or modalities, to be available to the broader research community, and the use of dashboards and automated programs with high utility for visualization and monitoring of recruitment, data completeness, demographics, and importantly QA/QC that includes ethical, human subjects and safety issues. These tools will be implemented in the next clinical trial stage of AMP-SCZ.

6.2. DATA OPERATIONS FOR THE AMP SCZ PROJECT

Sylvain Bouix^{*1}, Justin Baker², Tashrif Billah³, Kang-Ik Kevin Cho³, Yoonho Chung², Michaela Ennis², Grace R. Jacobs³, Einat Liebenthal², Daniel Mathalon⁴, Spero Nicholas⁴, Ofer Pasternak³, Habiballah Rahimi-Eichi², Phillip Wolff⁵, René Kahn⁶, Martha E. Shenton³

¹*École de Technologie Supérieure*, ²*McLean Hospital, Harvard Medical School*, ³*Brigham and Women's Hospital, Harvard Medical School*, ⁴*University of California, San Francisco*, ⁵*Emory University*, ⁶*Icahn School of Medicine At Mount Sinai*

Background: Modern research management assumes a data governance model in which grantees are considered stewards rather than owners of important data sets, and thus there is an expectation that samples are shared with the widest possible community of researchers who can collaborate to gain insights. This presents challenges in the study of complex, heterogeneous conditions involving sensitive health information, which require balancing privacy and autonomy of individuals with the needs of the research community. Here, we report on the data operation ecosystem crafted for the AMP SCZ project, a complex, international multisite observational study of young individuals who are at clinical high risk (CHR) for developing a psychotic condition, such as schizophrenia.

Methods: The data flow for this project is unique in that it requires coordination between two research networks each managing different data capture ecosystems, the Data Processing Analysis Coordination Center (DPACC) overseeing data QC, processing, and visualization, and the NIMH Data Archive (NDA) where curated data is disseminated. To handle this heterogeneous federated model, DPACC developed an aggregation tool, Lochness, which can pull data from a wide range of data capture systems, organize the data files on a local data lake, and perform de-identification procedures. This tool has been deployed on two separate servers, one within each research network's IT infrastructure.

De-identified data from both networks are then automatically transferred daily to the DPACC for QC and processing. Key QC and study monitoring metrics are displayed in a custom study dashboard. Data are then further transformed to comply with the NDA data dictionaries and uploaded to the NDA, where data can be explored by AMP SCZ partners in a private collaboration space. Data is also shared with the wider community via traditional NDA data releases.

QC is assessed in near real-time for all data types. Form data are checked for missingness and valid ranges. Automated and manual QC pipelines have been established for all complex data types including EEG, MRI, A/V, fluid and digital biomarker data, monitored by DPACC and AMP SCZ domain experts. All findings are reported back to the research networks management team for follow-up.

Results: The AMP SCZ dataset includes form data from 68 instruments, capturing 14,355 unique variables. In addition to this tabular data, we capture and process MRI (structural, diffusion and resting state), EEG (task and resting state), A/V recordings (20-minute open interview) at two time points, as well as high-frequency data from participant's smartphones and a wearable actigraphy device.

As of October 23rd, 2023, we have QCed data from 763 participants, including 860 EEGs, 841 MRIs, 891 blood and 875 saliva sample collections, 755 open interviews and associated transcripts, as well as smartphone data from 429 participants, totalling over 30TB worth of data.

The first public NDA data release is planned for November 2023, and will have baseline raw data from 430 unique subjects (a total of 39 different measures). The second release is planned for Spring 2024, with a frequency of updates every 6-9 months.

Conclusions: Our process-oriented approach leverages automation to enhance data quality, data flow speed, and collaboration, thereby underscoring the project's contribution to the advancement of research practices involving complex, international multisite studies in sensitive mental health conditions. Near real-time QC allows for problematic measures to be

corrected or re-collected, and deviations in protocols are caught quickly. Finally, our harmonization efforts and tight collaboration with the NDA ensure wide dissemination of the dataset beyond AMP SCZ.

6.3. DATA ANALYSIS FOR THE AMP SCZ INITIATIVE – CHALLENGES AND INNOVATIONS

Ofer Pasternak*¹, Guillermo Cecchi²

¹*Harvard Medical School*, ²*IBM Research*

Background: The Accelerated Medicines Partnership® Schizophrenia (AMP® SCZ) initiative is a large international collaboration with the goal of developing algorithms to predict trajectories and outcomes of individuals at clinical high risk (CHR) for psychosis. The project involves collecting data from approximately 2000 CHR individuals and 640 matched healthy controls. This data includes a wide range of longitudinal assessments, such as clinical, environmental, cognitive, biobehavioral, neuroimaging, electrophysiology, and fluid biospecimens markers. Additionally, AMP SCZ collects speech and facial expression samples, as well as measures from novel digital health technologies, passive sensing and actigraphy. The data analysis for AMP SCZ is conducted by the Analysis and Visualization core (Core 3) of the Data Processing, Analysis, and Coordination Center (DPACC) in collaboration with experts from across AMP SCZ. Core 3 has two primary objectives: 1) developing prediction algorithms for clinical endpoints, and 2) creating algorithms to characterize clinical trajectories, the former to serve as enrichment tools to optimize the logistics of recruitment in future clinical trials, and the latter to optimize early detection of the effect of treatment and provide better mechanistic understanding of CHR trajectories.

Methods: To achieve these objectives, Core 3 is actively engaged in developing and piloting robust, flexible, and clinically-informed predictive algorithms, as well as computational and statistical models. These efforts are aimed at tackling the significant challenges posed by the analysis of a large and complex dataset, including: 1) defining appropriate and well-characterized prediction endpoints, 2) ensuring the generalizability of proposed methods, 3) combining predictive modeling across multiple modalities with a substantial number of features, 4) leveraging longitudinal information and accounting for different time scales across modalities, and 5) addressing issues related to missing data.

Results: Core 3 played a crucial role in defining and parametrizing the clinical endpoints of the observational study. Endpoints include conversion-to-psychosis, remission, and non-remission/non-conversion within assessment periods of 1- and 2-years. Using legacy data, we assessed the expected prevalence of these endpoints to guide our analyses. To ensure the robustness and generalizability of our prediction models, we have set aside 200 CHR individuals for independent validation. This set can validate predictors with an area under the curve of 0.7 or higher, and with a prevalence of 10% or higher. In tackling the challenge of dealing with multiple data modalities, we explored innovative methods for data fusion using legacy datasets that share similarities with the AMP SCZ study. Our findings highlighted the significant advantages of intermediate data fusion techniques, like multi-kernel learning (MKL), compared to single modality predictors. MKL offers interpretability, important for a better mechanistic understanding of CHR, and also identifies correlations across modalities. Applying MKL on legacy data that included clinical, cognitive, MRI and EEG data we found a significant increase of predictive accuracy for MKL (AUC:0.73) relative to the single modality with the highest predictive power (cognitive scores, AUC:0.69). Furthermore, Core 3 developed a novel algorithm inspired by wisdom of crowds. This algorithm combines predictions from 19 previously proposed models, and when applied to legacy data it resulted

with a substantial increase in the conversion rate from originally 10% to 33% in the enriched population (with balanced accuracy of 74.7% and 100% sensitivity). We also investigated the utility of Dynamic Time Warping approaches, demonstrating the predictive advantage of using longitudinal data as opposed to relying solely on single time point predictors. Additionally, we leveraged legacy data to quantify missing data, and tested models for data imputation.

Conclusions: The AMP SCZ initiative, and the innovative yet robust analyses reported above are important to advance the development and use of novel pharmacological interventions for CHR individuals. These analyses place the AMP SCZ project on track to identify important biomarkers for the prediction of clinical outcomes in CHR, and to pave the road for more effective and efficient clinical trials.

6.4. DISSEMINATION FOR THE AMP SCZ INITIATIVE – INFORMED BY LIVED EXPERIENCE

Tina Kapur*¹, Kathryn Lewandowski², Carlos Larrauri³, Ameneh Asgari-Targhi¹, Beier Yao⁴, Lisa Brown⁵, Suzanne Garcia⁶, Michael J. Coleman¹

¹*Brigham and Women's Hospital, Harvard Medical School*, ²*Harvard Medical School/McLean Hospital*, ³*Harvard Kennedy School and The University of Michigan Law School*, ⁴*McLean Hospital*, ⁵*Brigham and Women's Hospital*, ⁶*NIMH*,

Background: The dissemination of program resources developed by the AMP SCZ program is performed by the Dissemination core (Core 4) of the of the Data Processing, Analysis, and Coordination Center (DPACC), in close collaboration with experts from across AMP SCZ.

Methods: Led by investigators at Brigham and Women's Hospital and McLean Hospital, Core 4 works closely with all other cores in AMP SCZ program and with NIMH and FNIH to deliver a consistent message about the AMP SCZ program across participating sites and to the broader community. The mission of this group includes establishing and maintaining an internet presence for dissemination to the research community at large of all tools developed by the program, and for outreach via the website to those affected by CHR. Advocates from NAMI, OneMind, and Mental Health America regularly present their experiences around outreach and communication with an emphasis on considerations from a lived experience perspective to ensure that the voices of lived experience are amplified across the broader AMP-SCZ project. A Fortune 500 company was engaged to coach the Core 4 team on creating a website that is accessible to all, iterating on a Section 508 compliant design.

Results: The AMP SCZ website (<https://www.ampscz.org>) was launched in May 2022 and conveys the aims and activities of the AMP SCZ program in plain language for audiences including researchers, help seeking youth and their families, and clinicians. The website features information regarding (a) study participation including purpose, eligibility, FAQs, and information for clinicians; (b) a map of study sites with contact information, and educational information on schizophrenia and CHR; (c) materials for the research community including study design and protocols, data sharing, and software tools; and (d) study news and events including recruitment updates, published papers, videos, and other resources. The website includes links to advocacy organizations, and regularly features content by people with lived experience including articles, podcasts, and recorded talks. In the 16 months since launch, the site has garnered more than 13,500 sessions and more than 24,500 page views.

As previous literature suggests, we have seen positive effects of our deliberate inclusion of lived experience throughout all phases of AMP SCZ, including through our efforts at dissemination through our website. For example, approximately 18 percent of AMP SCZ website traffic is referral traffic, i.e., visitors clicked a hyperlink on a different website that

took them to the AMP SCZ website. The second highest source of referral traffic is the NAMI website, indicating that those with lived experience have been visiting the AMP SCZ website. This suggests that including people with lived experience and advocacy groups at all stages of the project both enhances the quality of the research and builds a bridge of trust between potential research participants and the scientific community, enhancing recruitment efforts and ensuring that participants are being treated by the research community with respect and proper consideration. The next most popular pages of the website are the “Study Sites” and “Schizophrenia and Clinical High Risk” pages, which display a searchable map of study sites world-wide and information about schizophrenia and clinical high risk, respectively.

Conclusions: DPACC Core 4 has overseen the dissemination of resources from the AMP SCZ program to the broader community using the program website and has promoted the voices of people with lived experience to enhance the work, resulting in better science and greater community partnership.

7. IMMUNE ACTIVATION AND SCHIZOPHRENIA: FOCUS ON RISK AND RESILIENCE TRAJECTORIES

Annamaria Cattaneo, *IRCCS Fatebenefratelli Institute, Brescia; University of Milan; Institute of Psychiatry, King's College*

Overall Symposia Abstract: Immune activation has long been associated with schizophrenia, however the dysregulation of the immune system may be pathologically relevant only in a subgroup of patients. For example, while maternal immune activation (MIA) represents a risk factor for schizophrenia, the majority of exposed offspring will not develop overt pathological sequelae, suggesting a substantial degree of resilience to the effects of MIA. Likewise, non-resolving inflammatory abnormalities are evident only in a subgroup of schizophrenia cases and may predict poorer clinical outcomes. Against this background, our multidisciplinary symposium will bring together key opinion leaders presenting novel data from animal models and clinical cohorts, providing a further understanding of the developmental trajectories and molecular underpinnings that determine risk and resilience to immune activation in schizophrenia. Prof. Urs Meyer (Univ of Zurich) will present data on vulnerability towards MIA in isogenic mouse models and will show how adult offspring can be stratified into resilient and susceptible based on behavioral and molecular signatures. He will also discuss how high social functioning at juvenile age may represent a resilience-promoting factor against long-term behavioral abnormalities and discuss strategies to promote social behaviour in vulnerable animals. Prof Anthony Vernon (King's College London) will present ex vivo structural MRI data obtained in MIA animal model and will discuss the neural correlates associated with risk and resilience. He will also show how multivariate analysis of both neuroanatomical and behavioural data can predict the differing behavioural phenotypes, highlighting the relevance of these data for advancing our understanding of the neurodevelopmental effects induced by MIA and for biomarker-guided approaches. Prof. Annamaria Cattaneo (University of Milan) will show central and peripheral transcriptomic data from a preclinical mouse model, in which immune activation is driven by prenatal stress. She will specifically focus on adolescence as a critical time window for the manifestation of a fully blown phenotype in exposed offspring. In addition, she will present novel transcriptomic analyses in blood samples of patients with schizophrenia and will highlight the presence of shared molecular alterations across species and tissues that could serve as biomarkers of risk prediction. Finally, Fabiana Corsi-Zuelli (Ribeirão Preto, University of São Paulo) will present novel data from two cohorts of individuals with schizophrenia. She will discuss the role of peripheral inflammation in

schizophrenia, spanning from early to chronic stages. She will focus on the association between IL6 and depressive and negative symptoms in individuals with early and chronic schizophrenia. She will also discuss relationships between IL6, brain structures, cognitive performance, and their impact on depressive and negative symptoms. Together with the discussant (Prof. Paola Dazzan, King's College London) this panel of experts will discuss how these findings can advance the understanding of mechanisms involved in vulnerability towards immune-related insults and the potential towards the identification of novel, more targeted strategies for preventive and therapeutic interventions.

7.1. IMPACT OF EARLY IN LIFE INSULTS ON VULNERABILITY AND RESILIENCE TO SCHIZOPHRENIA: HOW CAN WE TARGET IMMUNE RELATED RESPONSES TO PROMOTE PREVENTION AND TREATMENT EFFICACY?

Annamaria Cattaneo*¹, Giulia Petrillo², Ilari D'Aprile², Marco Andrea Riva²

¹*IRCCS Fatebenefratelli Institute, Brescia; University of Milan; Institute of Psychiatry, King's College,* ²*University of Milan*

Background: Exposure to early life adversities represents an important risk factor for the development of psychiatric disorders, including schizophrenia. The enhanced susceptibility to psychopathology may result from changes in gene transcription, which may either transiently affect specific brain structures or produce long-lasting modifications of key player for neuronal function. Animal models are particularly useful to identify the biological systems that are affected in the brain as consequence of such exposures, and peripheral biomarkers that can be translated in the clinical setting. Moreover, they could represent suitable targets for pharmacological interventions.

Methods: Pregnant dams have been exposed to prenatal stress (PNS), which leads to immune activation in pregnant dams, and offspring have been tested at adolescence (n=16 CTRL and n=18 PNS) and adulthood (n=32 CTRL and n=34 PNS per sex) for different behavioural tests (sociability, anhedonia, and cognition) and brain and blood samples have been collected during their neurodevelopment (PND42, PND 62 and PND90). Animals have been stratified into resilient and vulnerable based on the behavioural outcomes and RNAseq analyses have been performed in the brain (hippocampus and prefrontal cortex) and in blood samples. To translate findings into clinical level, RNAseq analyses have been performed also in blood samples of controls and patients with schizophrenia and convergent analyses have been performed. RNA-Sequencing data have been analysed by using DESeq2, whereas pathways analyses were performed by using Ingenuity Pathways Analysis software. At preclinical level, after having identified the most promising candidates from these analyses, we investigated their expression profile of immune related genes (IL-1beta, IL-6, TNF, MIF) and microglia activation (Iba1, CD68, CD45). We also investigated whether sub-chronic treatment with lurasidone (2 weeks), given during the peripubertal period, could modulate the changes originating from prenatal exposure.

Results: PNS exposed animals have been stratified into vulnerable and resilient both at adolescence and at adulthood: PNS adolescent vulnerable animals showed anhedonia and deficits in sociability (p LESS THAN 0.05) and when adult they continued to show reduced social interaction (p LESS THAN 0.05). RNAseq data from hippocampus and prefrontal cortex identified, only in vulnerable animals, a cluster of genes associated with an overactivation of pathways related to immune system, including the Neuroinflammation signaling pathway, Glucocorticoid receptor Signaling and miRNA30a signaling. Interestingly, IL-6 signaling

pathway was observed modulated also in blood samples of vulnerable animals (all p LESS THAN 0.05, FC $\pm$ 1.2, FRD corrected). Microglial activation markers and pro-inflammatory cytokines were differentially expressed in adolescent and adult rats exposed to PNS, with a more pronounced effect in vulnerable animals (+35%, $p=0.0002$; +33%, $p=0.039$ in vulnerable vs resilient animals). Also, in the blood the measured pro inflammatory cytokines (IL-1 β , MIF, and IL-6) are significantly increased in vulnerable animals only and the inflammatory z-score (considering both the blood and the brain) confirmed a pro inflammatory status in association with PNS in vulnerable animals. Importantly, sub-chronic treatment with lurasidone was able to prevent, to a large extent, the up-regulation of miR30a and of IL-6 as well as the changes on genes related to those pathways. In controls and patients with schizophrenia, RNAseq analyses revealed the modulation of 143 genes (p LESS THAN 0.05, FC $\pm$ 1.2, FRD corrected) involved in neurodevelopmental pathways and in immune/inflammatory processes.

Conclusions: In summary, our data suggest that PNS exposure produces a wide range of transcriptional changes in several biological systems, including stress, inflammation, and metabolism. Some of these changes show the peak during adolescence (IL-6 signaling and neuroinflammation), although most of them persist into adulthood. Interestingly, IL-6 pathways came up as the most significant one also in blood samples of patients with schizophrenia. Importantly, chronic lurasidone treatment during peri-puberty is able to counteract or prevent most of these molecular alterations that are known to contribute to stress-related psychiatric disorders, and thus it may be useful in minimizing the individual vulnerability for psychopathology.

7.2. ROLE OF SOCIAL FUNCTIONING IN DETERMINING RISK AND RESILIENCE TO SCHIZOPHRENIA-RELATED PATHOLOGY AFTER MATERNAL IMMUNE ACTIVATION IN ANIMAL MODELS

Ron Schär¹, Flavia Müller¹, Ulrike Weber-Stadlbauer¹, Urs Meyer*¹

¹*University of Zurich*

Background: Infectious or non-infectious maternal immune activation (MIA) during pregnancy is a risk factor for the offspring to develop schizophrenia and related disorders. Despite the increasing evidence for significant health consequences, the majority of MIA-exposed offspring will not develop overt pathological sequelae, suggesting that there is a substantial degree of resilience to the neurodevelopmental effects of MIA. We recently provided experimental evidence for this hypothesis using a mouse model of viral-like MIA, which revealed the existence of subgroups of adult offspring characterized by the presence or absence of behavioral, transcriptional and inflammatory anomalies even under conditions of genetic homogeneity. The present study aimed to investigate the developmental ontogeny and mechanisms underlying dissociable consequences of MIA in an isogenic mouse model of viral-like MIA.

Methods: In a first cohort, pregnant C57BL/6N mice were treated with the viral mimetic, poly(I:C) (5 mg/kg, i.v.) on gestation day 12 ($n = 8$ litters), whereas control dams received vehicle solution on the same gestational stage ($n = 6$ litters). Male and female MIA-exposed offspring ($n = 22$ males and 24 females) and control offspring ($n = 14$ males and 16 females) were subjected to a social interaction test at juvenile age (postnatal day [PND] 25) and were then left to mature into adulthood. At adult age (PND 100 onwards), the same offspring were tested in a number of behavioral tests, including open field exploration, social interaction, prepulse inhibition and working memory. A second cohort of MIA-exposed offspring (8 males and 8 females; from 8 litters) and control offspring (5 males and 5 females; from 5 litters) were

generated for analyses of hypothalamic oxytocin-expressing cells and plasma oxytocin levels after the social interaction test at juvenile age (PND 28). In a third cohort, MIA-exposed offspring (n = 30 males and 30 females, from 12 litters) and control offspring (n = 15 males and 15 females, from 6 litters) were stratified into resilient and susceptible subgroups based on their juvenile sociability index. Susceptible offspring with low juvenile sociability scores received pro-social stimulation (or sham stimulation only) throughout adolescence to early adulthood, after which they were tested at adult age (PND 100 onwards).

Results: Regardless of sex, MIA-exposed offspring could be stratified into two subgroups with low and high sociability scores, respectively, at juvenile age. MIA-exposed offspring with low juvenile sociability scores differed from control offspring with regards to social approach behavior at juvenile age (p LESS THAN .001). As adults, MIA-exposed offspring with low juvenile sociability scores continued to display reduced social interaction compared to control offspring and MIA-exposed offspring with high juvenile sociability scores (p LESS THAN .001) and also displayed significant deficits in prepulse inhibition (p LESS THAN .01) and working memory (p LESS THAN .05). Hypothalamic oxytocin-expressing cells and plasma oxytocin levels were reduced in MIA-exposed offspring with low juvenile sociability scores (oxytocin-expressing cells: p LESS THAN .01, plasma oxytocin: p LESS THAN .05), but not in MIA-exposed offspring with high juvenile sociability scores. Additional investigations are ongoing and will show whether or not pro-social stimulation throughout adolescence is capable of preventing the adult emergence of multiple behavioral and cognitive dysfunctions in susceptible MIA offspring with low juvenile sociability scores. These data will also be presented.

Conclusions: Our findings provide experimental evidence suggesting that the presence of social impairments at juvenile age is predictive of multiple behavioral dysfunctions in adulthood and associated with impaired production of the pro-social hormone, oxytocin. High social functioning at juvenile age may represent a resilience-promoting factor against long-term behavioral abnormalities after MIA.

7.3. STRUCTURAL NEUROIMAGING CORRELATES OF RESILIENCE AND SUSCEPTIBILITY TO MATERNAL IMMUNE ACTIVATION

Anthony Vernon^{*1}, Yi-An Liao¹, Flavia Mueller², Joseph Scarborough², Sina Schalbetter², Eugene Kim¹, Juliet Richetto³, Urs Meyer²

¹*Institute of Psychiatry, Psychology and Neuroscience, King's College London*, ²*University of Zurich*, ³*ETH Zurich*

Background: Infectious or non-infectious maternal immune activation (MIA) is an environmental risk factor for psychiatric and neurological disorders with neurodevelopmental origins. Whilst there is increasing evidence for significant health consequences, the effects of MIA on the offspring appear to be variable. We previously demonstrated that mouse offspring exposed to identical MIA could be stratified into distinct subgroups that were characterized by the presence (susceptible) or absence (resilience) of multiple behavioural dysfunctions. Here, we aim to identify the neuroanatomical correlates of this resilience and susceptibility to MIA using structural MRI.

Methods: MIA was induced in C57BL6/N mice by administration of the viral mimetic, poly(I:C), on gestation day 12 and the offspring clustered into either resilient or susceptible groups using 2-step-recursive clustering (Mueller et al. 2021). A subset of resilient (N=14 [8m, 6f]), susceptible (N=14 [8m, 6f]) and control offspring (N=16 [8m, 8f]) were sacrificed for ex vivo structural MRI. Group differences in neuroanatomy were analysed voxel-wise using tensor-based morphometry with correction for multiple comparisons (5% FDR). To map brain

and behaviour data into single multivariate model, we then applied sparse partial least squares analysis (sPLS).

Results: There were no statistically significant group-wise differences in either regional brain volumes or diffusion imaging parameters (FA, MD) after correction for multiple comparisons. Multivariate sPLS identified a single statistically significant latent variable (LV1) ($p=0.017$). Multivariate maps associated anxiety-like, social, cognitive and sensorimotor gating deficits with volumes of multiple prefrontal and limbic grey matter regions and volumes of major white matter tracts.

Conclusions: In this cross-sectional study, the neural correlates of susceptibility and resilience to MIA induced in identical mouse offspring are best-described using multivariate analysis of both neuroanatomical and behavioural data. These data have relevance for advancing our understanding of the variable neurodevelopmental effects induced by MIA and for biomarker-guided approaches in preclinical psychiatric research.

7.4. PRESSIVE AND NEGATIVE SYMPTOMS ALONG THE EARLY AND CHRONIC STAGES OF SCHIZOPHRENIA: INTEGRATING INTERLEUKIN-6 LEVELS, COGNITIVE PERFORMANCE, AND STRUCTURAL BRAIN ALTERATIONS

Fabiana Corsi-Zuelli^{*1}, Gary Donohoe², Sian Lowri Griffiths³, Cristina Marta Del-Ben¹, Andrew Watson⁴, Tom Burke², Paris Alexandros Lalouis⁵, Declan McKernan⁶, Derek Morris⁶, John Kelly⁷, Colm MacDonald², Jack Rogers³, Nicholas M Barnes³, Carmine Pariante⁵, Golam Khandaker⁸, John Suckling⁹, Bill Deakin¹⁰, Rachel Upthegrove³, Maria Dauvermann³

¹University of São Paulo - Ribeirão Preto Medical School - FMRP USP, ²Cognitive Genetics and Cognitive Therapy Group, The Centre for Neuroimaging, Cognition and Genomics (NICOG), School of Psychology and Discipline of Biochemistry, National University of Ireland Galway, ³University of Birmingham, ⁴UCL Institute of Neurology, ⁵Institute of Psychiatry, Psychology and Neuroscience, King's College London, ⁶National University of Ireland, Galway, ⁷National University of Ireland Galway, ⁸University of Bristol, ⁹University of Cambridge, ¹⁰University of Manchester

Background: Depressive and negative symptoms in schizophrenia (SZ) have been implicated in poor functional outcomes, including treatment resistance. Cognitive deficits, reduced brain structures (cortical thickness and volume), and elevated interleukin (IL)-6 levels may contribute to depressive and negative symptoms in SZ.

Methods: We applied structural equation modelling (SEM) to examine the unique and combined relationships between IL-6 levels, brain structures, cognitive performance, and their impact on depressive and negative symptoms, in two cohorts of participants in the early ($n=102$; 76.5% males, mean age 25.3 ± 4.9 ; BeneMin study) and chronic stages of SZ ($n=42$; 69.0% males, mean age 44.7 ± 10.3 ; iRELATE study). We ran SEM in two groupings of (i) all participants with early and established SZ; (ii) early SZ only. To address the relatively limited sample size in SEM, we also performed a series of exploratory generalised linear models (GLM) to evaluate the influence of IL-6 levels on various independent outcomes of a) depressive symptoms (BeneMin $n=201$; iRELATE $n=94$); b) negative symptoms (BeneMin $n=201$; iRELATE $n=93$); c) brain structure factors (BeneMin $n=102$; iRELATE $n=42$); and d) general cognitive performance factor (BeneMin $n=102$; iRELATE $n=42$). All statistical analyses were adjusted for sex, age, and chlorpromazine equivalent dose.

Results: SEM findings across all participants and in early SZ only showed that higher IL-6 levels were associated with lower brain structures (combined: Beta= -0.247, SE=0.078, p=0.002; early SZ only: Beta= -0.274, SE=0.092, p=0.003). In addition, brain structures were positively related to general cognitive performance (combined: Beta=0.353, SE=0.073, p LESS THAN 0.001; early SZ only: Beta=0.303, SE=0.090, p=0.001). Higher IL-6 levels were not associated with lower general cognitive performance (combined and early SZ only: p GREATER THAN 0.05). In addition, neither IL-6 levels nor brain structures predicted depressive or negative symptoms in SEM analyses (combined and early SZ only: p GREATER THAN 0.05). Exploratory GLM with larger sample size showed that higher IL-6 levels were uniquely associated with more depressive symptoms in early SZ (Beta=1.73, 95% CI=0.48; 2.97, p=0.006) and more negative symptoms in established SZ (Beta=1.02, 95%CI=0.37; 1.68, p=0.002). In addition, higher IL-6 levels were related to lower brain structures in both early (Beta= -0.49, 95%CI= -0.91; -0.07, p=0.021) and established SZ (Beta= -0.26, 95%CI= -0.40; -0.12, p LESS THAN 0.001). Nevertheless, higher IL-6 levels were not associated with general cognitive performance neither in early nor established SZ (p GREATER THAN 0.05). Combining early and established SZ yielded similar results of significant associations between higher IL-6 levels with more depressive (Beta=0.82, 95%CI=0.29; 1.35, p=0.002) and negative symptoms (Beta=0.77, 95%CI=0.14; 1.41, p=0.017), and lower brain structures (Beta= -0.27, 95%CI=-0.44; -0.10, p=0.002), with no association for general cognitive performance (p GREATER THAN 0.05).

Conclusions: We demonstrate that increased IL-6 levels are related to reduced brain structures and more depressive and negative symptoms along the early and chronic stages of SZ. The relationship between IL-6 levels and cognitive performance in SZ deserves further investigation. Our findings suggest that inflammation-related transdiagnostic symptoms may be useful for a better participant selection in anti-inflammatory trials, potentially leading to more effective treatments for individuals with SZ.

8. DISENTANGLING CONTRIBUTIONS TO SOCIAL AND NON-SOCIAL MOTIVATION TRANSDIAGNOSTICALLY

Deanna Barch, *Washington University*

Overall Symposia Abstract: Disruptions in motivation for both social and non-social outcomes and goals are experienced by individuals with psychotic disorders such as schizophrenia (SZ), but also by individuals with other psychosis spectrum illnesses, such as bipolar disorder (BD), as well as individuals with non-psychotic disorders such as major depression (MDD). While we have made some progress in understanding the potential mechanisms of such motivational impairments, there are numerous key open questions, including: a) are the psychological and neural mechanisms that contribute to motivational impairments the same or different across social versus non-social components of motivation? b) are there differential contributions of different types of clinical symptoms to social or non-social motivational impairments, such as depression versus anhedonia versus different forms of cognitive impairment? and c) are the etiological contributions or symptom associations the same or different across diagnostic boundaries? Here we bring together a diverse set of speakers working in both human and animal models to highlight recent innovations and novel data that help address these central questions. Chan and Barch will focus on both the transdiagnostic neural and psychological correlates of social and non-social motivation, including the differential associations with depression versus negative symptoms, a key unexplored topic in the literature. Specifically, Chan will present work showing that individuals with SZ demonstrate disruptions in the ability to adapt their goals and expectations

for financial outcomes relative to individuals with BD and MDD and that clinical measures of depression versus anhedonia/amotivation differentially associate with different aspects of motivation in SZ versus MDD. Barch will present work showing that individuals with SZ and BD demonstrate greater disruptions in effort-based decision-making for valued outcomes compared to individuals with MDD and that both depression and measures of social and non-social amotivation, as well as measures of cognitive control are each uniquely associated with such impairments in SZ and BD. Further, individuals with MDD show reduced activity in the ventral medial prefrontal cortex (putatively associated with subjective value processing) while individuals with SZ and BD show disruptions in activity of the dorsolateral prefrontal cortex (potentially associated with effort computations and goal planning). Catalano and colleagues address the potential key role of attention to social information in understanding disruptions in social motivation among individuals with SZ, using both behavioral and EEG data to show that individuals with SZ show the same level of initial enhanced orienting to social versus non-social stimuli, they show reduced sustained attention to social stimuli as indexed by a reduced late positive potential. Further, individuals with SZ show reduced memory for social and non-social information. Lastly, Powell brings an important pre-clinical perspective to our understanding of the neural mechanisms that drive variation in non-social and social motivation. This work shows that neurodevelopmental models of psychosis (e.g., maternal immune activation, juvenile social isolation) impinge upon social approach motivation. This animal work also illustrates how early social isolation in rodent models informs our understanding of social motivation. Together this set of presentations illustrates important new directions and insights into our understanding of social and non-social motivation impairments transdiagnostically, including both similar and unique pathways across putative diagnostic boundaries.

8.1. DISSOCIABLE NEURAL AND PSYCHOLOGICAL MECHANISMS OF MOTIVATION TRANSDIAGNOSTICALLY

Deanna Barch*¹, Erin Moran¹, Dror Ben-Zeev¹, Adam Culbreth²

¹Washington University School of Medicine, , ²University of Maryland School of Medicine

Background: Disruptions in the drive to achieve positive social, occupational and educational outcomes often reduces the quality of life among individuals with psychotic spectrum disorders, as well as individuals with other illnesses such as major depression. However, we do not know if the same or different neural and psychological mechanisms contribute to these disturbances across diagnostic boundaries. Further, we do not yet understand whether the clinical correlates of such disruptions are the same across diagnoses, including variation in depression symptoms and social and non-social motivation.

Methods: We examined performance on measures of willingness to exert cognitive and physical effort in healthy controls (HC; N=80), schizophrenia/schizoaffective disorder (SZ; N=50), bipolar disorder with psychosis (BD; N=58), current major depression (C-MDD; N=60), and past major depression (P-MDD; N=51). We examined associations to clinician and self-reported social and non-social motivation symptoms, working memory and cognitive control performance, and life function measured by ecological momentary assessment (EMA) and passive sensing. A subset of participants underwent functional neuroimaging during the performance of an effort allocation task. In this version of the EFFRT task, participants make choices between doing an easy task for a low reward, and a harder task (varying percentages of the maximum amount of finger tapping that they could do in a calibration set of trials) for

varying larger amounts of reward. Choices are made in the scanner, and then participants have to complete a random subset of their choices when they exit the scanner.

Results: Compared to HC, the SZ and BD groups, but not the C-MDD or P-MDD groups, showed reduced willingness to exert effort at the higher reward values. In the SZ/BD group, but not MDD, reduced willingness to exert effort for higher rewards was associated with greater clinician-rated motivation impairments, worse working memory and cognitive control performance, and less engagement in social and non-social goal-directed activities measured by EMA. In further EMA analyses, depressive symptoms in psychotic individuals related to both reduced anticipatory and consummatory pleasure in everyday life for both social and non-social activities, while higher negative symptoms related to reduced anticipatory but not consummatory pleasure. In whole brain FDR corrected analyses ($p < .05$), we saw reduced activity in the ventral medial prefrontal cortex (vmPFC) among C-MDD participants on trials where the harder effort task was accepted versus rejected (i.e., at the time of choice), consistent with a disruption in the computation of subjective value among the C-MDD participants. In a priori region of interest (ROI) based analyses, we saw reduced DLFPC activity among SZ and BD individuals at the time when the combined cues of reward and effort are presented. Further, we saw evidence for disrupted activity in the ventral striatum (VS) among the C-MDD individuals. Specifically, the HC, SZ, and BD all show greater VS activity on trials where they accept to do the harder task for more money than when they reject the harder task. In contrast, the C-MDD individuals show overall higher VS activity, but numerically greater VS activity on reject compared to accept trials.

Conclusions: These findings suggest that the neural and psychological mechanisms contributing to motivational impairments differ among individuals with psychosis spectrum disorders versus depression, suggesting dissociable pathways to seemingly similar disruptions. This suggests the need for targeted treatment approaches that are tailored to the particular pattern of disruptions leading to motivational impairments and life function.

8.2. TRANSDIAGNOSTIC RELEVANCE OF RANGE ADAPTATION FOR ANHEDONIA AND AMOTIVATION SYMPTOMS

Raymond Chan^{*1}, Ling-ling Wang², Hui-xin Hu³, Huang Yi-hang⁴, Yi Wang⁵, Jia Huang⁵, Xuan Wang⁴, Zhen-hua Zhu⁶, Hong-yan Sun⁶, Yuan Cai⁶, Wen-long Hou⁶, Gang Ye⁶, Zhao-peng Kang⁶, Simon Lui⁷, Li Hui⁶

⁶*Suzhou Guangji Hospital, The Affiliated Guangji Hospital of Soochow University*, ⁷*School of Clinical Medicine, The University of Hong Kong*

Background: Anhedonia and amotivation are transdiagnostic symptoms that shared by different mental disorders including schizophrenia (SCZ), major depressive disorder (MDD) and bipolar disorder (BD). Range adaptation is the ability to represent stimulus value based on its relative position in the range of prior stimulus values. Range adaptation is important for optimizing value representation, and atypical range adaptation may result in anhedonia and amotivation. In the current study, we explored whether atypical range adaptation is a

transdiagnostic feature found in SCZ, MDD and BD patients. We further investigated whether range adaptation would be associated with anhedonia, amotivation and depressive symptoms.

Methods: We recruited 69 SCZ patients, 37 MDD patients, 45 BD patients and 65 matched controls (HC). Participants complete the Effort-Expenditure for Reward Task-adaptive version which measures range adaptation for both expected value (EV) and outcome value (OV). We also administered clinical rating scales and questionnaires to measure anhedonia and amotivation symptoms.

Results: We found significant group difference in EV adaptation but not OV adaptation among clinical patients and controls. Specifically, SCZ patients showed reduced EV adaptation relative to MDD, BD and HC. Correlation analysis revealed that EV adaptation was positively and significantly correlated with self-reported anhedonia and amotivation, while OV adaptation appeared to be negatively correlated with depression symptom in SCZ patients. In MDD patients, OV adaptation was negatively correlated with interview-based anhedonia and amotivation. However, in BD patients, EV adaptation was positively correlated with self-reported and interview-based anhedonia, amotivation and depression symptoms.

Conclusions: Taken together, our results suggested that reduced EV adaptation is present in SCZ but not in MDD and BD patients. However, all these clinical groups exhibited correlations of OV and EV adaptation with anhedonia and amotivation symptoms. Range adaptation is also correlated with depressive symptoms in SCZ and BD patients. Our work highlights the role of range adaptation in anhedonia and amotivation symptoms across psychiatric disorders.

8.3. COGNITIVE COMPONENTS OF SOCIAL MOTIVATION IN SCHIZOPHRENIA: EXAMINING SOCIAL ATTENTION AND MEMORY

Lauren Catalano*¹, Jonathan Wynn², Michael Green³

¹VA Greater Los Angeles Healthcare System, ²VA Greater Los Angeles Healthcare System/UCLA, ³University of California, Los Angeles

Background: Many people with schizophrenia (SCZ) experience reductions in social approach motivation, or “asociality”, that lead to social isolation and broad functional impairment. Although the prevalence and pervasive negative impact of poor social motivation is well-documented, few studies have examined the causes of social motivation impairments in SCZ. A modern conceptualization of social motivation from the NIMH RDoC expert consensus group includes two cognitive components: (a) attention to social cues, and (b) social learning and memory associated with the formation of relationships. Social attention can be further parsed into separate stages of processing. In SCZ, social stimuli may initially capture attention, but the motivation to sustain attention over time may be impaired. Individuals may also have difficulty with subsequent retrieval of social information. The current study uses electroencephalography (EEG) and event related potentials to systematically evaluate each component and stages of processing to determine where the breakdown in motivation occurs.

Methods: EEG was recorded from a preliminary sample of 20 outpatients with SCZ and 19 healthy controls (HC). We compared SCZ and HC groups using the event related potentials of (a) social attention, and (b) social memory, to examine how these processes unfold over time. Social attention was evaluated using an oddball detection task, which measures initial attention capture (Early Posterior Negativity [EPN]) and sustained attention (Late Positive Potential [LPP]) for social (scenes of persons interacting) versus nonsocial stimuli (scenes with landscapes). Social memory was evaluated using a recognition memory task, which measures neural activity during retrieval (FN400) for social (faces) versus nonsocial stimuli (houses).

Results: Data collection is currently ongoing, with preliminary results presented here. During the oddball detection task, SCZ and HC participants showed similar patterns of initial attention

orienting, such that the EPN was slightly larger for social versus nonsocial stimuli ($F = 2.95$, $p = .09$). In terms of sustained attention, SCZ participants had significantly smaller LPP amplitudes than HC participants to both social and nonsocial stimuli, ($F = 4.658$, $p < .05$); the group by condition interaction was not significant. During the recognition memory task, the SCZ group had poorer recall than the HC group ($F = 5.51$, $p < .05$), and all participants showed better recall of social versus nonsocial images ($F = 33.53$, $p < .001$). The FN400 was larger (i.e., more negative) for new images than for old images during the retrieval phase, showing that individuals successfully remembered which images they had previously seen in the task. There were no significant main effects or interaction effects (group x condition [social, nonsocial]) at this stage of data collection.

Conclusions: While this is an ongoing study, there are some preliminary trends showing impairments in certain cognitive components of social motivation in SCZ. We found that SCZ participants show the same bias as HC to initially orient toward social versus nonsocial images (intact EPN) but have diminished overall sustained attention compared with HC (blunted LPP). Additionally, SCZ participants show better recall of social versus nonsocial information like HC, but they have overall worse memory than HC. Together, these results seem to suggest that there may be deficits at later stages of cognitive processing that may have a downstream influence on decision-making and goal-directed social behaviors. Future analyses will examine correlations between social motivation components (attention and memory), clinician-rated motivation, and social functioning via digital phenotyping.

8.4. NEURODEVELOPMENTAL MODELS: A TOOL TO DISTINGUISH SOCIAL AND NON-SOCIAL MOTIVATION IMPAIRMENTS

Susan Powell^{*1}, Michael Tranter¹, Dionisio Amodeo², Chi-Yu Lai³, Megan Sikkink¹, Mark Geyer¹, Neal Swerdlow¹, Jared Young¹, Samuel Barnes¹, M. Margarita Behrens³

¹University of California San Diego, ²California State University San Bernardino, ³The Salk Institute

Background: Several neuropsychiatric disorders, including psychotic disorders, have developmental origins. Disruption of the maternal environment during prenatal development can significantly contribute to risk for neuropsychiatric disorders such as schizophrenia. There is increasing evidence that prenatal exposure to viruses and other immune-activating factors increases risk for neurodevelopmental psychiatric disorders. Additionally, lack of appropriate social contact early in life alters neurobehavioral development and contributes to neuropsychiatric disorders. Hence, preclinical animal models focusing on prenatal risk factors (e.g. maternal immune activation) and early environmental stressors (e.g. social isolation) have been developed to inform the relationship between social and non-social motivation, their relationship to other cognitive domains, and their neurobiological underpinnings.

Methods: To induce maternal immune activation (MIA), timed pregnant dams are administered PolyI:C (20 mg/kg) or vehicle at E12.5. Offspring are weaned at P24 and tested in a social approach task to measure social motivation and a probabilistic reversal learning task to measure feedback-driven decision-making. For social isolation rearing (SIR) studies, male and female rats are weaned on postnatal day 24 and housed either in isolation (1/cage) or socially in groups of 2/cage. Rats are tested in a social approach task, a probabilistic reversal learning task, and a progressive ratio breakpoint task to measure non-social motivation.

Results: Maternal immune activation, which is associated with decreased social behavior ($t(15) = 3.90$, $p < 0.01$), also produces deficits in probabilistic reversal learning (significant main effect of treatment, $t(15) = -5.18$, $p < 0.001$). Reversal learning deficits in the MIA model were associated with the level of social approach behavior as well

as long-term effects on expression of 24 genes, including genes involved in glutamatergic neurotransmission, mTOR signaling and potassium ion channel activity. SIR rats spent more time exploring the stranger rat compared to the Object ($p < 0.05$); whereas SIR rats did not prefer the stranger rat over the object, i.e. less social approach behavior. Similar to our previous studies, all rats learned the probabilistic reversal learning task as evidenced by increased reversals over test days [main effect of Day; $F(11,286)=16.36$, $p < 0.001$]. SIR rats showed an overall decreased number of reversals across the 12-day training period [Housing, $F(1,26)=34.43$, $p < 0.001$; Housing x Day, $F(11,286)=2.23$, $p < 0.05$] and completed fewer overall trials compared to social rats [$F(1,26)=21.44$, $p < 0.001$]. Conversely, SIR rats do not show impairments in motivation for food reward in a Progressive ratio breakpoint study.

Conclusions: Decreased social motivation is associated with cognitive flexibility deficits across two neurodevelopmental models relevant to psychosis, maternal immune activation and social isolation rearing. Social motivation deficits in MIA mice are associated with deficits in cognitive flexibility and alterations in gene expression in frontal cortex. SIR rats display deficits in social motivation and probabilistic reversal learning, but no deficits in motivation for food reward as measured in a progressive ratio breakpoint task. While experimenter-imposed social isolation provides a viable experimental model for understanding some biological mechanisms linking social dysfunction to clinical and neural pathology in schizophrenia, it bypasses critical antecedents to social isolation in schizophrenia, notably deficits in social reward and social motivation. Recent efforts at modeling social motivation using effort-based tasks in rodents have the potential to quantify these antecedents, identify models (e.g. developmental, genetic) that produce deficits, and advance pharmacological treatments for social motivation deficits.

9. RESPONDING TO CHALLENGES: APPLYING NOVEL METHODS TO THE STUDY OF VIOLENCE IN PSYCHOSIS ACROSS THE LIFESPAN AND CULTURAL CONTEXTS

Unn Kristin Haukvik, *Institute of Clinical Medicine, University of Oslo*

Overall Symposia Abstract: Violence and aggression committed by persons with schizophrenia are major challenges to treatment, outcome, and societal safety, and lead to stigmatization of a large patient group. A key to prevent such events is to understand the complex biopsychosocial underpinnings of violence associated with severe mental disorders and their interaction with each other, across the lifespan and cultural contexts.

Adolescence is a critical time periods for emergence of disruptive behaviour as well as prodromal psychosis symptoms and constitutes a crucial developmental window for early intervention. Several overlapping environmental risk factors for antisocial behaviour and psychosis have been identified, e.g., childhood adversities and substance abuse. Neuroimaging studies have shown brain-based correlates of violence and anti-social behaviour in psychosis, such as abnormalities in the prefrontal and the limbic regions, central hubs of the emotion regulatory circuitry. Novel methods within imaging genetics research show distinct brain anatomical patterns involved in behavioural traits and mechanisms underpinning mental illness. This opens new possibilities for understanding the complex gene-environment-interactions and mechanistic underpinnings of violence in psychosis.

In this symposium, we will present how the application of state-of-the art methodologies in genetics and neuroimaging can provide novel insights about the neurobiology of violence in psychosis, the developmental trajectories and comorbidity during adolescence, and how risk-

factors for violent behaviour in psychosis manifest in a population from the global south. We will combine research using extensive datasets from international databases and collaborative mega-analyses conducted by research centers worldwide with research studying individual profiles, recognizing that the co-occurrence of disruptive behavior and psychotic symptoms leading to violence and criminal offending is observed only in a minority of psychosis patients.

The first presentation explores the genetic overlap between psychosis and anti-social traits by applying molecular genetic methods in a large cohort comprising 22 000 adolescents. With high heritability estimates of conduct disorder at 40-50% and psychosis at 40-80%, this study addresses the molecular genetic underpinnings of this vulnerability at the developmental stage.

The second presentation investigates the complex interactions between childhood trauma and aggression and how these factors affect social cognition, known to be impaired both in psychosis and violence. To expand the cultural context, this study is conducted among the Xhosa population in South Africa, which represents a sociodemographic marginalized and vulnerable population.

The third presentation addresses the fact that there is a striking inter-individual variability in neurobiology which is lost in regular case-control studies of brain morphology. By applying a novel computational method based on brain anatomical deviations from the norm (normative modelling), this heterogeneity can be mapped at the individual level.

Finally, the fourth study reveals a complex genetic relationship between antisocial behavior, substance use, and psychiatric traits. Significant genetic correlation and the identification of shared genetic loci associated with antisocial behaviour and related traits, suggest a common genetic basis for these conditions.

9.1. GENETIC ASSOCIATIONS BETWEEN PSYCHOTIC AND ANTISOCIAL TRAITS IN ADOLESCENTS

Natalia Tesli*¹, Piotr Jaholkowski², Andreas Jangmo³, Jaroslav Rokicki⁴, Viktoria Birkenæs⁵, Christine Friestad⁶, Ole A. Andreassen⁷, Martin Tesli⁸, Unn K. Haukvik⁹

¹University of Oslo and Oslo University Hospital, ²Norwegian Centre for Mental Disorders Research (NORMENT), Institute of Clinical Medicine, University of Oslo and Oslo University Hospital,, ³Division of Mental and Physical Health, Norwegian Institute of Public Health, ⁴Centre of Research and Education in Forensic Psychiatry, Oslo University Hospital, ⁵NORMENT Centre for Psychosis Research, Oslo University Hospital and University of Oslo⁶Centre for Research and Education in Forensic Psychiatry, Oslo University Hospital, University College of Norwegian Correctional Service,⁷NORMENT KG Jebsen Centre for Psychosis Research, Oslo University Hospital and Institute of Clinical Medicine, University of Oslo,Oslo University Hospital, ⁸Norwegian Institute of Public Health, Oslo, Norway; Centre of Research and Education in Forensic Psychiatry, Oslo University Hospital, ⁹Norwegian Centre for Mental Disorders Research (NORMENT), University of Oslo, NORMENT, Oslo University Hospital, Oslo University Hospital, Centre of Research and Education in Forensic Psychiatry, Oslo University Hospital,

Background: Antisocial behavior in youth has serious consequences for the individuals involved, close environment and the society at large. At the same time late childhood and

adolescence are critical time periods for emergence of prodromal psychosis symptoms. Co-occurrence between these two domains of psychopathology may aggravate aggression and later lead to adverse outcomes such as violent behaviour and criminality. Previous family studies have indicated common genetic determinants for psychotic and aggressive traits. However, we lack in-depth knowledge of putatively shared genetic liability between disruptive behaviour and psychosis symptoms using molecular genetic methods.

Methods: Firstly, we interrogated phenotypic overlap between disruptive traits and psychotic-like experiences in adolescents in the Norwegian Mother, Father and Child Cohort Study (n=22096). Secondly, we investigated bidirectional associations between polygenic risk scores (PRSs) for antisocial behavior and schizophrenia and disruptive traits and psychotic-like symptoms. We corrected the models for sex, age, and the first 10 ancestry principal components.

Results: We found phenotypic overlap between disruptive traits and psychotic-like experiences. This was reflected on the genetic level, as we found significant associations between PRS for antisocial behavior and psychotic-like symptoms [p-value FDR-corrected = .0007]. The associations between PRS for schizophrenia and disruptive behaviour (including conduct disorder [p-value FDR-corrected = .021] and oppositional defiant disorder traits [p-value FDR-corrected = .002]) were also present, but to a lesser degree.

Conclusions: The observed overlap between disruptive traits and psychotic-like symptoms in youth may be partially explained by common genetic liability. These findings highlight the importance of a broad clinical assessment and closely monitoring of youth at high risk for psychosis and disruptive traits, in order to prevent harmful consequences for the individuals and their environment.

9.2. LIFE HISTORY OF AGGRESSION IN A SOUTH AFRICAN STUDY OF XHOSA PEOPLE LIVING WITH SCHIZOPHRENIA

Christine Friestad¹, Christina Bell², Olivia Wootton^{*3}, Jaroslav Rokicki⁴, Natalia Tesli⁵, Anja Vaskinn⁶, Gabriela Hjell⁷, Thomas Fisher-Vieler⁸, Ruben Gur⁹, Ezra Susser¹⁰, Unn K. Haukvik¹¹, Dan Stein³

¹Centre for Research and Education in Forensic Psychiatry, Oslo University Hospital, College of Norwegian Correctional Service, ²University of Oslo, Oslo University Hospital, ³University of Cape Town, ⁴Centre of Research and Education in Forensic Psychiatry, Oslo University Hospital, ⁵University of Oslo and Oslo University Hospital, ⁶Norwegian Centre for Mental Disorders Research, Institute of Clinical Medicine, University of Oslo, ⁷University of Oslo and Østfold Hospital, ⁸University of Oslo, Oslo University Hospital, ⁹University of Pennsylvania, ¹⁰Columbia University, ¹¹NORMENT, Norwegian Centre for Mental Disorders Research, Institute for Clinical Medicine, University of Oslo, Institute of Clinical Medicine, University of Oslo, Centre for Research and Education in Forensic Psychiatry, Oslo University Hospital

Background: People living with schizophrenia (PLS) are at increased risk of committing acts of violence as well as experiencing violence themselves. The causes of violence in psychosis are multifactorial and many risk factors for violent behaviour have been identified, including adverse childhood experiences and social cognitive impairments. However, few studies have investigated the risk factors for violence in psychosis in low- and middle-income settings where differences in the socioeconomic context may affect the interaction between known risk factors and violent behaviour.

Methods: A subsample of participants (PLS = 179; controls = 357) from The Genomics of Schizophrenia in The South African Xhosa People Study completed The Childhood Trauma Questionnaire (CTQ), Life History of Aggression (LHA), Penn Emotion Identification Test, and Structured Diagnostic Interview for DSM-IV Axis I Disorders. Between group differences for childhood trauma, LHA, social cognition, and selected demographic and clinical factors were assessed using t-tests and chi-square tests. We tested if total scores for the LHA or CTQ were able to predict current social cognitive performance using multivariable linear regression.

Results: Scores for the CTQ and LHA were significantly higher for PLS and social cognitive performance was significantly worse for PLS compared to the control group. Current social cognitive performance was significantly associated with childhood trauma but not with aggressive behaviour over the lifetime.

Conclusions: The null relationship between current social cognition and lifetime aggression may be due to the relatively low rates of aggression reported in our sample. The significant relationship between social cognition and childhood trauma in this sample provides evidence that the effect of childhood trauma on social cognition in adulthood persists even in environments where adverse childhood experiences are relatively prevalent.

9.3. INDIVIDUAL-LEVEL DEVIATIONS FROM NORMATIVE BRAIN MORPHOLOGY IN VIOLENCE, PSYCHOSIS AND PSYCHOPATHY

Jaroslav Rokicki¹, Thomas Wolfers², Natalia Tesli³, Christina Bell⁴, Gabriella Hjel⁵, Thomas Fisher-Vieler⁶, Nina Bang⁷, Ingrid Melle⁸, Ole Andreassen⁹, Kirsten Rasmussen¹⁰, Ingrid Agartz¹¹, Lars Tjelta Westlye¹², Christine Friestad¹³, Unn Haukvik⁹

¹*Centre of Research and Education in Forensic Psychiatry, Oslo University Hospital,*

²*University of Tübingen,* ³*University of Oslo and Oslo University Hospital,* ⁴*University of Oslo, Oslo University Hospital,* ⁵*Østfold Hospital Trust, Graalum,* ⁶*University of Oslo, Oslo University Hospital,* ⁷*Norwegian University of Science and Technology (NTNU),* ⁸*NORMENT Centre for Psychosis Research, University of Oslo,* ⁹*University of Oslo,* ¹⁰*Norwegian University of Science and Technology, NTNU,* ¹¹*NORMENT, Division of Mental Health and Addiction, University of Oslo, and Diakonhjemmet Hospital,* ¹²*Oslo University Hospital, NORMENT,* ¹³*Centre for Research and Education in Forensic Psychiatry, Oslo University Hospital, Oslo, Norway; University College of Norwegian Correctional Service*

Background: Neuroimaging research has shown brain morphological abnormalities associated with violence and psychosis, but individual differences are substantial and results not consistent across studies. Recently developed normative modeling of brain MRI-features provides a possibility to parse this heterogeneity by mapping inter-individual brain characteristics, which potential has not yet been explored in forensic psychiatry.

Methods: We explored brain heterogeneity in persons with a history of severe violence with or without a schizophrenia spectrum disorder (n=58), non-violent patients with schizophrenia spectrum disorders (n=138), and healthy non-violent controls from lifetime normative trajectories of cortical thickness, surface area, and subcortical volumes. Normative models were based on Freesurfer derived regions of interest from 58,836 individuals (ages 2-100) from 82 sites. Group differences and associations between brain deviations and psychopathy traits (PCL-R scores) were investigated.

Results: Across groups, we found an overall heterogeneous pattern of individual-level deviations, with a significantly higher frequency of extreme negative deviations in persons with a history of severe violence with or without a schizophrenia spectrum disorder (p=.020, d=.31) and non-violent patients with schizophrenia spectrum disorders (p=.019, d=.48), than healthy

non-violent controls. Group differences were mostly present in subcortical volumes and cortical area, but not thickness, with significant regional group-level differences within the subcallosal and insular cortices, and the cerebellum, and no significant associations to psychopathy traits.

Conclusions: By applying normative modeling, this proof-of-concept study demonstrates the heterogeneous pattern of brain morphometry deviations associated with violence and psychosis. While the results warrant replication, studies addressing individual brain deviations may contribute to improved understanding of the complex underpinnings of violence in forensic psychiatry.

9.4. THE SHARED GENETIC ETIOLOGY OF ANTISOCIAL BEHAVIOUR, SCHIZOPHRENIA, SUBSTANCE USE AND RELATED BRAIN MORPHOLOGY

Megan Campbell^{*1}, Olivia Wootton¹, Natalia Tesli², Unn K. Haukvik³, Dan Stein¹, Jaroslav Rokicki⁴

¹University of Cape Town, ²University of Oslo and Oslo University Hospital, ³NORMENT Norwegian Centre for Mental Disorders Research, Institute for Clinical Medicine, University of Oslo, Institute of Clinical Medicine, University of Oslo, Centre for Research and Education in Forensic Psychiatry, Oslo University Hospital, ⁴Centre of Research and Education in Forensic Psychiatry, Oslo University Hospital,

Background: Individuals with antisocial behaviour (ASB) exhibit increased risk of substance use disorders, likely linked to shared genetic vulnerabilities and overlapping neural pathways involved in reward processing and impulse control. This susceptibility is further accentuated by the comorbidity of ASB with various psychiatric disorders, suggesting common genetic underpinnings. Despite this there remains a paucity of work examining the shared genetic etiology of ASB, related neuropsychiatric traits and relevant brain regions.

Methods: Using GWAS of ASB (n=50,252), surface area and thickness of cortical frontal regions, volumes of the amygdala nuclei, psychiatric and substance use phenotypes, we utilized Linkage Disequilibrium Score Regression (LDSC) to assess the genetic correlation between these phenotypes. We then leveraged genetic overlap to boost discovery of genomic loci associated with ASB, and to identify specific shared loci associated with both ASB and each phenotype, using the conditional/conjunctional false discovery rate (cond/conjFDR) approach. FUMA was used for functional analyses.

Results: Using LDSC, we identified significant genetic correlations between ASPD and drinks per week (rg= 0.28; p=1.33×10⁻⁹), cannabis (rg= 0.37; p= 1.91×10⁻⁸), bipolar disorder (BD, rg= 0.20; p=1.95×10⁻⁵), major depressive disorder (MDD, rg= 0.53; p=1.09×10⁻¹⁵) and marginally significant correlations with caudal anterior cingulate surface area (rg=-0.17; p=0.04), superior frontal surface area (rg=0.18; p=0.03), and global measures of cortical surface area (rg=-0.15 ; p=0.02) and thickness (rg=-0.13 ; p=0.04) and ICV (rg=-0.2 ; p=0.01). A total of 54 loci, representing 127 independent SNPs, became significant after conditioning on related psychiatric disorders (8 SCZ, 7 BD, 11 MDD), substance use traits (18, drinks per week; 10, cannabis use) and the corpus callosum (11 anterior, 7 mid anterior, 8 central, 6 mid posterior, 9 total CC). These SNPs have been associated with schizophrenia, disruptive behaviour, risk taking behaviours, substance use disorders and cortical surface area in prior GWAS. Two biological processes were implicated: ethanol oxidation and metabolism.

Conclusions: Our results reveal a complex genetic relationship between substance use, psychiatric traits, and ASB. We provide strong evidence for existence of distinct genetic loci exhibiting pleiotropic effects in both ASB and related traits. Our findings provide convergent

evidence to suggest that substance use traits and psychiatric disorders have shared genetic underpinnings with ASB.

10. DIGITAL TECHNOLOGIES AND RECOVERY: CURRENT AND FUTURE DIRECTIONS TO IMPROVE CARE IN SCHIZOPHRENIA SPECTRUM DISORDERS

Élisabeth Thibadeau, *McGill University, Douglas Mental Health University Institute*

Overall Symposia Abstract: The use of digital technologies in schizophrenia spectrum disorders has significantly increased in the last decades and has several advantages to support recovery such as ecological momentary assessments, increased engagement, flexibility and empowerment. These technologies have been used for different purposes and encompass a wide array of methods to support different components of recovery, including clinical symptoms, cognitive impairments and return to work or to school. This symposium provides an overview of recent developments in digital technologies to support recovery in schizophrenia spectrum disorders. Further, given the very rapid development of these emerging technologies, this symposium also aims to provide insight into the development, co-design with service users and implementation of these technologies to ensure a coherent development between scientific and experiential knowledge to decrease research-to-practice gap.

Dr Haesebaert will present how digital technologies can be used to monitor and plan recovery goals. He will present the development and preliminary results of PLAN-e-PSY, a youth-friendly mobile application targeting goals planning and monitoring for first-episode psychosis. This application based on the recovery framework for first-episode psychosis care was developed through a user-centered design iterative co-building methodology. Positive preliminary results from the initial assessment of a feasibility and acceptability study will be presented.

Dr Raucher-Chéné will present how digital technologies can be used to deliver remote interventions. She will present the results from the ongoing iCog-CA trial, a multisite nationwide study in Canada assessing the acceptability, effects and implementation of remote group-based cognitive interventions targeting clinical symptoms and cognitive impairments in schizophrenia spectrum disorders, including the Metacognitive training (MCT) and the Action-Based Cognitive Remediation program (ABCR).

Dr Thibadeau will present how digital technologies can be used to treat social cognitive deficits remotely. She will present the results from an ongoing trial assessing the acceptability, feasibility, and preliminary effects of the remote administration of RC2S, an avatar-based cognitive remediation program for social cognitive impairments using paper and pencil exercises and digital relational simulations. The cultural adaptation of this intervention for North American English and French-Canadian languages will be presented, along with the preliminary results regarding the positive effects on social cognition, recovery, functioning and symptoms, as well as its acceptability and implementation both in people with lived experience and therapists.

Dr Smith will present how digital technologies can support functional recovery, using virtual reality job interviews (VR-JIT). He will discuss his recent work assessing the effectiveness, implementation outcomes and qualitative experiences of using VR-JIT within Individual Placement and Support (IPS) programs. This presentation will focus on both people with lived experience of schizophrenia spectrum disorders and IPS employment specialists and present

the positive outcomes observed in terms of effectiveness for competitive employment, interview skills, and interview anxiety as well as acceptability and implementation.

This symposium will provide insight about the development, use and implementation of digital technologies which represent a fast-growing approach to support recovery in schizophrenia spectrum disorders, from clinical to functional outcomes.

10.1. PLAN-E-PSY, A MOBILE APPLICATION CO-BUILT WITH ENDUSERS TO IMPROVE CASE MANAGEMENT FOR PATIENTS WITH FIRST EPISODE OF PSYCHOSIS (FEP)

Frederic Haesebaert¹, Mathilde Marchal², Amelie Pavard^{*3}, Laurent Magaud², Eric Fakra⁴, Julie Haesebaert⁵

¹PSYR2 Team, INSERM U1028, CNRS UMR5292, Lyon Neuroscience Research Center, Université Claude Bernard Lyon 1, ²Hospices Civils de Lyon, Public Health Center, Research and Clinical Epidemiology Department, F-69003 Lyon, France, ³CH Le Vinatier, Lyon, ⁴Pôle Psychiatrie, Centre Hospitalier Universitaire de Saint-Etienne, Saint-Etienne, Rhône-Alpes, France., ⁵University Claude Bernard Lyon 1, Research on Healthcare Performance (RESHAPE), INSERM U1290

Background: First-episode psychosis (FEP) affects 3% of the population worldwide, mainly young adults. International guidelines for FEP are based on the principles of intensive case management (CM). To improve the relevance of CM and thus patient engagement and functional outcomes, the care objectives must not be solely clinical, but placed within an individualized "recovery" perspective, taking into account the patient's point of view, goals and context. The use of clinical tools co-built end users (patients, caregivers, carers) and adapted to recovery goals appears essential. In addition, the use of mobile applications as clinical tools can enhance the engagement of young patients.

Objective: Our research aims to co-build a youth-friendly mobile application (PLAN-e-PSY) based on the recovery framework for planning and monitoring FEP care goals.

Methods: We used a "user-centered design" iterative co-building methodology. Workshops were led by a psychiatrist and a psychologist. Two patients, 2 case managers, a caregiver, a peer-worker, a developer and an ergonomist were involved. Thematic content analysis following the workshops was conducted in order to refine the specifications of a beta version of the mobile application. Direct interviews were conducted with 3 CMs, 2 peer workers, a caregiver and a patient, after testing the beta version of PLAN-e-PSY.

Results: The application's architecture and content were defined on the basis of workshop participants' own representations of recovery, based on their own experiences. Participants also helped to define together the application's graphics, ergonomics and content. Interviews conducted following the beta test revealed that the beta version of PLAN-e-PSY was easy to use (4.5/5) and perceived as useful (3.5/5). They enabled us to improve the application: personalize it and include a joint crisis plan.

Conclusions: Co-building with end-users enabled us to create a relevant application for patients, their families and professionals. A funded randomized controlled trial on 168 patients will assess the app's effectiveness in FEP care settings.

10.2. ICOGCA: PRELIMINARY RESULTS ON RECOVERY BY PROMOTING COGNITIVE HEALTH THROUGH ONLINE INTERVENTIONS FOR PERSONS LIVING WITH A SCHIZOPHRENIA-SPECTRUM DISORDER.

Delphine Raucher-Chéné*¹, Élisabeth Thibaudeau², Genevieve Sauvé³, Katie Lavigne², Christopher Bowie⁴, Mahesh Menon⁵, Synthia Guimond⁶, Michael Best⁷, Michael Bodnar⁸, Todd Woodward⁹, Martin Lepage²

¹Douglas Research Centre, Montréal, ²Douglas Research Centre, Montréal, QC, Canada; McGill University, ³Douglas Research Centre, Montréal, QC, Canada; Université du Québec À Montréal, ⁴Queen's University, Kingston, ON, Canada, ⁵University of British Columbia, Vancouver, BC, Canada, ⁶The Royal's Institute of Mental Health Research, University of Ottawa, ON, Canada, ⁷University of Toronto Scarborough, Toronto, ON, Canada, ⁸The Royal Ottawa Institute of Mental Health Research, University of Ottawa, ON, Canada, ⁹BC Mental Health and Addictions Research Institute; University of British Columbia, Vancouver, BC, Canada

Background: To promote recovery in individuals living with schizophrenia-spectrum disorder (SSD), there is an important need to ameliorate overall cognitive health. Hence, cognitive impairments and biases collectively represent a core feature of SSD and adversely impact the social functioning and well-being of this population. By increasing access to cognitively stimulating activities, the iCogCA study - a national Canadian collaborative effort to implement online psychological interventions – aims to promote recovery in SSD.

Methods: Five sites across Canada (Quebec, Ontario, British Columbia) are part of the project. Participants living with SSD are recruited and assessed for symptoms, cognition, functioning and recovery pre- and post-intervention. Two evidence-based group interventions promoting cognitive health are conducted remotely through videoconference: Action-Based Cognitive Remediation (ABCR) and MetaCognitive Training (MCT) with each site running four groups annually (2 ABCR, 2 MCT).

Results: We will provide the first-year results of this entirely online trial. To date, among the 39 SSD participants screened, 22 enrolled in an intervention and 19 completed it (86%). Completers had a mean age of 33.84±7.4 years old, were in remission (i.e., mean PANSS-6 score LESS THAN 14), and had moderate to severe difficulties in at least one area of functioning before the intervention. Post-intervention assessment highlighted a progression in the process of recovery (i.e., a significant change in the Questionnaire about the Process of Recovery score; $t=-2.41$, $p=0.028$, $d=0.58$) with an increase in self-esteem ($t=-2.02$, $p=0.061$, $d=0.49$). No significant change was detected in symptoms, cognition, or functioning at that stage.

Conclusions: The iCogCA project has immense potential for reaching people in need who are otherwise unable to attend in-person settings, thus improving accessibility to care and health equity. These preliminary results on the effectiveness of remotely-delivered ABCR and MCT are encouraging, highlighting the potential impact of these interventions in the recovery process. By supplementing the results from the other groups given during the year, the impact of each intervention can be analyzed, as well as the other potential effects of these interventions on overall functioning and well-being.

10.3. A REMOTE AVATAR-BASED COGNITIVE REMEDIATION FOR SOCIAL COGNITION IN SCHIZOPHRENIA SPECTRUM DISORDERS: PRELIMINARY RESULTS OF THE ACCEPTABILITY, FEASIBILITY AND EFFECT OF RC2S

Élisabeth Thibaudeau*¹, Elodie Peyroux², Nicolas FRANCK³, Martin Lepage¹

¹McGill University, Douglas Mental Health University Institute, ²Le Vinatier Hospital,

³University of Lyon, Vinatier Hospital

Background: Social cognitive (SC) deficits are prevalent in schizophrenia spectrum disorders (SSD) and are associated with impairments in functional recovery. Cognitive remediation (CR) has shown its efficacy to improve these deficits, but the effect on functioning remains limited. Digital technologies could support the training and transfer of SC skills to daily life. The French program RC2S is a broad-based and personalized program using digital relational simulations to emulate real-life social interactions. While preliminary evidence of efficacy is available for RC2S, there is a need to increase remote access to culturally adapted CR for SC. The goals of this study were to 1) culturally adapt RC2S in North American English and French-Canadian and 2) to assess the feasibility, acceptability and preliminary effects of a remote version of RC2S in SSD.

Methods: For the first objective, the translation for the North American English version was performed by a professional agency. For both versions, all scenarios were revised to culturally adapt the expressions, turns of phrase, and names of places and characters. All audio files were recorded by professional actors. For the second objective, so far, we recruited eight (mean age 37.8, 5 men) symptomatically stable participants with SSD with objective and/or subjective SC impairments. A pre-post quasi-experimental design using mixed methods was used. Participants were assessed before and after the intervention for primary (SC, goal attainment) and secondary (symptoms, functioning, recovery) outcomes and completed in-session questionnaires assessing their motivation, perception of therapeutic alliance and appreciation of the remote intervention. RC2S includes 24 individual one-hour sessions with a therapist, twice a week with the first session dedicated to paper-pencil exercises to learn strategies and the second session using digital relational simulations with an avatar to practice skills. We also recruited five therapists offering the intervention with a graduate degree in psychology. They completed similar in-session questionnaires as participants with SSD. Descriptive statistics were used to summarize data and linear mixed models, along with effect-size d were used to assess the preliminary effect of RC2S on primary and secondary outcomes.

Results: The participants completed a mean of 20.4 sessions. For primary outcome, a significant effect was observed for goal attainment ($F(1,6.498)=62.031$, $p < 0.001$). The effects were marginally significant with medium-large effect sizes for theory of mind ($d=0.74$), subjective assessment of emotion recognition ($d=1.25$) and attributional bias ($d=0.75$). For secondary outcomes, the effect on cognitive biases was marginally significant, with small to moderate-large effect sizes for the scales Belief Inflexibility bias ($d=0.10$), Subjective complaints ($d=0.7$) and Safety behaviors ($d=0.11$). In addition, moderate-large effect sizes were observed for symptoms of social anxiety ($d=0.5$), depression ($d=0.52$), recovery ($d=0.75$), social functioning ($d=0.85$) and intimacy ($d=0.76$). Regarding the in-session questionnaires, for both participants with SSD and therapists, therapeutic alliance was perceived as good and remained relatively stable throughout the intervention ($p=0.082$), with a similar pattern for motivation (all scales > 0.05). High scores were obtained also obtained for the satisfaction questionnaires.

Conclusions: These preliminary results suggest that the remote administration of RC2S is feasible and acceptable and yields positive effects. While these results must be replicated in a randomized-controlled trial, they support the use of digital technologies to support SC impairments and functional recovery in SSD.

10.4. THE EVIDENCE FOR VIRTUAL JOB INTERVIEW TRAINING TO SUPPORT JOB-SEEKING ADULTS WITH SCHIZOPHRENIA

Matthew Smith^{*1}, Justin Smith², Shannon Blajeski³, Brittany Ross¹, Susan McGurk⁴, Kim Mueser⁵, Morris Bell⁶, Eugene Oulvey⁷, Jane Burke-Miller⁸, Neil Jordan⁹, Karley Nelson¹⁰, Tovah Lieberman¹⁰, Nicole Pashka¹⁰, Lisa Razzano¹¹

¹University of Michigan, ²University of Utah, ³Portland State University, ⁴Boston University, ⁵Center for Psychiatric Rehab, Boston University, ⁶Yale University School of Medicine, ⁷State of Illinois, Illinois Department of Human Services, Division of Rehabilitation Services, ⁸University of Illinois Chicago, ⁹Northwestern University, ¹⁰Thresholds, ¹¹University of Illinois, Chicago; Thresholds, Inc.

Background: About 20% of people with schizophrenia are employed and the field's gold standard vocational rehabilitation model, Individual Placement and Support (IPS), increases this employment rate to 55%. Thus, a large percentage of adults with schizophrenia remain unemployed, which contributed to an economic burden of \$343 billion in 2019 (largely driven by unemployment and productivity loss). Virtual Reality Job Interview Training (VR-JIT; a zoom-like job interview simulator with automated feedback) was developed with adults with serious mental illness and results from a randomized controlled trial (RCT) demonstrated initial efficacy that (within 6 months) trainees had more job offers compared to the control group (48% vs. 14%, $p < .05$). This initial data led to our current RCT evaluating VR-JIT effectiveness within IPS, initial implementation outcomes, and the qualitative experience of using VR-JIT.

Methods: First, ninety participants with schizophrenia or other serious mental illnesses were randomly assigned to IPS+VR-JIT (N=54) or IPS as usual (N=36). Intent-to-treat logistic regression, Cox proportional hazard and mixed-effects linear regressions evaluated the primary (employment rate, time-to-employment) and secondary outcomes (interview skills, interview anxiety). Fifty-one percent of participants were IPS nonresponders (i.e., no employment within their first 90 days of IPS). Second, a sequential, complementary mixed-methods design used qualitative data to gain greater depth of understanding of implementation process outcomes. Eleven IPS employment specialists trained to deliver VR-JIT completed VR-JIT acceptability, appropriateness, and feasibility surveys. Forty-two VR-JIT recipients completed acceptability and usability surveys. We then conducted five focus groups and thirteen semi-structured interviews with IPS staff and VR-JIT implementers and recipients, followed by an integrated analysis process. Lastly, we analyzed semi-structured interviews (n=8) with IPS employment specialists across four community IPS sites (distinct from the RCT site) implementing VR-JIT and analyzed secondary qualitative data from the implementation evaluation. All focus group and interview data were analyzed using grounded theory methodology.

Results: The IPS+VR-JIT group had greater odds of obtaining competitive employment as compared to the IPS-as-usual group (OR=3.0, $p=.027$). Moreover, IPS nonresponders in the IPS+VR-JIT group, as compared to the IPS-as-usual group, had greater odds of obtaining a job (OR=5.82, $p=0.01$) and shorter time to employment (HR=2.70, $p=0.04$). The IPS+VR-JIT as compared with the IPS as usual group had improved interview skills ($p=0.006$) and interview anxiety ($p=0.019$). IPS employment specialists found VR-JIT to be highly acceptable, appropriate for integration with IPS, and feasible for delivery. VR-JIT recipients reported the intervention to be highly acceptable. Qualitative results added perceived advantages for IPS employment specialists and adaptations for future delivery. The client experience yielded participants appreciated exposure to a simulated interview in a safe environment and receiving feedback which supported improved confidence and engagement in the job seeking process.

Conclusions: VR-JIT enhances access to competitive employment, interview skills, and interview anxiety among IPS clients with schizophrenia and other serious mental illnesses. The results were especially notable among IPS nonresponders who traditionally lag in their access

to employment. Moreover, IPS staff and clients view VR-JIT as acceptable and feasible to deliver within IPS as it provides a safe space to practice and get feedback on job interview skills. Staff reported that their clients were more engaged in the job search process after using VR-JIT. While the field seeks to understand the determinants of VR-JIT implementation, we recommend that IPS programs begin piloting delivery of VR-JIT to provide evidence-based practice for their most vulnerable IPS clients.

Plenary Session II: Raquel Gur - Brain Development and Psychosis

2:00 p.m. - 3:00 p.m.

11. BRAIN DEVELOPMENT AND PSYCHOSIS

Celso Arango, *Hospital General Universitario Gregorio Marañón*

11.1. BRAIN DEVELOPMENT AND PSYCHOSIS

Raquel Gur, *University of Pennsylvania*

Individual Abstract: Integration of brain-behavior measures in the study of psychosis has capitalized on advances in several research domains that are critical for progress and contribute to investigating the psychosis dimension neurodevelopmentally. In the domain of clinical phenotyping, it has been recognized that clinical manifestations are an evolving process ranging from subthreshold to schizophrenia spectrum disorder (SSD). To examine the emergence of psychosis, continuous measures were deployed for quantifying specific aspects of behavior that can be examined longitudinally.

In the domain of neurobiology, advanced measures of brain structure, function and connectivity are applied to large samples in collaborative efforts to parse the clinical heterogeneity based on the involvement of brain systems and the relation to neurobehavioral deficits that characterize SSD and are evident earlier in development.

Concomitantly, large-scale genetic studies have identified gene network associated with SSD that are implicated in brain development and are evident in other neurodevelopmental disorders such as autism spectrum disorders (ASD). Furthermore, large datasets on common and rare genetic variants, associated with increases incidence of SSD, have become available yielding sufficient power for probing underlying cellular-molecular mechanisms. The study of the exposome supports the contribution of the environment with advanced quantitative methodology for measuring its effects. Novel methodologies for mining such large data sets are needed and are applied increasingly incorporating artificial intelligence and machine learning approaches.

The presentation will illustrate efforts to integrate data across these domains and highlight challenges, opportunities, and future directions towards precision psychiatry applied to psychosis.

Concurrent Symposia

3:30 p.m. - 5:30 p.m.

12. BEYOND D2 BLOCKERS: NEW MECHANISTIC APPROACHES BASED ON GLUTAMATERGIC AND DOPAMINERGIC CIRCUIT TARGETS

Oliver Howes, *MRC LMS and KCL*

Overall Symposia Abstract: D2 blockers are the mainstay of drug treatment for schizophrenia but don't work for many patients and are poorly tolerated by many more. This highlights the need to identify new targets to guide the development of novel treatments. This symposium focuses on glutamatergic and dopaminergic circuits thought to underlie schizophrenia. It will cover new molecular and genetic data on regulators of these circuits.

The first talk (Sportelli) will present unpublished data on genetic regulators of the dopaminergic abnormalities implicated in psychosis, and integrate this with PET imaging data to identify proteins that modulate striatal dopamine circuit function. This identifies a number of targets, including the indirect dopamine pathway, that could be used to modulate striatal dopamine circuits to treat schizophrenia.

The second talk (Howes) will focus on the role of trace amine receptors in the regulation of dopaminergic circuits. It will present unpublished preclinical data showing that TAAR1 knock-out leads to the same meso-striatal dopaminergic dysfunction seen in schizophrenia, and an interventional study in patients showing that a TAAR1 agonist reduces meso-striatal dopamine dysfunction in schizophrenia, and that this is related to improvements in symptoms.

The third talk (Mizrahi) will present new in vivo imaging data in patients showing that cortical and striatal brain levels of MAO-B, an enzyme involved in both glutamatergic and dopaminergic circuits, are lower in people with a first episode of psychosis and in people at clinical high risk of psychosis. It will also present evidence that MAO-B brain levels are modulated by cannabis use, linking this system to a risk factor for the development of psychosis.

The final talk (Fan) will present new data from a prospective treatment study in antipsychotic naive first episode psychosis, showing that baseline cortical glutamate levels predict treatment response. It will also show that the gap between predicted and actual brain structural age increases during the first 3 months after the onset of psychosis during antipsychotic treatment irrespective of response status. These data identify cortical glutamate elevation as a potential treatment target for patients who do not respond to D2 blockers and highlight brain structural changes are not related to response to D2 blockers.

The discussant has expertise in the role of both the glutamatergic and dopaminergic circuits in schizophrenia, and in translational studies to identify and develop new treatments for the disorder. She will discuss the data presented and place it in this context to draw out the areas where findings converge. The discussion will also identify limitations and areas where the field needs to focus future studies to address key questions on the pathophysiology of the disorder. Finally, she will also consider the data in terms of other novel treatment strategies being developed in schizophrenia to consider the most promising approaches.

12.1. DOPAMINE AND SCHIZOPHRENIA FROM BENCH TO BEDSIDE: DISCOVERY OF A STRIATAL CO-EXPRESSION RISK GENE SET THAT PREDICTS IN VIVO MEASURES OF STRIATAL FUNCTION.

Leonardo Sportelli*¹, Daniel Eisenberg², Roberta Passiatore³, Enrico D'Ambrosio³, Linda Antonucci³, Qiang Chen⁴, Jasmine Czarapata², Aaron Goldman⁴, Michael D. Gregory², Kira

Griffiths⁵, Thomas M. Hyde⁴, Joel Kleinman⁴, Antonio Pardinas⁶, Madhur Parihar⁴, Teresa Popolizio⁷, Antonio Rampino³, Joo Heon Shin⁴, Mattia Veronese⁸, William Ulrich⁴, Caroline Zink¹⁰, Alessandro Bertolino³, Oliver Howes⁸, Karen F. Berman², Daniel Weinberger⁴, Giulio Pergola⁴

¹Lieber Institute for Brain Development, ²National Institute of Mental Health, National Institutes of Health, ³University of Bari 'Aldo Moro', ⁴Lieber Institute for Brain Development, Johns Hopkins Medical Campus, ⁵Holmusk Technologies Inc, ⁶MRC Centre for Neuropsychiatric Genetics and Genomics, Cardiff University, ⁷IRCCS Casa Sollievo Della Sofferenza,, ⁹Institute of Psychiatry, King's College London, ¹⁰Baltimore Research and Education Foundation

Background: Schizophrenia (SCZ) is characterized by a polygenic risk architecture implicating diverse molecular pathways important for synaptic function. However, how polygenic risk funnels through these pathways to translate into syndromic illness is unanswered. We aimed to identify a set of genes implicated both in genetic risk and in differential expression in a brain circuit of three brain regions and to study how gene-set-specific SCZ risk translated into brain circuit function.

Methods: To evaluate biologically meaningful pathways of risk, we used tensor decomposition to characterize gene co-expression in post-mortem brain of neurotypical controls (NC; N=154), patients with SCZ (N=84), and GTEx samples (N=120) from caudate nucleus (CN), hippocampus (HP), and dorsolateral prefrontal cortex (DLPFC). We associated the identified gene sets with SCZ diagnosis and genetic risk via ANCOVA and linear models respectively and assessed tissue, cell-type, and biological pathway specificity through gene enrichment analyses. We assessed the replication of the identified gene sets in the GTEx samples by means of Jaccard Index (JI: overlap/union of gene sets). We then computed a Parsed Risk Score (PaRS) by mapping risk polymorphisms within PGC3 SCZ loci to a dopamine-linked group of genes. We also computed a measure of cumulative SCZ risk burden based on GWAS risk genes not included in this gene set (complementary-PaRS) as negative control. We associated the PaRS and complementary-PaRS with in vivo striatal dopamine synthesis capacity measured by [18F]-FDOPA PET uptake in NC (N=65) and SCZ patients (N=20) by means of fixed-effect model meta-analysis. We replicated PET results in an independent NC cohort (N=150) through multiple linear regression. Finally, we associated the two type of scores to reward anticipation-related fMRI activation in an independent discovery sample of 86 NC and replicated the results in an independent cohort of 55 NC.

Results: We identified a CN-predominant gene set showing dopaminergic selectivity ($p[\text{FDR}] = 1.9 \times 10^{-57}$) that was enriched for genes associated with clinical state ($F[1,210] = 11.4$, $p = .0009$, $p[\text{FDR}] = .038$) and SCZ genetic risk ($t[93] = 1.67$, one-tailed $p = .048$). This gene set was also replicated in the NC GTEx cohort ($\text{JI} = .19$; empirical $p \text{ LESS THAN } .001$). Besides genes necessary for presynaptic dopamine biosynthesis, such as DRD2, TH and DDC, this gene set also included 17 genes preferentially expressed by indirect pathway medium spiny neurons, such as PENK, GPR6, HTR4 and again DRD2. Parsing polygenic risk score for SCZ based on this specific gene set (PaRS), we found that greater PaRS predicted greater in vivo striatal dopamine synthesis capacity in three independent cohorts of NC and patients (total N=235; discovery meta-analytic coefficient[95% CI]: $0.33[0.01, 0.65]$; $p = .0037$; $p[\text{Bonferroni}] = .037$; replication: $t[149] = 3.95$; $k = 16$; $p[\text{FWE}] \text{ LESS THAN } 0.05$) and greater fMRI striatal activation during reward anticipation in two additional independent NC cohorts (total N=141; discovery: $p[\text{TFCE-FDR}] = 0.01$; $Z = 3.54$; $x = 17$; $y = 15$; $z = -5$; 73 voxels; replication: $p[\text{TFCE-FDR}] = 0.03$; $Z = 4.04$; $x = 18$; $y = 17$; $z = 5$; 20 voxels). We found no significant association in any of the PET and fMRI samples using the complementary-PaRS.

Conclusions: We identified a dopamine-linked group of genes whose specific risk variants predict striatal presynaptic dopamine synthesis and striatal activity during reward anticipation in the living human brain, both outcomes concordant with known SCZ-associated phenotypes. Remarkably, the association was only seen with our parsed polygenic risk score and not with the scores including all all variants outside the pathway we considered. This unpublished translational body of work provides empirical evidence for striatal dopamine-relevant gene network involvement in the etiology of SCZ, pinpointing a specific biological pathway of risk that affect illness relevant striatal neurochemistry and neurofunction, and may open new possible avenues for studying clinical heterogeneity and drug treatment response.

12.2. TARGETING THE PATHOPHYSIOLOGY OF SCHIZOPHRENIA: A COMBINED PRECLINICAL AND CLINICAL STUDY OF THE ROLE OF THE TRACE AMINE-ASSOCIATED RECEPTOR 1

Oliver Howes^{*1}, Luke Vano², Grazia Rutigliano², Alice Petty³, Sridhar Natesan², Courtney Zeni⁴, Dominic Withers⁵, Nina Dedic⁶, Stephen Kaar², Seth Hopkins⁴, Robert McCutcheon², Kenneth S. Koblan⁷

¹MRC LMS and KCL, ²Institute of Psychiatry, Psychology and Neuroscience, King's College London,, ³Imperial College London, ⁴Sunovion Pharmaceuticals, ⁵LMS-MRC, Imperial College London, ⁶Sunovion Pharmaceuticals, Inc., , ⁷Sunovion Pharmaceuticals Inc

Background: Meta-analysis of PET evidence indicates that the major dopaminergic abnormality in schizophrenia is elevated dopamine synthesis and release capacity, and that this is associated with the development of the first psychotic episode and the severity of symptoms. The trace amine associated receptor 1 (TAAR1) has recently emerged as a promising target in the treatment of schizophrenia and other psychiatric disorders. TAAR1 is expressed in dopamine neurons and modulates their firing, suggesting it could target the dopamine pathophysiology of schizophrenia. This is further supported by recent results with ulotaront, a TAAR1/5-HT1A receptor agonist, which reduced dopamine synthesis capacity in a ketamine mouse model of hyperdopaminergia. However, it is not known whether the effects on dopamine synthesis capacity are directly linked to TAAR1 and/or translate to humans. To address this, we conducted two studies. The first study evaluated dopamine synthesis capacity in TAAR1 knockout (TAAR1-KO) mice, whilst the second tested the effect of ulotaront on dopamine synthesis capacity in patients with schizophrenia.

Methods: Study 1: Adult, male AAR1^{-/-}(B6-Taar1^{tm1}(NLSLacZ)Blt (TAAR1-KO) mice and wildtype littermates (8-12 weeks old) were used and experimental procedures were performed in accordance with EU directive 2010/63/EU. 18F-DOPA PET was utilized to measure striatal Ki (dopamine synthesis capacity) in TAAR1-KO (n=12) and WT (n=11) animals. In addition, locomotor activity at baseline and in response to amphetamine (2.5 mg/kg) i.p. was assessed in both genotypes. Study 2: Patients with a DSM-5 diagnosis of schizophrenia on a stable dose of a single antipsychotic medication participated. They received a baseline 18F-DOPA PET scan and symptom measures (PANSS ratings) followed by treatment with ulotaront up to 75mg/day added to their existing antipsychotic for a period of 14 days. On day 14, the 18F-DOPA PET scan was repeated approximately 2-4 h after the final ulotaront dose and PANSS ratings repeated. The primary endpoint was change from baseline in striatal Ki across its three functional subdivisions at day 14 measured by 18F-DOPA PET scan.

Results: Study 1: Striatal Ki was significantly elevated in TAAR1-KO animals (n=12; mean (sem) Ki=0.024 (0.0023)) relative to wildtype (n=11; mean (sem) Ki=0.018 (0.0015)),

$t(21)=2.09$, p LESS THAN 0.05) with an effect size of 0.85. There was no significant difference in locomotion between genotypes for the habituation or saline trials, however there was a significant increase in the locomotor response to amphetamine in the TAAR1-KO animals compared to wildtype controls (p LESS THAN 0.005). Study 2: 19 subjects (14 male); mean (SD) age, 32.9 (6.7) yrs; black ($n=8$), white ($n=8$), other ($n=3$) participated. Mean (SD) age at initial diagnosis-28.6 (6.5) yrs; baseline mean (SD) PANSS total score 79.3 (7.3), PANSS positive subscale 19.2 (4.6), PANSS negative subscale 22.8 (6.1). There was a significant effect of treatment (p LESS THAN 0.05) and striatal subregion (p LESS THAN 0.05) on Ki but no treatment by subregion interaction (p GREATER THAN 0.8). Treatment Cohen's d effect size were: associative striatum= -0.4 (95% CI: -0.89, 0.11); motor striatum= -0.4 (95% CI: -0.89, 0.11); and limbic striatum= -0.7 (95% CI: -1.28, -0.19). There was a significant correlation between change in striatal 18F-DOPA Kicer and change in Marder Positive Factor score on the PANSS ($r=0.5$, p LESS THAN 0.05) but no significant relationship with change in PANSS total symptom score ($r=0.2$, p GREATER THAN 0.05).

Conclusions: The knock-out of TAAR1 in mice results in elevated striatal dopamine synthesis capacity and locomotor response to amphetamine, showing that TAAR1 is involved in regulating dopamine synthesis and behavioural response to a dopaminergic challenge. Treatment with a TAAR1 agonist, ulotaront, is associated with a reduction in striatal dopamine synthesis capacity in people with schizophrenia that is related to clinical improvement. Together these results highlight the potential of targeting TAAR1 to address the dopaminergic pathophysiology underlying psychosis in schizophrenia.

12.3. IMAGING MONOAMINE OXIDASE B, AN ASTROGLIA MARKER KEY FOR NEUROTRANSMITTERS HOMEOSTASIS, IN EARLY PSYCHOSIS

Romina Mizrahi*¹, Kankana Aji², Pablo Rusjan¹

¹McGill University, ²CaTS lab, Douglas Hospital

Background: Astrocytes regulate homeostasis of neurotransmitters including dopamine and glutamate. Considering the fundamental involvement of astrocytes in glutamatergic processes, including biosynthesis, reuptake, and release, decreased astrocyte function could impact glutamatergic neurotransmission. For instance, altered astrocyte expression of excitatory amino acid transporter 1 (EAAT1) and EAAT2 may lead to impaired glutamate clearance from synapses, resulting in prolonged glutamate signaling. Interestingly, EAAT1 knock-out mice exhibited schizophrenia-like behavioural and cognitive disturbances, and postmortem brain tissue studies in schizophrenia patients have demonstrated reduced expression of EAATs in the cortical regions studied. Furthermore, diminished astrocyte function could relate to an impaired regulation of D-serine and glycine levels, both of which act as endogenous co-agonists for glutamatergic NMDARs. Notably, studies in schizophrenia patients have reported reduced serum and cerebrospinal fluid (CSF) D-serine levels implicating NMDAR hypofunction, resulting in overstimulation of glutamate release, consistent with the glutamatergic hypothesis of schizophrenia. Importantly, MAO-B is responsible for the independent catabolism of dopamine and other amines in brain. Thus, astrocyte dysfunction, as indexed by lower MAO-B levels, is consistent with both dopaminergic and glutamatergic transmission abnormalities previously reported in psychosis. However, this has never been tested in living brains of early psychosis patients. A novel radiotracer, [11C]SL25.1188 targets monoamine oxidase-B (MAO-B) enzyme primarily found in astrocytes, enabling in vivo astrocyte status quantification.

Methods: Objective: To investigate whether MAO-B distribution volume (MAO-B VT), an astroglia marker, is reduced in early psychosis. This is a cross-sectional study performed in a tertiary care psychiatric hospital, Ontario, from October 2018 to November 2019. Participants (n=38) included antipsychotic-free/minimally exposed patients with first episode psychosis (FEP), clinical high-risk (CHR) individuals and Healthy volunteers (HVs). Participants were excluded if tested positive on urine drug screen (except for cannabis and tobacco). All participants underwent a 90-minute positron emission tomography (PET) scan with [¹¹C]SL25.1188, to measure MAO-B VT, an index of MAO-B density.

Results: In total, 14 FEP patients (mean[SD] age, 25.7[5.7] years; 6 F), 7 CHR (mean[SD] age, 20.9[3.7] years; 4 F) and 17 HV (mean[SD] age, 31.2[13.9] years; 9 F) completed all study procedures. We found a significant effect of study group ($F(2,37.48)=5.30$, $p=0.009$, Cohen's $f=0.53$) on regional MAO-B VT, with significant reductions in CHR compared to HV (Cohen's $d=1.05$) and FEP (Cohen's $d=0.83$). We report a significant cannabis use effect on MAO-B VT ($F(1,39.47)=12.45$, $p=0.001$, Cohen's $f=0.56$), with a significant group-by-cannabis interaction ($F(2,37.35)=3.81$, $p=0.03$, Cohen's $f=0.45$), indicating lower MAO-B VT in cannabis using patients. We observed more pronounced MAO-B VT reductions in striatal regions compared to cortical regions, in both clinical groups ($F(12,46.07)=2.00$, $p=0.046$, Cohen's $f=0.72$) and in cannabis users ($F(6,46.07)=6.01$, $p < 0.001$, Cohen's $f=0.89$). All tests were controlled for tobacco use.

Conclusions: Reduced MAO-B levels could reflect diminished capacity to terminate dopaminergic synaptic signalling, resulting in the well replicated increased dopaminergic tone in psychosis, particularly in striatal regions. Further, reduced MAO-B could mean astrocyte dysfunction, which would also be consistent with glutamatergic transmission abnormalities previously reported in psychosis. Finally, reduced astrocyte status, or specifically MAO-B downregulation, also supports glial cell dysfunction, consistent with meta-analytic in-vivo evidence of reduced microglial density in schizophrenia. In this context, pharmacological interventions that restore MAO-B containing astrocytes or increase MAO-B density could potentially be targeted in patients.

12.4. THE ROLE OF CORTICAL GLUTAMATE LEVELS IN THE PATHOPHYSIOLOGY OF ANTIPSYCHOTIC NON-RESPONSIVE SCHIZOPHRENIA: A LONGITUDINAL IMAGING STUDY IN FIRST-EPISODE PSYCHOSIS

Lejia Fan^{*1}, Liangbing Liang², Xiaogang Chen³, Lena Palaniyappan⁴

¹Central South University, Changsha, ²Western University, ³The Second Xiangya Hospital, Central South University, ⁴Douglas Mental Health University Institute, McGill University

Background: A subgroup of patients with schizophrenia is believed to have aberrant excess of glutamate in the anterior cingulate cortex (ACC); this subgroup is thought to show poor response to first-line antipsychotic treatments that focus on dopamine blockade. Meanwhile, brain age gap (BAG), i.e., the difference between actual age and biologically predicted age based on brain structure, is higher in schizophrenia; this may relate to the effect of glutamate-mediated excitotoxicity and accelerated brain tissue loss. If we can identify a subgroup with higher glutamate and BAG early in the course of illness, we can reduce the repeated use of first-line antipsychotics and potentially stratify first episode patients to intervene early with clozapine. We must first establish if there is robust evidence linking elevations in BAG and glutamate metabolites to poor response, and determine if the use of antipsychotics worsens the glutamatergic excess and BAG in eventual nonresponders. We use proton magnetic resonance spectroscopy (1H-MRS) to measure glutamatergic metabolites (Glutamate and Glx (glutamate

plus glutamine)) to establish if stratification using MRS and structural imaging before starting antipsychotics in the future.

Methods: In this study, we obtained proton magnetic resonance spectroscopy of glutamatergic metabolites at perigenual (pACC) and dorsal (dACC) ACC and whole brain T1 imaging at 3-Tesla scanner in 42 drug-naïve patients with schizophrenia and 41 health controls (HC). We then treated schizophrenia patients with risperidone at a standard dose range of 2-6 mg/day (titrated as per clinician-patient shared decision making) and followed them up for 3 months to categorize their response status. Patients were divided into responders (N =27) and non-responders (N =15) based on whether the percent PANSS total score reduction was above or below 50%. Brain age was predicted by the model using XGBoost method.

Results: Nonresponders had higher glutamate than responders, but both patient groups did not differ in glutamate and Glx from HC group before treatment-onset ($F_{1,79} = 3.20$, $p = 0.046$, partial $\eta^2 = 0.075$). Glutamatergic metabolites did not change significantly over time in both nonresponders and responders over the 3 months of antipsychotic exposure ($F_{1,31} = 1.26$, $p = 0.270$, partial $\eta^2 = 0.039$). Both responders and nonresponders showed an improvement in symptom burden over 12 weeks, with the exception that nonresponders showed no notable improvement in negative symptoms ($t = -0.41$, $p = 0.688$). Contrary to our expectations, both responders and nonresponders had worsening BAG with time compared to healthy controls ($F_{2,77} = 3.20$, $p = 0.003$, partial $\eta^2 = 0.137$). Higher baseline Glu in dACC is associated with smaller BAG both at baseline ($r = -0.34$, $p = 0.032$) and 12 weeks ($r = -0.45$, $p = 0.005$) for patients as a group. Higher Glu ($r = -0.34$, $p = 0.032$) and Glx ($r = -0.32$, $p = 0.043$) in pACC is associated with smaller BAG at baseline for HC.

Conclusions: We note that while BAG and glutamate levels are correlated in patients, it is only the ACC glutamate signal that relates to non-response. Irrespective of responder status, all patients show worsening BAG. But glutamate levels do not continuously deteriorate over time. The use of antipsychotics without prior knowledge of later response delays symptom relief in a subgroup of first-episode patients. BAG may reflect a process that is related to hyperglutamatergia, but unrelated to response status. Given the current practice of nonstratified use of antipsychotics, longer-time follow-up MRS studies are required to see if improvement in symptoms accompanies a dynamic shift in glutamate profile.

13. UTILISING ENVIRONMENTAL RISK FACTORS TO IMPROVE PREDICTION AND PATHWAYS TO CARE IN ULTRA-HIGH RISK FOR PSYCHOSIS

Brian O'Donoghue, *University College Dublin*

Overall Symposia Abstract: There are a number of well-established, robust environmental risk factors for the development of a first episode of psychosis, including migrant or ethnic minority status, neighbourhood deprivation or fragmentation and cannabis use. However, these findings have not been utilised to improve prediction in the ultra-high risk (UHR)/ clinical high-risk (CHR) state for psychosis. In fact, it has been found that minority groups and individuals from more deprived areas are often under-represented within these cohorts. There has been a decline in the transition rates to a full-threshold psychotic disorder in those identified as UHR since the initial establishment of these services. Over 40% of UHR individuals transitioned to a full-threshold psychotic disorder in the initial studies in the mid-1990s and then there has been a steady decline in rates to approximately 15%. Therefore, it could be possible to further enrich the UHR cohorts based on the presence of environmental risk factors for psychotic disorders, thereby bringing the characteristics of the UHR cohort to resemble that of the FEP cohort more closely.

In this symposium, we will first explore the association between environmental risk factors and the symptoms and outcomes of the UHR state and then examine how this knowledge could assist in further refining the criteria or enriching UHR cohorts with individuals at greater risk of transition. In the first presentation, Dr Benson Ku, an assistant professor at the Emory University School of Medicine in the US, will discuss trajectories of impaired social functioning in childhood and young adulthood and their associations with area-level social fragmentation and school maladaptation among youth at clinical high risk for psychosis. He will be presenting additional unpublished findings from the North American Prodrome Longitudinal Study. This talk will be followed by Dr Mariapaola Barbato, who will present findings on the symptoms and outcomes of migrants who are identified as Ultra-high risk for psychosis. Associate Professor Brian O'Donoghue, a psychiatrist in Dublin, Ireland will present unpublished data on the accumulative effect of individual, family and neighbourhood level environmental risk factors on the transition rates in young people identified as ultra-high risk for psychosis from the PACE Clinic in Melbourne, Australia. Finally, Dr Dominic Oliver, a postdoctoral researcher from Oxford, UK, will describe the Psychosis Polyrisk Score (PPS), which was developed from 16 environmental risk factors and enables an UHR individual's risk of transition to be predicted. Dr Oliver will present findings on the validation of the PPS in large UHR cohort. Finally, Dr Sheri Oduola, who has published widely on pathways to care for psychosis, will act as a discussant for the symposium.

13.1. RELATIONS OF AREA-LEVEL SOCIAL FRAGMENTATION AND SCHOOL MALADAPTATION DURING CHILDHOOD ON SOCIAL FUNCTIONING AMONG YOUNG ADULTS AT CLINICAL HIGH RISK FOR PSYCHOSIS

Benson Ku^{*1}, Jean Addington², Carrie Bearden³, Kristin Cadenhead⁴, Tyrone Cannon⁵, Michael Compton⁶, Barbara Cornblatt⁷, Benjamin Druss⁸, Sinan Guloksuz⁹, Daniel Mathalon¹⁰, Diana Perkins¹¹, Ming Tsuang⁴, Elaine Walker¹², Scott Woods⁵, Ricardo Carrion¹³

¹Emory University School of Medicine, ²University of Calgary, ³University of California, Los Angeles, ⁴University of California, San Diego, ⁵Yale University, ⁶College of Physicians and Surgeons, Columbia University, ⁷The Zucker Hillside Hospital, ⁸Emory University Rollins School of Public Health, ⁹Maastricht University, ¹⁰University of California, San Francisco, ¹¹University of North Carolina at Chapel Hill, ¹²Emory University, ¹³Institute of Behavioral Science, Feinstein Institutes for Medical Research

Background: Studies have identified area-level social fragmentation index as a significant risk factor for psychotic disorders. However, it is unknown whether it may impact social functioning. This study investigates whether social fragmentation during childhood predicts maladaptation to school as well as social functioning among healthy youth and those at clinical high risk (CHR-P).

Methods: This study sample included 133 young adults at CHR-P and 90 healthy comparisons from the baseline cohorts across 8 sites from the second North American Prodrome Longitudinal Study (N = 223, 54.7% males; average age range = 21.8). Area-level characteristics, including social fragmentation, were derived from county-level data from the U.S. Decennial Censuses. Cities or towns where individuals spent the majority of their childhood were linked to the primary county 5-digit Federal Information Processing Standards

codes. Social fragmentation was measured as the average of the z-scores of the following area-level characteristics which have been previously shown to measure social fragmentation and to be associated with psychotic disorders: residential instability (percent of residents who changed their address in the past five years), percent of residents with renter-occupied housing, percent of residents who are divorced, and percent single-parent households. Maladaptation to school and social functioning during childhood were assessed retrospectively and social functioning in adulthood was assessed at baseline. Generalized linear mixed regression models adjusted for covariates including age, sex, family history of mental illnesses, White non-Hispanic race/ethnicity, high school parental education, total traumatic events, area-level deprivation, and unique counties.

Results: During childhood, greater social fragmentation was associated with greater maladaptation to school in childhood (unadjusted $\beta = 0.25$; 95% CI: 0.08 to 0.42) even after adjusting for seven covariates (adjusted $\beta = 0.21$; 95% CI: 0.02 to 0.40). However, social fragmentation was not associated with social functioning in childhood (unadjusted $\beta = -0.08$; 95% CI: -0.31 to 0.15). In contrast, greater social fragmentation during childhood predicted poorer social functioning in young adulthood (unadjusted $\beta = -0.56$; 95% CI: -0.86 to -0.26) even after adjusting for seven covariates (adjusted $\beta = -0.43$; 95% CI: -0.79 to -0.07). Greater maladaptation to school during childhood predicted poorer social functioning in adulthood (adjusted $\beta = -0.38$; 95% CI: -0.61 to -0.15). Maladaptation to school had a significant indirect effect on the association between social fragmentation during childhood and social functioning in adulthood (adjusted $\beta = -0.07$; 95% CI: -0.17 to LESS THAN -0.01) and explained 15.7% of this association. CHR-P status significantly interacted with social fragmentation during childhood in predicting poorer social functioning in adulthood (adjusted $\beta = -0.42$; 95% CI: -0.82 to -0.02) such that the slope between social fragmentation and social functioning was more negative among youth at CHR-P compared with HC.

Conclusions: This is the first study to find associations between area-level social fragmentation during childhood and social functioning in early adulthood. This association is mediated by greater maladaptation to school during childhood. Moreover, this association is moderated by CHR-P status such that childhood social fragmentation has an even stronger association with adult social functioning among youth at CHR-P compared to HC. Perhaps, exposure to cumulative social stressors from area-level social fragmentation during childhood might impact social functioning through repeated and chronic adverse social experiences (e.g., lack of feeling of belongingness or not fitting in) at school. Further research will be needed to explore the mechanisms of these associations and better understand the perceived experiences of area-level social fragmentation, the specificity of the developmental time period of exposure in relation to its impact on social functioning, and how social fragmentation and genetic vulnerability might interact in contributing to poorer social functioning.

13.2. THE IMPACT OF MIGRANT STATUS ON CLINICAL SYMPTOMS AND FUNCTIONING IN YOUTH AT CLINICAL HIGH RISK FOR PSYCHOSIS

Mariapaola Barbato^{*1}, Lu Liu², Carrie E. Bearden³, Kristin S. Cadenhead⁴, Barbara A. Cornblatt⁵, Matcheri Keshavan⁶, Daniel H. Mathalon⁷, Thomas H. McGlashan⁸, Diana O. Perkins⁹, Larry J. Seidman⁶, William S Stone⁶, Ming T. Tsuang⁴, Elaine F. Walker¹⁰, Scott W. Woods⁸, Tyrone D. Cannon⁸, Jean Addington²

¹Zayed University, ²Hotchkiss Brain Institute, University of Calgary, ³University of California, Los Angeles, ⁴University of California San Diego, ⁵Zucker Hillside Hospital, ⁶Harvard Medical School, Beth Israel Deaconess Medical Center, ⁷University of California, San Francisco, ⁸Yale University, ⁹University of North Carolina, ¹⁰Emory University

Background: Migrant status is a known risk factor for schizophrenia and other psychotic disorders. Among migrants, the risk seems to vary according to several factors, including country of birth, host country, ethnic minority status and refugee status. The pathways to psychosis, however, for migrants and their offspring, are still largely unknown. Recent studies have begun to explore whether migrant status predicts transition to psychosis in individuals who are at clinical high risk (CHR) for psychosis. The results of systematic reviews and meta-analyses however have been inconclusive. Our study assessed the impact of migrant status on clinical symptoms and functional outcome in individuals at CHR for psychosis who took part in the North American Prodrome Longitudinal Study (NAPLS-3).

Methods: Participants' migrant status was classified as native-born, first-generation, or second-generation migrant. Clinical symptoms were assessed using the Structured Interview for Psychosis-Risk Syndromes (SIPS); functional outcome was measured using the Global Functioning Scales: Social and Role (GF:S; GF: R). Assessments were conducted at baseline, 12-months, 18-months, and 24-months follow-up. We used generalized linear mixed models for repeated measures to examine group differences and changes over time.

Results: The overall sample included 710 individuals at CHR for psychosis (54.2% males; Age: $M=18.19$; $SD=4.04$). A mixed model analysis was conducted, and no significant differences between groups in symptoms or functioning were observed at any time point. Over time, significant improvement in symptoms and functioning was observed within each group. The rate of conversion to full-blown psychosis was similar across the three groups (native-born: 20%; first-generation migrant: 20%; second-generation migrant: 21%; $X^2 = 0.27$, $p = 0.87$).

Conclusions: To the best of our knowledge our study was the first to focus on migrant status, clinical symptoms and functioning in CHR individuals, and our results await replication. Nevertheless, we will discuss potential factors that might explain the lack of group differences in our sample. Overall, migrants are a heterogeneous population. Discerning the impact of migration from that of neighborhood ethnic density, social disadvantage or socio-economic status of different ethnic groups could help better understand vulnerability and resilience to psychosis.

13.3. ENRICHING ULTRA-HIGH RISK FOR PSYCHOSIS COHORTS BASED ON ACCUMULATED EXPOSURE TO ENVIRONMENTAL RISK FACTORS FOR PSYCHOTIC DISORDERS

Brian ODonoghue^{*1}, Andrew Thompson², Patrick McGorry², Barnaby Nelson²

¹University College Dublin, ²Orygen

Background: Transition to psychosis rates within ultra-high risk (UHR) services have declined and the characteristics of UHR cohorts are often different from first episode psychosis (FEP) services. It may be possible to 'enrich' UHR cohorts based on the environmental risk factors seen more commonly in FEP cohorts. This study aimed to determine whether transitions rates varied according to the accumulated exposure to environmental risk factors at the individual, family and neighbourhood level.

Methods: The study included UHR young people aged 15-24 who attended the PACE clinic from 2012-2016. Information according to environmental risk factors at the individual (migrant status, asylum seeker/refugee status, indigenous population, cannabis/methamphetamine use), family (family history or parental separation) and neighbourhood (population density, social deprivation and fragmentation) level were collected at the time of presentation. The transition rates and the corresponding hazard ratios according to the level of accumulated exposure was determined.

Results: Of the 461 young people included, 55.5% were female and median follow-up was 307 days (I.Q.R.:188-557) and 17.6%(n=81) transitioned to a psychotic disorder. Of those who had no exposure to an environmental risk factor, 11.1% transitioned compared to 18% with one or two individual-level factors present. The proportion that transitioned increased incrementally with the accumulated exposure and 33.3% transitioned with exposure to five factors. Accumulated exposure to family or neighbourhood level environmental risk factors was not associated with transition.

Conclusions: There is a dose-response relationship between exposure to individual level psychosis-related environmental risk factors and transition to psychosis risk in UHR patients, although the numbers were small in the later groups and lacked statistical power. If replicated, this finding could be incorporated into a novel approach to identifying highest risk individuals within clinical services.

13.4. CONTRIBUTION OF THE PSYCHOSIS POLYRISK SCORE (PPS) AND POLYGENIC RISK SCORE IN PREDICTING PSYCHOSIS ONSET IN INDIVIDUALS AT CLINICAL HIGH RISK FOR PSYCHOSIS

Dominic Oliver*¹, Matthew Kempton², Daniel Stahl², Philip McGuire², Paolo Fusar-Poli³

¹University of Oxford, ²Institute of Psychiatry, Psychology, and Neuroscience, King's College London, ³ Institute of Psychiatry, Psychology, and Neuroscience, King's College London, OASIS team, South London and the Maudsley NHS Foundation Trust, University of Pavia,

Background: The complex interplay between environmental factors and genetics in the development of psychosis remains poorly understood. Genetics, through the polygenic risk score (PRS), have been shown to explain between 9-12% of the variance in CHR-P transition risk (Perkins et al., 2020), which remains sub-optimal. To address this, the Psychosis Polyrisk Score (PPS) was developed, piloted and digitally implemented as a multivariate assessment of environmental risk factors for psychosis. The PPS combines information from 16 systematically selected environmental risk factors to predict an individual's psychosis risk. It can therefore be used to potentially improve prognosis of individuals at clinical high risk for psychosis (CHR-P). It is currently unknown what proportion of variance can be explained by the PPS and its combination with genetics.

Methods: N=410 CHR-P individuals were recruited as part of the EU-GEI study. We assigned a PPS score to all participants comprised of age, gender, non-right handedness, urbanicity, pollution, ethnicity, migrant status, paternal age, paternal socioeconomic status, parental severe mental illness, stressful life events, tobacco use, cannabis use, hearing impairments, childhood trauma and trait anhedonia. The weights for each factor were based on meta-analytic Odds Ratios from a previously published umbrella review (Radua et al., 2018). First, we compared PPS total score between CHR-P individuals who transitioned and those who did not using Welch's t-test. Second, we used a Cox proportional hazards model to estimate the risk of transitioning psychosis. Three models were conducted including: i) PRS alone; ii) individual PPS factors alone; iii) PRS and individual PPS factors. The primary outcome was the proportion of variance explained, indexed by Nagelkerke's pseudo R².

Results: N=57 (13.9%) CHR-P individuals transitioned over 730 days follow-up. PPS scores ranged from -3.5 to 40.5 with a mean (SD) of 16.7 (9.7). PPS scores were significantly higher in CHR-P individuals who transitioned to psychosis (MD=3.4, 95%CI=0.89-5.93, d=0.36, t(80)=2.7, p=0.009). PRS alone explained a small proportion of variance (R²=0.03). Individual PPS factors explained a greater degree of variance (R²=0.17). Combining PRS and PPS individual factors (R²=0.23) explained the most variance.

Conclusions: Significantly higher PPS total scores in individuals who transitioned to psychosis suggest heightened exposure in those most at risk. Preliminary results suggest that a simple multivariate environmental risk assessment for psychosis risk is able to explain substantially more variance in transition risk in CHR-P than more expensive and invasive genetic tests. However, we may gain more prognostic value by considering genetic and environmental risk as complementary approaches.

14. BEYOND THE BIOLOGICAL MODEL: INVESTIGATING SOCIAL DETERMINANTS, LONELINESS, AND ADVERSITY IN THE PSYCHOSIS SPECTRUM

Katrina Rbeiz, *Vanderbilt University*

Overall Symposia Abstract: Social determinants of health include socioeconomic status, social support and networks, cultural and social norms, racial/ethnic identity, and education levels, to name a few. The intersection between these factors and the development of psychosis is a critical area of study, carrying significant implications for addressing mental health disparities. The theory of social defeat stresses the importance of environmental factors in psychosis-risk, and posits that experiences of social adversity may amplify the risk for developing psychosis. The intricate relationship between these factors underscores the need to move beyond the traditional neurobiological models of schizophrenia to focus on the broader influence of social and environmental factors. In this symposium, we begin with an overview of how various forms of exclusion, discrimination, and adversity may play a role in the development of psychosis, particularly among marginalized groups of people across global contexts. Katrina Rbeiz will present data from a cross-sectional study investigating the risk and resilience factors associated with the development of psychosis, with a focus on Middle Eastern and North African immigrant experiences. Jill Laquidara's presentation will further explore the social defeat hypothesis, which posits that people with increased perceived discrimination and sense of inferiority will be at higher risk for psychosis. Renata Botello will explore the connection between social adversity and loneliness in first-episode psychosis patients, and will shed light on the psychosocial challenges faced by individuals as they navigate the early stages of the psychosis spectrum. Zeynep Akcaoglu will present experience sampling methodology findings from Belgium looking at moment-to-moment levels of distress and social isolation, and how they may be associated with psychotic experiences. This temporal investigation underscores the dynamic nature of these factors and how they may influence the trajectory of psychosis. Of note, the participants in each of these studies represent diverse and underrepresented populations, and their social identities will be at the crux of each presentation, providing new insights into culturally informed interventions. Finally, Dr. Hans Oh will synthesize the presentations and share his thoughts on future directions and interventions addressing social adversity, isolation, and risk factors in the development of psychosis spectrum disorders. Attendees will gain insights into the social determinants that may impact the development of psychosis across the schizophrenia spectrum, and will hopefully think critically about environmental factors and social networks when designing studies. This symposium challenges existing models rooted in biology by emphasizing the need to integrate people's social, cultural, and environmental contexts.

14.1. EXPERIENCES OF STIGMA AMONG PSYCHOLOGY TRAINEES WITH PSYCHOSIS SPECTRUM DISORDERS

Emily Turner*¹, Emily Treichler², Katrina Rbeiz³

¹*Psychin Out*, ²*University of California, San Diego*, ³*Vanderbilt University*

Background: Psychosis spectrum conditions (e.g., bipolar disorder, schizophrenia, psychosis) are highly stigmatized in our culture, and these systemic biases permeate mental health service professions despite this being contrary to the field's values and mission (Elliott and Ragsdale, 2020; Peris et al., 2008; Arboleya-Faedo et al., 2023). Mental illness stigma exacerbates feelings of burnout and reduces treatment-seeking among psychology trainees (Berger, 2022; Devendorf et al., 2023; Victor, Schleider, et al., 2022). While psychology trainees are clearly vulnerable to the effects of mental illness stigma (Grice et al., 2018), their unique experiences with psychosis spectrum conditions have not been studied. This exploratory study aims to investigate the levels of stigma of psychosis conditions and discrimination experienced by psychology trainees.

Methods: 200 psychology trainees (full-time predoctoral researchers and doctoral students in psychology) with mental health conditions were administered a battery of four validated scales to assess experiences of mental illness stigma and discrimination (Everyday Discrimination Scale, Williams et al., 1997; Internalized Stigma of Mental illness - Brief, Boyd-Ritscher et al., 2003; Berger Stigma Scale, Reinius et al., 2018; EMIC Community Stigma Scale, Chowdhury et al., 2001). Of these 200 participants, 65 trainees identified as having a psychosis spectrum condition. Using bivariate correlations, t-tests, and MANOVA, we will investigate whether experience with psychosis spectrum conditions is associated with higher levels of discrimination, internalized stigma, and community stigma. We will also investigate whether demographic variables (e.g., education, race, income, gender) play a role in increased stigma surrounding their given psychosis spectrum condition.

Results: We hypothesize that psychology trainees with experience of a psychosis spectrum condition will report higher levels of stigma and everyday discrimination than those with a history of other more common mental health problems. We also hypothesize that lower income and education, as well as people who identify as gender and racial minorities, will have increased reports of stigma and discrimination.

Conclusions: To our knowledge, this is the first study investigating stigma and discrimination among psychology trainees with a psychosis spectrum condition entering the mental health field. Understanding of lived experience of this population can inform anti-stigma and anti-discrimination efforts from graduate programs to professional organizations, to help support recruitment and retention of the next generation of diverse psychologists.

14.2. MEASURING PERCEPTIONS OF SOCIAL DEFEAT, DISCRIMINATION, AND SENSE OF INFERIORITY IN CLINICAL HIGH RISK FOR PSYCHOSIS

Madeline Ward*¹, Jill Laquidara¹, Taylor Johnson¹, Sarah Hope Lincoln¹

¹*Case Western Reserve University*

Background: The social defeat hypothesis of schizophrenia suggests that socially defeating or excluding experiences increase risk for psychosis (Selten et al., 2005). However, social defeat can be operationalized in several ways, including broad feelings of defeat, specific experiences of exclusion or discrimination, and perceptions of oneself as inferior (Schalbroeck, 2020). Various conceptualizations of social defeat may vary in how they are related to the psychosis spectrum. The present study aimed to explore three different measures of social defeat in a clinical high risk (CHR) population. We hypothesized that social defeat broadly, as well as perceived inferiority and discrimination more specifically, would be higher in clinical high risk

(CHR) participants than in healthy control (HC) participants, which would be in line with the social defeat hypothesis of schizophrenia.

Methods: Adults ages 18-35 (N = 66 [32 HC, 34 CHR], 58% female, M-age = 25.6 ± 4.17) completed self-report measures and clinical interviews in a research study conducted online, using the Zoom platform and REDCap. Measures included the Structured Interview for Prodromal Syndromes (McGlashan et al., 2001), Structured Clinical Interview for DSM-5 (First, 2015); Defeat Scale (Gilbert and Allan, 1998), Social Comparison Scale (Allan and Gilbert, 1995), Everyday Discrimination Scale (Williams et al., 1997), Brief Core Schema Scale (Fowler et al., 2006), Global Functioning: Social Scale (Carrión et al., 2019), and Wechsler Abbreviated Scale of Intelligence (Wechsler, 1999). Analyses included between-groups t-tests and correlation analyses.

Results: Social defeat was significantly higher in the CHR group than the HC group when operationalized as Defeat Scale scores, $t(64) = 4.09$, $p < .001$ and Everyday Discrimination Scale scores, $t(63) = 3.66$, $p < .001$. However, when operationalized as feelings of inferiority, social defeat was not significantly different between groups, $p > .05$. Of note, the CHR and HC groups did not differ in terms of gender or sexual minority status ($p > .05$), but a greater proportion of the CHR group were people of color, $\chi^2(1, N=65) = 4.4$, $p = .04$.

Conclusions: Broad feelings of social defeat, and more specifically discrimination, were both higher in the CHR group. In contrast to our hypothesis, feelings of inferiority were not greater in the CHR group. Inferiority may be distinct from other aspects of social defeat in how it is experienced by individuals at risk for psychosis. It is notable that the CHR group had a greater proportion of people of color than the control group. Next steps will involve looking at the perceived reasons for discrimination endorsed by participants. Discrimination and defeat may be higher in the CHR group due to racial bias as well as other types of defeating experiences, perhaps those related to symptom presentation and mental health stigma. It is also possible that for CHR individuals, the defeat and discrimination they experience feels even more salient due to symptom-related attention to threat, social anxiety, or schemas involving danger. It is likely that these factors all play a role in helping to explain the finding that CHR individuals experience greater feelings of social defeat and discrimination than healthy controls. In line with the social defeat hypothesis, this study demonstrates higher reports of perceived social defeat in individuals with subthreshold psychosis.

14.3. SOCIAL ADVERSITY AND LONELINESS IN FIRST EPISODE PSYCHOSIS

Renata Botello^{*1}, Arti Gandhi¹, Nicholas Wagner¹, Hans Oh², Kim Mueser¹, Daniel Fulford¹

¹Boston University, ²University of Southern California

Background: Aspects of social adversity, including poverty, trauma, exposure to crime, and homelessness, may contribute to psychosis risk, at least partly through the effects of structural racism (Anglin et al., 2021; DeVlyder et al., 2023). Research has also shown that structural racism and other forms of social exclusion are highly prevalent in people with psychosis and are related to more severe symptoms of depression, anxiety, and positive symptoms (Berg et al., 2011). Loneliness, the subjective experience of social disconnection (Hawkey and Cacioppo, 2010), could result from various forms of social adversity and associated exclusion. Loneliness is more prevalent among both people with psychosis (Badcock et al., 2015) and marginalized individuals in the general population (Visser and El Fakiri, 2016). However, the extent to which social adversity contributes directly to loneliness among people with psychosis is relatively unknown. Thus, in the current study we aimed to understand the extent to which

social adversity contributes to loneliness, accounting for demographic and social network variables, in first episode psychosis.

Methods: Four-hundred and four participants ages 15-40 completed baseline assessments as part of the Recovery After an Initial Schizophrenia Episode-Early Treatment Program. Loneliness was measured using a composite set of self-report items from the Well Being Scale and the Stigma Scale (e.g., “I often feel lonely because I have few close friends with whom to share my concerns.”). Social network characteristics (e.g., degree of recent social contact, including close friends, relatives, and acquaintances) were measured using the Quality of Life Scale (QLS). We created a latent variable of social adversity that included trauma history (number of reported traumatic experiences), education (highest parental level of education), health insurance (Medicaid status), and poverty (deferral/food stamp receipt). We first tested measurement models of loneliness and social adversity, followed by estimating a path model of the relationships among these variables, accounting for race/ethnicity and social network characteristics.

Results: Our hypothesized measurement models of social adversity ($X^2 = 10.261$, CFI = 0.821, TLI = 0.643, RMSEA = 0.077, SRMR = 0.044) and loneliness ($X^2 = 5.185$, CFI = 0.992; TLI = 0.984; RMSEA = 0.049; SRMR = 0.050) both resulted in adequate fit. All items demonstrated adequate loadings (β s GREATER THAN 0.40, p LESS THAN 0.01). Our hypothesized path model of the association between social adversity and loneliness resulted in moderate fit ($X^2 = 86.56$, CFI = 0.76, TLI = 0.65, RMSEA = 0.067, SRMR = 0.061). Greater social connection (i.e., social network characteristics) was associated with significantly lower self-reported loneliness ($\beta = -0.384$, p LESS THAN .01) and social adversity ($\beta = -0.381$, p LESS THAN .001). Importantly, greater social adversity was associated with significantly higher self-reported loneliness ($\beta = 0.376$, p LESS THAN .01), after accounting for social network characteristics and race/ethnicity.

Conclusions: Findings highlight the potential contribution of social adversity to the experience of loneliness in first episode psychosis. Social adversity, including trauma, limited resources, and other stressful experiences, could contribute to feelings of loneliness by way of either reduced opportunities for meaningful social contact, or perceived discrimination or other racialized experiences. In future work, it will be important to identify the extent to which discrimination and other racialized experiences contribute directly to social disconnection. Nonetheless, this study emphasizes the need to consider markers of adversity and other important social determinants of health when developing loneliness interventions for marginalized individuals with first-episode psychosis.

14.4. THE TEMPORAL ASSOCIATION BETWEEN SOCIAL ISOLATION, DISTRESS AND PSYCHOTIC EXPERIENCES IN INDIVIDUALS AT CLINICAL HIGH-RISK FOR PSYCHOSIS

Zeynep Akcaoglu^{*1}, Thomas Vaessen¹, Eva Velthorst², Ginette Lafit¹, Robin Achterhof³, Barnaby Nelson⁴, Patrick McGorry⁵, Frederike Schirmbeck⁶, . ¹¹AMC-Academisch Psychiatrisch Centrum, ¹²King's College London, ¹³Open University,
¹⁴Maastricht University, ¹⁵Maastricht University Medical Center, ¹⁶Central Institute of
Mental Health, University of Heidelberg

Background: Psychotic experiences (PEs) and social isolation (SI) seem related during early stages of psychosis, but the temporal dynamics between the two are not clear. Literature so far suggests a self-perpetuating cycle wherein momentary increases in PEs lead to social withdrawal, which, subsequently, triggers PEs at a next point in time, especially when SI is associated with increased distress. The current study investigated the daily-life temporal associations between SI and PEs, as well as the role of SI-related and general affective distress in individuals at Clinical High Risk for psychosis (CHR).

Methods: We used Experience Sampling Methodology (ESM) in a sample of 137 CHR participants. We analyzed the association between SI, PEs and distress using time-lagged linear mixed-effects models.

Results: Social isolation did not predict next-moment fluctuations in PEs, or vice versa. Furthermore, although SI-related distress was not predictive of subsequent PEs, general affective distress during SI was a robust predictor of next-moment PEs.

Conclusions: Our results suggest that SI and PEs are not directly related on a moment-to-moment level, but a negative emotional state when alone does contribute to the risk of PEs. These findings highlight the role of affective wellbeing during early-stage psychosis development.

15. MULTI-SCALE, MULTI-SPECIES APPROACHES TO ADVANCE SCHIZOPHRENIA RESEARCH

Royhaan Folarin, *Olabisi Onabanjo University*

Overall Symposia Abstract: New approaches that bridge knowledge across genes and proteins to cells to whole-brain networks and to behaviour are beginning to transform our understanding of how the brain works in health and disease. Magnetic resonance imaging (MRI) is widely available for mapping brain structure, function, connectivity and neurochemistry safely and non-invasively, and can be done in human populations and in model organisms. However, a key barrier for translation of this information into the clinic is that we do not know how they are specifically linked to cells and molecules. Translation of novel neuroimaging results depend on this mechanistic understanding and is critical for the discovery of new druggable targets. This symposium will provide an in-depth view into state-of-the-art tools and approaches bridging the gap between the structural and functional organization of the brain and the underlying cellular and molecular mechanisms across humans and experimental animals.

First, Modinos (UK) will introduce translational approaches linking the effects of pharmacological modulation on multi-modal MRI profiles in individuals at clinical high-risk for psychosis (CHR-P) and bridge this to cross-species evidence from relevant animal models. She will also present new data linking MRI-based markers of brain function in CHR-P individuals and people with schizophrenia spectrum disorders to specific cellular and molecular signatures. Next, Di Biase (Australia) will illustrate the power of combining imaging and genetics/transcriptomics to bridge outstanding knowledge gaps in schizophrenia research, including the biological basis of heterogeneity and the impact of medical comorbidities. This will be complemented by Yee (Canada), who will describe brain structural covariance

networks, their biological basis, and applications to psychosis using multi-species imaging datasets (in mice and humans). Finally, van den Heuvel (Netherlands) will present data on how genetic vulnerability, cellular changes and MRI findings in schizophrenia are associated. The symposium will conclude with a discussion led by Folarin (Nigeria), expert in the broader basic science modelling of schizophrenia and other neuropsychiatric disorders, who will integrate this set of findings to facilitate a stimulating discussion with the audience. Overall, this interdisciplinary symposium will offer new insights and tools to investigate brain complexity at multiple spatial and temporal scales, to advance our understanding of the mechanisms underlying schizophrenia spectrum disorders and contribute to unlocking the discovery of new pharmacological targets.

15.1. STRUCTURAL COVARIANCE NETWORKS FROM RODENTS TO HUMANS: MULTI-SCALE METHODS AND APPLICATIONS TO PSYCHOSIS

Yohan Yee^{*1}, Jason Lerch², Mallar Chakravarty¹

¹*McGill University*, ²*University of Oxford*

Background: Structural covariance refers to group-wise correlations that are observed between the structural properties (cortical thickness, volume) of brain regions. These correlations have been shown to capture developmental processes and differ in states of disease. By examining correlations between every pair of brain regions, network neuroscience approaches can be used to understand inter-regional structural relationships, and the ability to construct structural covariance networks from conventional structural magnetic resonance imaging (MRI) scans makes it an appealing type of brain network from which symptom etiology can be understood.

Methods: Here, we will demonstrate the usefulness of structural covariance analyses in understanding psychosis. First, using high-resolution and longitudinal MRI of healthy mouse brains and linking these to viral tracing and transcriptomic datasets, we examined the biological basis of structural covariance, and further examined network differences in mouse models of disease. Next, using a human pediatric population dataset that consists of MRI scans and a neurocognitive battery (the Philadelphia Neurodevelopment Cohort; PNC), we constructed structural covariance networks for subgroups based on reported psychosis-related symptoms and measures.

Results: Using mouse imaging data, we show that structural covariance captures functional relationships, is sensitive (but not specific) to structural connectivity, and largely mimics transcriptomic similarity between regions. Using longitudinal data acquired at 9 postnatal timepoints, we find that regional correlations are highest at the earliest timepoints. Together, we posit that structural covariance networks primarily reflect early-life coordinated neurodevelopment, and through examining network differences in mouse models of disease, aberrant early neurodevelopment can be captured via structural covariance analyses. Subsequently, using human data (PNC), we demonstrate and interpret similarities and differences between these networks constructed for psychosis-related subgroups. Finally, as structural covariance is a group-wise measure, we highlight approaches in which data-driven subtypes can be obtained.

Conclusions: Using multiscale datasets on spatial gene expression and viral tracing, we examined the biological basis for structural covariance networks and provide evidence that these networks reflect early-life coordinated neurodevelopment. Using multispecies imaging

datasets (in mice and humans), we demonstrate that differences in these inter-regional relationships related to neurodevelopment can be assessed through structural MRI data.

15.2. MULTI-SYSTEM CHARACTERIZATION OF BRAIN-BODY HEALTH IN SCHIZOPHRENIA AND OTHER COMMON MENTAL DISORDERS

Ye Tian^{*1}, Maria Di Biase¹, Philip Mosley², Michelle Lupton², Ying Xia³, Jurgen Fripp³, Michael Breakspear⁴, Vanessa Cropley¹, Andrew Zalesky¹

¹The University of Melbourne, ²QIMR Berghofer Medical Institute, ³CSIRO Health and Biosecurity, ⁴The University of Newcastle

Background: Physical health and chronic medical comorbidities are underestimated, inadequately treated, and often overlooked in psychiatry. A multi-organ, system-wide characterization of brain and body health in mental illnesses will enable systematic evaluation of brain-body health status in patients and potentially identify new therapeutic targets. This study aims to systematically investigate brain and body health in four common mental health conditions, including schizophrenia, bipolar disorder, depression and generalized anxiety disorder.

Methods: Brain imaging data (structural and diffusion-weighted MRI), and physical and physiological data (where available) were sourced from the following consortia studies: the UK Biobank, the Australian Schizophrenia Research Bank, the Human Connectome Project Young Adult and the HCP Aging. T1-weighted MRI brain images were available for 22,005 individuals (age range 18-95 years, mean 60.8±11.5, 9,061 males), collectively sourced from the seven consortia; diffusion-weighted MRI brain images were available for 20,283 individuals (age range 18-95 years, mean 60.6±11.5, 8,139 males) from all cohorts except AIBL. Physical and physiological assessments were sourced from 175,944 individuals (age range 37-74 years, mean 54.8±8.1, 72,339 males) participating in the UK Biobank. Generalized additive models for location, scale and shape were used to establish sex-specific normative reference ranges (mean and centiles) across the adult lifespan for each brain and body phenotype, based on healthy comparison individuals (HC, n=87,420) without any neuropsychiatric disorders or other serious medical conditions. A principled approach was developed to summarize phenotypic deviation scores at an organ/system level, yielding composite organ health scores (OHS) indexing the health and function of the brain and 7 body (pulmonary, musculoskeletal, renal, metabolic, hepatic, cardiovascular, immune) systems in individuals with one or more neuropsychiatric disorders (n=92,254). Phenotypic deviation scores were used to predict diagnoses (disorder vs HC) and differentiating between diagnoses (disorder vs disorder).

Results: Body health, especially composite scores indexing metabolic (mean OHS range: -1.41~-0.45), hepatic (-0.82~-0.21) and immune (-0.65~-0.19) health significantly deviated (p LESS THAN 0.05, FDR corrected) from normative reference ranges for all four mental disorders studied (schizophrenia: N=2,100; bipolar disorder: N=5,853; depression: N=81,631; anxiety: N=11,456). Poor body health was a more pronounced illness manifestation compared to brain changes. Body phenotype deviation scores provide the most accurate diagnostic classification for schizophrenia (body: AUC (area under the curve)=0.82; brain: AUC=0.80), bipolar disorder (body/brain = 0.68/0.57), depression (0.67/0.58), and anxiety (0.63/0.57). However, brain health enabled more accurate differentiation between distinct mental illness diagnoses than body health (average AUC: body/brain, schizophrenia-others: 0.70/0.79; bipolar disorder-others: 0.60/0.65; depression-others: 0.61/0.66; anxiety-others: 0.63/0.66).

Conclusions: Mental disorders share a substantial and largely overlapping imprint of poor body health. Despite the unequivocal neural basis of common mental disorders, we conclude

that poor body health and function are important illness manifestations that require ongoing management in patients. Routinely monitoring body health and integrated physical and mental health care in psychiatric practice may provide cost-effective targets for reducing the adverse impact of physical comorbidity on people with mental illness.

15.3. UNCOVERING AND MODULATING BIOLOGICAL SIGNATURES OF BRAIN VULNERABILITY FOR PSYCHOSIS

Gemma Modinos*¹

¹*King's College London*

Background: Preclinical evidence has shown that hyperactivity of the hippocampus due to neural excitatory (glutamatergic) – inhibitory (GABAergic) imbalance leads to psychosis-relevant electrophysiological and behavioural abnormalities. Importantly, peripubertal exposure to the GABA-enhancing drug diazepam prevented such psychosis-like phenotypes from emerging in adulthood in experimental animals. In humans, previous functional MRI work, including our own, found that hippocampal hyperactivity (by resting cerebral blood flow, rCBF) is a robust feature in individuals at clinical high-risk for psychosis (CHR-P). We also recently demonstrated a link between specific GABAergic interneuron disruption and increased hippocampal rCBF by back-translation in a genetic rodent model. Here, I will present novel findings on (1) whether diazepam exposure can restore hippocampal rCBF in individuals at CHR-P, and (2) the specific cellular and neurochemical signatures of rCBF-based profiles from CHR-P individuals and people with schizophrenia spectrum disorders (SSD).

Methods: Our first experiment used a within-subject, double-blind, placebo-controlled, randomised, cross-over design in 24 CHR-P individuals. Participants underwent MRI scanning twice, once under a single dose of diazepam (5mg) and once under placebo, with a minimum 3-week washout period between visits. rCBF was measured using pseudo-continuous arterial spin labelling, and a T1-weighted structural scan was acquired for co-registration. The hippocampus and its subfields were segmented for each subject per hemisphere and mean rCBF values were extracted in native space. Statistical/imaging analyses were done in R/4.2.2, including mixed ANCOVA models (healthy controls (HC) vs. CHR-P placebo, covarying for age, sex, and global CBF) and linear mixed-effects models (CHR-P placebo vs. CHR-P diazepam, covarying for subject_ID as random effect). Significance was set at pFDR LESS THAN 0.05. Our second study linked case-control rCBF alterations to gene and neuroreceptor expression in individuals with SSD (n=122) and people at CHR-P (n=129) versus their matched HC (n=116 and n=58, respectively). Case-control t-maps produced in SPM12 were parcellated into 100 cortical and 22 subcortical regions (Schaefer+Xiao atlases) with the mean value across each region z-scored to ease comparison across maps. Gene expression data was accessed via the Allen Human Brain Atlas (AHBA). Neuroreceptor maps were constructed from 19 publicly available PET images, covering nine neurotransmitter systems. Gene expression and receptor maps were all parcellated into the same 100 cortical and 22 subcortical regions as the rCBF maps. Correlations between case-control rCBF differences and (1) gene expression and (2) neurotransmitter systems were assessed with Spearman's rank correlations and dominance analyses. Significance was determined using FDR-corrected spatial-autocorrelation preserving null models.

Results: Diazepam (vs placebo) significantly reduced hippocampal and subfield (subiculum, CA1, CA4/dentate gyrus) rCBF in CHR-P individuals (all pFDR LESS THAN 0.05), to the extent that it was no longer significantly different from HC. At the whole-brain level, diazepam

(vs placebo) significantly reduced rCBF globally in CHR-P, greatest in pre/postcentral gyrus, dorsolateral prefrontal cortex, cingulate, hippocampus, insula, and striatum (all pFDR LESS THAN 0.05). The rCBF profile of CHR vs HC alterations tracks the distribution of oligodendrocyte, oligodendrocyte progenitor, and endothelial cell gene markers, as well as of D2, DAT, NET and NMDA receptors (all pFDR LESS THAN 0.05). In contrast, the SSD vs HC rCBF profile tracks the distribution of oligodendrocyte, pericyte, oligodendrocyte precursor and microglia gene markers, and of 5-HT2A and GABA-A receptors (all pFDR LESS THAN 0.05).

Conclusions: These novel mechanistic insights into the effects of diazepam on rCBF in CHR-P individuals support the development of GABA-enhancing compounds for psychosis, ideally with more selectivity for hippocampus. Furthermore, our findings implicate cell-types involved in stress response and inflammation, as well as dopamine, GABA-A, and NMDA receptors as distinct cellular and neurochemical signatures of rCBF profiles in SSD and CHR-P. Decoding the biological properties underlying MRI-based markers in CHR-P and SSD may unlock their translational potential to inform mechanisms that may be amenable to treatment.

15.4. TOWARDS CROSS-SCALE PSYCHIATRY: LINKING MICRO- AND MACRO FINDINGS OF MENTAL CONDITIONS

Martijn van den Heuvel*¹

¹*VU Amsterdam*

Background: The human brain is a complex multi-scale system with neural elements working at multiple levels of organization concurrently. At the microscale level, neurons, dendritic and axonal projections form the basic elements of brain architecture and at the meso- and macroscale system level, large-scale brain regions, functional pathways and white matter connections form the infrastructure for system-level brain communication. How disease effects manifest across these different scales at the same time remains an open question. In this talk we will discuss recent insights into how disease-related alterations at one level of organization may underlie alterations observed at other scales of brain network organization and discuss the importance of a cross-call understanding of the ethology of neuropsychiatric conditions.

Methods: Examining schizophrenia, we will discuss results of integration of genetic, transcriptomic, cellular and system-level MRI findings, discussing a particular vulnerability of higher-order cognitive brain areas at multiple levels of brain organisation. Data from GWAS and regional and single-cell gene expression is combined with recordings from macroscale functional resting-state networks across multiple datasets and cohorts. Cross-scale correlations across brain patterns are examined and tested by means of specific null-models and statistical tests.

Results: We show evidence of strong concordance of disease involvement of genetic, transcriptomic, cellular and macroscale system effects in schizophrenia. Regional gradients of expression of schizophrenia risk genes across cortical areas are found to show significant overlap with MRI disease patterns (p LESS THAN 0.001), combined with consistent patterns of changes in pyramidal structure at the cellular level. Results will be presented across several sensitivity and validation analyses and discussed in light of several studies showing cross-scale relationships.

Conclusions: Our findings suggest a robust relationship between disease effects across multiple levels of brain organisation in schizophrenia. We will discuss our findings in light of a developing field of multiscale neuroscience studies that illustrate the importance of studying

cross-scale interactions among the genetic, molecular, cellular, and macroscale levels of brain circuitry and connectivity and behavior.

16. COMPUTATIONAL APPROACHES FOR STUDYING FORMAL THOUGHT DISORDER: CURRENT AVENUES AND FUTURE PROSPECTS

Isaac Fradkin, *Max Planck UCL Centre for Computational Psychiatry and Ageing Research*

Overall Symposia Abstract: Disturbances in thought processes play a key role in historical and current conceptualizations of schizophrenia. Such disturbances, referred to as Formal Thought Disorder (FTD), are usually inferred based on alterations in the form and organization of speech. Yet, the complex and dynamic nature of language complicates objective measurement of FTD. Furthermore, the inherently covert nature of thought processes themselves hinders analysis of mechanisms involved in FTD based on linguistic output alone. A rapidly growing approach meeting these challenges involves the use of computational approaches to assess dynamics of language and thought. Two types of computational approaches can be identified. First, recent advances in natural language processing (NLP) are becoming an increasingly popular tool to quantify language incoherence, and even predict transition to psychosis. Whereas these methods hold promise to transform FTD measurement, their inherent biases and interface with traditional clinical ratings scales remain underexplored. A second type of model focuses on formalizing the covert cognitive dynamics governing the emergence and regulation of thought and its dynamic expression in language in FTD. In this symposium we will introduce up-to-date research in these two adjacent approaches, and endeavor to outline future prospects for progress and integration in the field.

Following a brief introduction by I. Fradkin, N. Lundin will discuss recent work focused on understanding potential cognitive processes underlying FTD through a semantic foraging framework. She will show how suboptimal semantic retrieval among individuals with psychosis may reflect a reduced ability to use the patchy structure of semantic memory to aid retrieval and discuss the emerging roles of hippocampal and cerebellar neural activity in semantic foraging and FTD.

Broadening the scope of computational-mechanistic approaches from the analysis of experimental cognitive tasks to the study of naturalistic speech, M. Nour will present a novel NLP pipeline that allows us to cast free speech as trajectories through semantic spaces. The potential of this approach to improve our understanding of the cognitive processes involved in naturalistic speech in FTD will be demonstrated in a large and diverse clinical sample.

Considering the potential biases involved in NLP methods for FTD, N. Mota will discuss the effects of formal education on clinical and computational assessment of FTD. She will show how patients' attained education and educational deficits can bias state-of-the-art NLP metrics of FTD but also serve as protective factors.

Finally, A. Voppel will present an application of a novel NLP framework for analyzing FTD symptom dimensions, as defined across different ratings scales. He will show how NLP methods can be used not only to quantify patients' speech output, but also as a tool for integrating different clinical views of FTD, thereby clarifying its fundamental clinical conceptualization.

To conclude the symposium, L. Palaniyappan will lead a discussion regarding the promises, limitations, and potential integration of the different computational approaches, while focusing on theoretical and clinical implications.

16.1. SUBOPTIMAL FORAGING IN SEMANTIC SPACE: POTENTIAL MECHANISMS OF THOUGHT DISORDER IN PSYCHOSIS

Nancy Lundin*¹

¹*The Ohio State University Wexner Medical Center*

Background: Advances in natural language processing have increased capacity to quantify speech organization and content, bolstering the widespread study of thought disorder among individuals with psychosis. Despite these advances, further research is needed to understand the underlying mechanisms of thought disorder. Semantic foraging is a novel framework which holds promise for understanding these mechanisms. Just as bears search for berries by alternating between local exploitation and global exploration in physical space, humans may search their memories for related concepts using an explore-exploit trade-off in semantic space. This has been studied using word search retrieval tasks such as verbal fluency tests (VFT). Individuals with higher VFT response rates tend to alternate between clustering and switching between groups of semantically similar items aligning with predictions within optimal foraging theories. While studies have broadly found VFT impairments among individuals with psychosis, open questions include how semantic foraging strategies vary among individuals with psychosis and the neural correlates of semantic foraging.

Methods: Samples included participants with schizophrenia (SZ), first-episode psychosis (FEP), schizotypal personality disorder (SPD) traits, and individuals without psychiatric illness. Participants completed 1–3 minute VFT in which they named as many items as possible from a particular category. Responses were transcribed. In a non-clinical sample, participants completed VFT during functional magnetic resonance imaging. VFT responses were designated as cluster or switch-related in various ways based on semantic similarity thresholds (using BEAGLE or word2vec), common subcategories, and participant evaluations of their own responses. Search metrics analyzed included: the number of generated responses, interitem semantic similarity and response times, indices of clustering and switching, and neural activity during search phases.

Results: Findings across studies revealed that participants with SZ and FEP generated fewer correct VFT responses than non-psychiatric and SPD comparison groups. During local search within patches of related words, participants with SZ had prolonged search times, and participants with FEP produced responses that were lower in semantic similarity. Among individuals with FEP, generating more VFT responses and a higher percentage of clustered responses related to lower disorganized and negative (but not positive) psychotic symptom severity, as well as greater processing speed and overall cognitive function. Finally, in a non-clinical sample, individuals showed greater neural activation during switching than clustering in the hippocampus or posterior cerebellum, depending on how patch boundaries were operationalized. Neural activity in these regions was also found to increase during within-patch search and reset at switch responses, potentially indexing a cognitive monitoring process guiding the search.

Conclusions: This work provides evidence of altered semantic foraging patterns among individuals with persistent and early course psychotic illness, while also highlighting the heterogeneity of cognitive search strategies among individuals with psychosis. Future studies will focus on consolidating methods to improve replicability, optimizing algorithms to define patch boundaries, and identifying neural correlates of semantic search strategies among individuals with psychosis. Finally, future work will investigate whether semantic explore-

exploit processes serve as a reliable index for organization of speech and narrative more broadly to identify intervention targets for recovery from thought disorder.

16.2. TRAJECTORIES THROUGH SEMANTIC SPACES IN PSYCHOSIS

Matthew Nour^{*1}

¹*University of Oxford*

Background: The ‘aberrant cognitive mapping’ hypothesis proposes that psychotic symptoms such as conceptual disorganisation and delusions stem from abnormalities in how the brain forms structured representations of the world. Current measurement tools are inadequate to test this hypothesis: symptom rating scales lack connection to theories of neural computation, while behavioural tasks offer a shallow window onto internal representations, and lack scalability and ecological validity. Advances in natural language processing (NLP) – notably, transformer-based large language models (LLMs, like chat-GPT) - signal a step change in our ability to extract cognitively-rich information from language behaviour, and thus test cognitive mapping hypotheses in clinical samples. In this presentation I will showcase work that applies novel machine learning and NLP tools to free speech transcripts from patients across a psychosis spectrum, and illustrate how these tools can inform neurocognitive theories of schizophrenia - including those pertaining to how related concepts are represented and retrieved. The talk will begin with a brief primer on foundational computational principles, followed by a detailed walkthrough of a novel analytic pipeline for speech data, and end with a presentation of unpublished empirical results from a clinical study of speech in psychosis.

Methods: The analytic pipeline has been developed and validated on study data comprising free speech samples from 200 individuals across a psychosis spectrum (from ‘at risk’ to chronic schizophrenia) and healthy volunteer controls. Participants were asked to provide free speech samples under 3 experimental contexts (paradigms) chosen to elicit speech with differing levels of directedness and constraint by external stimuli. These contexts were: picture descriptions, storyboard descriptions, and story recall. Participant speech was first transcribed, and then subjected to a novel NLP pipeline designed to track the temporal evolution of semantic and emotional information. This pipeline comprises sentence parsing (splitting the sequence of words into utterances, e.g., using BERT LLM to predict probability of period after each token), semantic embedding (embedding each utterance in LLM vector space, e.g., OpenAI ‘embeddings’ models), and cluster-based topic modelling (using the Uniform Manifold Approximation and Projection [UMAP] nonlinear dimensionality reduction algorithm and Hierarchical Density-Based Spatial Clustering of Applications with Noise [HDBSCAN] algorithm). These algorithms yield ‘topic solutions’, which can be tuned to have higher or lower numbers of topics (topic granularity) through tuneable UMAP and HDBSCAN hyperparameters. This pipeline signals an advance over extant approaches that track superficial semantics (e.g., word similarity) or eschew temporal or semantic information altogether (‘bag-of-words’ or ‘speech-graph’ methods).

Results: I will present three key results. The first demonstrates the validity of the NLP pipeline to detect semantically-coherent topic clusters in free speech. I will show how the pipeline can be fine-tuned to increase sensitivity to detect recurrent topics across participants, and topic variability within participants. Second, I will show that the intermediate NLP variables extracted by the pipeline are sensitive to subtle differences in speech structure collected across different experimental paradigms (contexts). Such main effects include an increased semantic

trajectory tortuosity in picture description vs storyboard contexts. Finally, I will show how NLP speech variables (e.g., semantic path tortuosity) are correlated with psychotic symptoms and differentiate early-stage vs. chronic patients.

Conclusions: These findings demonstrate the feasibility of indexing the structure of internal conceptual organisation in clinical samples using advanced NLP tools applied to free speech data, thus speaking to cognitive mapping hypotheses of symptoms. This work contributes new methods that can be applied to the study of speech and cognition in psychiatric samples with minimal attentional or task-comprehension requirements for participants. These methods and associated proof-of-concept findings, lay the foundation for future transdiagnostic studies, with the ultimate aim of developing NLP-based diagnostic and treatment-prediction tools for patients.

16.3. THE IMPACT OF FORMAL EDUCATION IN LANGUAGE DISTURBANCES IN PSYCHOSIS: CRUCIAL CONSIDERATIONS FOR AN UNBIASED CLINICAL PRACTICE

Natália Mota*¹

¹*Federal University of Rio de Janeiro*

Background: Recently, with the advance of natural language processing tools and artificial intelligence algorithms, different strategies have been applied to quantify language disturbances related to mental suffering. Word recurrence graphs have been applied to study word trajectories in the past decade. The method was inspired by the descriptions of formal thought disorders associated with psychosis and successfully demonstrated low connectedness related to non-affective psychosis in different stages. To advance knowledge in applicable strategy, it is crucial to understand confounder effects that could jeopardize actual clinical practice, such as access to education. In this talk, I will summarize studies on how this novel strategy to look into language is impacted by written language contact. Considering that by learning and practicing reading and writing, a child masters grammar and syntax rules, adopting this formal communication in oral storytelling, access to formal education is a vital confounder effect.

Methods: We will discuss how word recurrence graphs and sentiment analysis are associated with negative symptomatology in the early stages of psychosis. To address educational attainment impact, we will also study associations between language markers and years of education in different stages of disorder and how it could be a confounder or even a protective factor.

Results: In a sample under chronic psychosis, there was no association between low connectedness and years of education, unlike a control sample. Chronical psychosis seems resistant to traditional formal education, or symptomatology independently explains this variance. Moreover, in a first-episode psychosis sample, low connectedness was independently associated with symptoms and years of education, demonstrating a protective effect of education at this stage (in a significant multilinear correlation – R^2 0.67, negative symptoms were positively associated with a low connectedness – coefficient 0.41, while years of education were negatively associated – coefficient -0.53). A similar result was also found for a clinical high-risk sample. Alternatively, educational attainment seems to mediate the association between symptoms and emotional expression in the early stages of psychosis.

Conclusions: The results reveal crucial considerations regarding the social impact of psychosis, how formal education could protect communication, and the need to consider this factor on novel language markers in an unbiased clinical practice.

16.4. HOW COHERENT ARE OUR RATING SCALES? APPLYING NLP ON FTD ITEM DESCRIPTIONS

Alban Voppel^{*1}, Manaan Karray², Sohee Park³, Lena Palaniyappan⁴

¹McGill University, ²Princess Alexandra Hospital, Brisbane, ³Vanderbilt University, ⁴McGill University, Douglas Mental Health University Institute; Western University, Robarts Research Institute

Background: Formal thought disorder (FTD), a core symptom of schizophrenia-spectrum disorders, is commonly rated using scales such as TLC, TALD or PANSS. The design of these rating scales (choice and description of items) are informed by clinical observations and historical concepts of FTD pursued by the authors. As a result, different items of these scales may map on to the same or a small number of clinical phenomena presenting as disorganized speech, thoughts, or communication disturbances. For example, one scale might rate words per minute, others posit subjective poverty of speech or rate difficulties upholding a flow of information, which could all be grouped under “poverty of thought”. As a result, factor analysis undertaken with different scales often produce cross-cutting factors with inconsistent item loading across scales, and varying number of factors. Here, we probe the conceptual construct of FTD elicited using these rating scales by employing a semantic language model. We also provide a limited two-scale comparison in a single cohort, to illustrate the conceptual overlap. Natural Language processing has resulted in more theory-neutral methods of assessing language through the usage of large models, such as BERT or GPT. These models can be used to assess the semantic content of language and to quantify and compare language produced by participants. Here, we apply this methodology to the scales themselves; we use semantic models to examine the item-level description of 7 commonly used thought disorder different rating scales and compare them. Through the usage of NLP, we perform content clustering on these descriptions across scales, to extract the “backbone” of FTD from item-level descriptions.

Methods: We collected 7 commonly used FTD rating scales and used a sentence-level Bidirectional Encoder Representations from Transformers (BERT; all-mpnet-base-v2) model to perform item-level embedding of each item for each rating scale. These 7 scales were TALD, SAPS-SANS, PANSS, TLI, TLC, BIT and CLANG. We filtered out examples but kept all other content. We calculate item-to-item sentence similarity, resulting in a connectivity matrix for 100+ FTD item scales, with each rating-scale item receiving a similarity between 0 and 1 to each other item. The resulting similarity matrix allowed a range of operations, including the assessment of the relation between item-descriptions of FTD scales. We sparsified the matrix, leaving the “backbone” of the network, and detected similar communities of items, clustering content-similarity rating-scales items together. Finally, we applied these clustered item-level descriptions of different rating scales and see how they perform compared to classic factor analysis.

Results: We computed embeddings of TALD, SAPS-SANS, PANSS, TLI, TLC, BIT and CLANG item-scale descriptions. We noted differences in richness of scale descriptions as a quantitative comparison, such as the presence of examples or floridness of descriptions. We found 4 major groups of item-level symptoms when using the TLC network as a backbone; we repeated this finding using the TALD. Rating all items as semantically either more positive and negative FTD and showed high concurrence with published factors (81% overlap with TALD division). Ranked CLANG and TLC item correlation and canonical factor loadings from a cohort of 98 subjects overlap 72.2% with semantic clustering, with 88.8% of items within communities of clusters.

Conclusions: We found finite clusters of meaning in different rating scales-based item-level descriptions. These descriptions can be unified using NLP methods. Resulting unified

descriptors overlap with previously reported conceptual divisions, such as positive and negative FTD but allowing other divisions to be made. Our approach serves as an “intuition pump” for integrating different clinical views and rating scales of FTD, thereby clarifying its clinical conceptualization. This approach can be extended and applied to other symptom rating scales. Finally, new rating scales would benefit from the approach here to test descriptive validity of their measures.

17. LET’S FOCUS ON CLINICAL RECOVERY – IN LONG-TERM MODERN COHORTS OF INDIVIDUALS DIAGNOSED WITH SCHIZOPHRENIA FOLLOWED FOR MORE THAN TWO DECADES ON SEVERAL CONTINENTS – AND PROPOSE A CONSENSUS DEFINITION?

Nikolai Albert, *Copenhagen Research Center for Mental Health – CORE*

Overall Symposia Abstract: The course of schizophrenia is complex and therefore the concept of clinical recovery is present and relevant but as of now we still do not have a consensus definition. More than 100 years ago, Kraepelin was the first to use the term recovery in the field of psychiatry. He reported that 2.6% of his patients with schizophrenia had a “permanent recovery” and 13% experienced time-limited periods of recovery. So, what we as clinicians could ask ourselves now is: “Do modern cohorts of individuals diagnosed with schizophrenia experience more favorable outcomes?” Or is the prognosis still as Kraepelin reported back in the 19th century or in other words “Are we getting better at getting our patients better?”

Over the years, several meta-analyses among individuals with schizophrenia have found recovery rates ranging between 13.5% to 57%. These inconsistencies in recovery percentages have been hard to uncover since meta-analytic methods could not explain the variation due to clinical study characteristics such as chronic or first episode illness, gender, duration of follow-up or strictness criteria of the recovery definition. Older WHO-led studies have found significant differences between continents as well as developed- and developing-countries but the mechanisms behind this are still not fully understood.

With the criteria for symptomatic remission presented by the Remission in Schizophrenia Working Group (RSWG), we now have a foundation to build on a consensus definition for clinical recovery.

Bringing this panel of experts together we hope to develop the concept of recovery further and enlighten the audience on the inconsistencies on clinical recovery rates among long-term modern cohorts diagnosed with schizophrenia followed for more than two decades on several continents. Firstly, Dr. Hansen will present data from the 20-year follow-up of the OPUS trial including 578 individuals diagnosed with first episode schizophrenia focusing on remission status and clinical recovery through 20 years. Secondly, Dr. Weibell will present new data on a 20-year follow-up of a prospective cohort of individuals with a first episode of psychosis in Norway. Thirdly, Dr. Jonas will present data on remission and recovery rates from the Suffolk County Mental Health Project Cohort, including 628 individuals followed longitudinally for 25 years after a first episode of psychosis in the US. Finally, Dr. Chan will present preliminary results from a 20-years follow-up of patients with first-episode schizophrenia spectrum disorder in Hong Kong and elaborate on predictors of clinical remission and functional recovery.

Overall, the presenters will be able to discuss how we define clinical recovery in different studies and what measurements are used? Also, which patients recover and what do they have in common? Furthermore, are there any differences between continents among those who recover? AND finally let's propose a consensus definition on clinical recovery in order to promote long-term positive outcomes for individuals diagnosed within the schizophrenia spectrum.

17.1. DESCRIPTIVE PATTERNS OF CLINICAL RECOVERY AND SYMPTOM REMISSION FOLLOWING 547 INDIVIDUALS DIAGNOSED WITH FIRST-EPISODE SCHIZOPHRENIA OVER 20 YEARS - RESULTS FROM THE OPUS TRIAL

Helene Gjervig Hansen^{*1}, Marie Starzer², Carsten Hjorthøj³, Nikolai Albert⁴, Merete Nordentoft⁵

¹*Copenhagen Research Centre for Mental Health, University of Copenhagen*, ²*Copenhagen University Hospital, Mental Health Center Copenhagen, Copenhagen Research Center for Mental Health - CORE*, ³*Mental Health Center Copenhagen, University of Copenhagen, Denmark*, ⁴*Copenhagen Research Center for Mental Health – CORE*, ⁵*Mental Health Centre Copenhagen*

Background: Through decades, clinical recovery outcomes among individuals diagnosed with schizophrenia have been highly inconsistent ranging from 13.5%-57%. The primary objective of this study was to report on 20-year patterns of clinical recovery and symptom remission in a clinical cohort of individuals diagnosed with a first episode of schizophrenia.

Methods: A total of 547 individuals with a first episode schizophrenia spectrum disorder were included into the trial between 1998 to 2000 and allocated to either two years of Early Intervention Services (EIS) or Treatment As Usual (TAU). Over the years multiple follow-ups of the entire clinical cohort has been conducted at one-, two-, five-, ten- and now 20 years. For the analyses of symptom remission and clinical recovery rates, individuals diagnosed with schizotypal disorders were excluded, since a diagnosis of schizotypal disorder excludes any major psychotic symptoms.

Results: A total of 164 participants (30%) out of 547 were reassessed at the 20-year follow-up, (mean [SD] age, 45.9 [5.6] years, 51.8% female sex). Approximately, 40% (n=53) of the participants obtained symptom remission and 18% (n=23) of participants were in clinical recovery at the 20-year follow-up. Symptom remission accounted for 37.5% (n=24) in the EIS-group and 42% (n=29) in the TAU-group, P=.59. Clinical recovery accounted for 14.1% (n=9) in the EIS-group and 21.2% (n=14) in the TAU-group, P=.27. Furthermore, in total 28.8% (n=57) of participants (observed cases) experienced clinical recovery at least once through the past 20 years. Only 35% of individuals in symptom remission were in treatment with antipsychotics. Also, 50% of individuals in symptoms remission receiving no antipsychotic treatment were in clinical recovery at the 20-year follow-up. Of individuals reporting self-perceived recovery (n=47) only 28% were in clinical recovery. Investigating psychotic illness trajectories over 20 years, significantly higher clinical recovery rate (22%) was found among those with continues remission of psychotic symptoms. Also, 37% of individuals following a trajectory of remission of negative symptoms over 20 years were in clinical recovery. Stratifying for parenthood, we found that significantly more parents were in symptom remission (59.5% vs. 22.4%, P LESS THAN .001) and in clinical recovery (29.7% vs. 11.1%, P=.002) compared to non-parents at the 20-year follow-up. Finally, of the entire sample, a total

of 82 individuals (14.4%) had died over the past 20 years. Predictors of high mortality were substance use and chronic somatic illness whereas predictors of low mortality were symptom remission without antipsychotic treatment and clinical recovery.

Conclusions: A clinical recovery rate of 18% and symptom remission of 40% was found at the 20-year follow-up of the OPUS trial. No significant differences were found on clinical recovery and symptom remission between the EIS-group compared to TAU, implying that modern era treatment facilities have not enhanced these outcomes in schizophrenia. Overall, a substantial proportion of 14-18% were in clinical recovery over 20 years with app. 30% (n=57) of participants experiencing clinical recovery at least once through the past 20 years. These results imply that new initiatives for individuals with schizophrenia are needed to improve the rates of both clinical recovery and symptom remission.

17.2. CIOMPI REVISITED: TRAJECTORIES OF REMISSION AND RECOVERY IN FIRST EPISODE PSYCHOSIS OVER 25 YEARS

Katherine Jonas^{*1}, Sara Tramazzo², Wenxuan Lian¹, Olesya Ajnakina³, Gabrielle Carlson¹, Evelyn J. Bromet¹, Roman Kotov¹

¹*Stony Brook University*, ²*Hofstra University*, ³*Institute of Psychiatry KCL*

Background: Understanding prognosis is critical to anticipating public health needs and providing care to individuals with psychotic disorders. However, the long-term course of remission and recovery remains unclear. Cross-sectional estimates of remission and recovery vary widely, and there are relatively few studies with a follow-up greater than 10 years. In this cohort of individuals followed for 25 years since first admission for psychosis, we describe the most common trajectories of illness course.

Methods: Participants are from the Suffolk County Mental Health Project, an epidemiological study of first-admission psychosis. Data for the present study was gathered from six follow-ups. 311 individuals were assessed at the 25-year follow-up. Symptom remission was operationalized according to Andreasen's definition, while recovery was defined according to criteria from Liberman's definition. Tetrachoric correlations were used to assess stability of remission and recovery across follow-ups. Common patterns of remission and recovery were assessed in the baseline cohort of 591 individuals and the subsample observed at the 25-year follow up. Multinomial regression was used to identify predictors of patterns of remission and recovery.

Results: Among those ascertained at first admission, 41.9% of those with other psychotic disorders and 27.2% of those with schizophrenia spectrum disorders were recovered 6 months after first admission. However, rates declined over time, and at the end of the 25-year follow-up only 28.1% of those with other psychoses and 14.2% of those with schizophrenia spectrum disorders were in recovery. Remission rates followed a similar trajectory, beginning at 46.2% in other psychotic disorders and 24.9% in schizophrenia spectrum disorders, and falling to 20.0% and 7.4%, respectively. Among those with schizophrenia spectrum disorders, the most common pattern in both the baseline and 25-year cohort was a trajectory of no remission and no recovery. Among those with other psychotic disorders, the modal pattern in both the baseline and the 25-year cohort was one of intermittent remission and recovery. Those with other psychotic disorders were more likely to experience stable remission (15.1%) and stable recovery (21.1%), outcomes that were rare in schizophrenia spectrum disorders (0% and 0.6%, respectively). Gender, diagnosis, and avolition predicted patterns of both remission and recovery. Race and treatment with mood stabilizers at discharge predicted recovery, while socioeconomic predicted remission.

Conclusions: The most common trajectory for individuals with schizophrenia spectrum disorders is one of no remission and no recovery. The increasing stability of symptoms across the follow-up period indicates more effective treatments are needed to impact the course of remission and recovery in schizophrenia spectrum disorders, and illuminates the need for sustained intervention and support for this population. The modal longitudinal pattern for those with other psychoses is one multiple transitions into and out of symptomatic and functional recovery. Engagement in a long-term health care plan may help individuals with other psychotic disorders detect and respond to changes. Our results emphasize a need for continued research and treatment for individuals with psychotic disorders in midlife and beyond.

17.3. 20-YEAR REMISSION AND RECOVERY IN FIRST EPISODE PSYCHOSIS

Melissa Weibell*¹, Jone Bjørnstad², Inge Joa³, Carmen Simonsen⁴, Torill Ueland⁵, Ingrid Melle⁶, Wenche ten Velden Hegelstad³

¹Stavanger University Hospital, ²TIPS Centre for Clinical Research in Psychosis, Stavanger University Hospital, University of Stavanger, ³TIPS Centre for Clinical Research in Psychosis, Stavanger University Hospital, . Network for Medical Sciences, University of Stavanger, ⁴NORMENT, Oslo University Hospital and Institute of Clinical Medicine, University of Oslo, Early Intervention in Psychosis Advisory Unit for South East Norway, Oslo University Hospital, ⁵NORMENT, University Hospital and Institute of Clinical Medicine, University of Oslo, University of Oslo, ⁶NORMENT Norwegian Centre for Psychosis Research, Oslo University Hospital and Institute of Clinical Medicine, University of Oslo, Oslo University Hospital,

Background: The TIPS 20-year sample encompasses patients followed up more than 20 years after their first-episode of psychosis in one early, and one usual detection area. Recovery is a key element, and patients are assessed through multiple instruments and interviews. The aim of the overall long-term follow-up is to investigate long term outcomes in an early versus a usual detection area. In the sub-study presented here, the aim was to establish rates of remission and recovery across both areas.

Methods: 281 patients, 18-65 years old with a first episode of non-affective psychosis were included between 1997-2001. Of these, 74 patients have by October 2023 been followed up at more than 20 years and assessed for symptoms and recovery defined as living independently, seeing friends at least weekly, and being competitively employed (if not retired, homemaker or not working due to other circumstances than mental illness) in addition to being in stable remission (GREATER THAN 6 months with no scores above 3 on the PANSS positive subscale).

Results: Forty-six participants (62,2%) had been in symptom remission for at least the last six months. Preliminary analyses indicate that 24 (32,2%) out of the participants hitherto assessed were in stable long-term recovery. Seventeen (22,9%) participants were currently psychotic, and 10 (13,5%) had been continuously psychotic since inclusion. 57 (77%) were living independently, 23 (31,3%) were in stable relationships, and 19 (25,6%) were competitively employed or studying part- or full time. In addition, 49 (66.2%) had digital contact with friends or equivalent at least once per week and 45 (60.8%) saw their friends at least weekly. Data presented in this abstract should be considered preliminary, pending detailed analyses and publication.

Conclusions: Rates of symptomatic remission as well as recovery including adequate functioning and remission increased from 10-20 years. After 20 years, it becomes apparent that

our definition of recovery does not take into account that as time passes, other reasons than psychosis could be the reason for patients not working or studying.

17.4. CLINICAL REMISSION AND FUNCTIONAL RECOVERY OF PATIENTS WITH FIRST-EPISODE SCHIZOPHRENIA-SPECTRUM DISORDER: COMPARISON OF 10 YEAR AND 20 YEAR FOLLOW UP

Sherry Kit Wa Chan*¹

¹*The University of Hong Kong*

Background: Schizophrenia-spectrum disorder is a chronic condition and most of the long-term follow up suggested that only about 20-30% of patients recovered. Some earlier studies of very long-term follow up study suggested that some patients recover at later stages. The current study aimed to compare the clinical remission and functional recovery of patients with first-episode schizophrenia-spectrum disorders at 10 year and 20 year follow up. Baseline demographic and clinical information as possible factors associated with the 20 year clinical remission and recovery will also be explored.

Methods: Patients with first-episode schizophrenia-spectrum disorders with age 15-25 who attended the public psychiatric service in Hong Kong between June 2000- July 2002 were identified and face-to-face interviews with clinical and functional assessment at 10 year and 20 year follow up were conducted. Their baseline demographics and clinical information, and clinical information over the initial three years of service attendance were obtained from the electronic and written clinical records. PANSS was used for clinical assessment, SOFAS was used for functional assessment. Employment and general living conditions at 10 and 20 year follow up were assessed. SF 36 was used to assess subjective quality of life. Within subject comparison was conducted between the 10 year and 20 year follow up time point. Association analysis was conducted to examine the relationship of the baseline demographics and early clinical factors and longer-term recovery and remission. Andreasen cross-sectional criteria was used to define the clinical remission and functional recovery. Patients who fulfil criteria of both are considered as having complete recovery.

Results: A total of 110 patients were interviewed at both 10 year and 20 year follow up and were included in the analysis. At 20 year follow up, the mean age was 43.2 with 50% male. 61.8% of patients had clinical remission, 60.9% had functional recovery, 50% had complete recovery, 55.5% were engaged in open employment at 20 year follow up. Though no significant differences in clinical remission rate between 10 and 20 year follow up, significantly more patients were in functional recovery and complete recovery between 10 and 20 year follow up. 49% and 39.3% who were recovered functionally and completely recovered respectively at 10 year follow up were considered functionally recovered and completely recovered at 20 year follow up. Though no significant differences in employment rate between 10 and 20 year follow up, 42.1% patients who were unemployed at 10 year follow up were engaged in open employment at 20 year follow up. Educational years was consistently associated with clinical remission and functional recovery. No significant changes of subscore of SF 36 between 10 and 20 years follow up apart from a trend significant increase ($p=0.051$) of subscale of pain between the two time points.

Conclusions: Though clinically there is not much improvement between the 10 years, a substantial number of patients have improved in functioning as well as employment status. However, there are no significant changes in quality of life between the two time points apart from a possible deterioration of experience of physical pain. This suggests that there are different trajectories for domains of recovery over time.

Plenary Session III - Sara Evans-Lacko: Stigma and Economic Determinants

9:00 a.m. - 10:00 a.m.

18. STIGMA AND ECONOMIC DETERMINANTS

Nicolas Crossley, *Facultad de Medicina, P. Universidad Catolica de Chile*

18.1. THE ROLE OF STIGMA AND SOCIO-ECONOMIC FACTORS IN PERPETUATING INEQUALITIES FOR PEOPLE WITH PSYCHOSIS

Evans-Lacko Sara, *Care Policy and Evaluation Centre, London School of Economics and Political Science*

Individual Abstract: This presentation considers the intricate relationship between socio-economic factors and the stigma experienced by individuals with psychosis. It will highlight how socio-economic disadvantage and stigma are intertwined, impacting a range of life domains and contributing to ongoing inequalities that those with psychosis face. By addressing the stigma embedded within structures, institutions, policies, and cultural attitudes, alongside explicit consideration of socio-economic factors, the presentation will propose actionable strategies to mitigate these inequalities. It will emphasise the need for integrated approaches that not only confront stigma directly but also robustly address the socio-economic underpinnings that hinder recovery and perpetuate disparities in outcomes. The presentation will advocate for interventions that are embedded within policy and societal change, aiming to dismantle both the overt and subtle forms of stigma while addressing socio-economic factors as a core component of mental health recovery and to chart a pathway towards equity,

Concurrent Symposia

10:30 a.m. - 12:30 p.m.

19. THE CHANGING WORLD OF ANTIPSYCHOTIC MEDICATION USE: THE LATEST EVIDENCE FROM THE INTERNATIONAL TRIALS IN THE TAPER (TAPERING ANTI-PSYCHOTICS AND EVALUATING RECOVERY) CONSORTIUM

Marieke Begemann, *University Medical Center Groningen*

Overall Symposia Abstract: During the last few years, the risk-vs-benefit debate on antipsychotic medication use has intensified. This is partly due to the growing emphasis on the patient perspective, as many wish to discontinue their medication due to side effects or stigma. While most guidelines advise to use medication for at least 1 year after remission of a first psychotic episode, up to 58% of patients discontinue early - without clinical consultation. In addition, growing findings on the impact of antipsychotic medication are being published, including alarming side effects such as metabolic disease, heart disease, cognitive impairment, and potential brain volume reductions. To help patients make informed choices, clinicians and researchers face the responsibility of providing evidence-based counselling. However, evidence on the long-term impact of maintenance treatment vs early tapering is scarce when it

comes to an outcome prioritized by patients: personal and functional recovery. The two randomized trials completed so far have left us with contradictory results. Moreover, formal guidelines on how to safely reduce antipsychotic dosage to minimize the risk of withdrawal effects and relapse are scant. Recent suggestions of gradual, hyperbolic tapering as opposed to abrupt discontinuation have not yet been tested in RCTs, and tapering strategies may need to differ for first-episode compared with multi-episode psychosis.

This symposium will present the latest evidence from clinical trials and observational studies on optimal tapering. Presenters are members of the TAPER Research Consortium, uniting researchers involved in previous and current trials from Australia, China, Denmark, France, the Netherlands, Taiwan, and the UK. We extend the traditional focus on relapse risk by also examining the impact of tapering on social functioning and quality of life, providing a more holistic view of the risk-vs-benefit ratios of antipsychotic medication.

Dr. Horowitz will kick-off this symposium by premiering the results from RADAR (UK). This RCT compared a gradual and structured method of dose reduction to maintenance treatment in 253 people with recurrent psychosis. Next to relapse rates and social functioning at 24-months follow-up, he will share qualitative data on how RADAR participants had experienced dose reduction.

Dr. Liu will complement the current evidence by presenting 2-year outcomes from GARMED (Taiwan). This RCT applied a pragmatic-based tapering protocol, empowering 51 patients with remitted psychosis to evaluate their readiness for a next tapering attempt. Different dose-tapering patterns were identified and linked to functioning and quality of life.

Shiral Gangadin continues the discussion on tapering trajectories by evaluating tapering speed as predictor for relapse risk. He will present a subset of the data from the ongoing Dutch HAMLETT trial (450 FEP patients). As self-report data on medication use is not always accurate, he included unique dispensation data from pharmacies.

Dr. Ødegaard Nielsen shares evidence from three Danish studies in first-episode as well as multi-episode psychosis. Apart from survival curves and relapse rates, she will discuss qualitative data showing that clinicians still seem reluctant to let service users make decisions and how tapering affected patients' attitude towards drugs. This will form the foundation for discussing the upcoming priorities in the field.

19.1. RANDOMISED CONTROLLED TRIAL OF ANTIPSYCHOTIC DOSE REDUCTION AND DISCONTINUATION VERSUS MAINTENANCE TREATMENT IN PEOPLE WITH SCHIZOPHRENIA AND OTHER RECURRENT PSYCHOTIC DISORDERS (THE RADAR TRIAL)

Mark Horowitz*¹, Joanna Moncrieff²

¹*North East London NHS Foundation Trust*, ²*University College London*

Background: Antipsychotics reduce psychotic symptoms in the short-term, have some unpleasant subjective effects and some negative health consequences. Many patients wish to stop these medications. A previous Dutch RCT involving people with FEP found improved functioning and the same level of relapse in people who reduce or stop their antipsychotics compared to those who maintain their dose at long follow-up. We wished to determine whether these results could be replicated in the UK in people with recurrent disorders.

Methods: An RCT was conducted in 19 NHS Trusts in England comparing maintenance of antipsychotic medication in people with chronic psychotic conditions versus gradual, supported dose reduction and/or cessation (RADAR trial). Patients were excluded if they had experienced a mental health crisis in the last month, were deemed a serious risk by the treating clinician or were legally mandated to take antipsychotics. The intervention was evaluated quantitatively and qualitatively, with primary outcome being social functioning (measured by the Social Functioning Scale).

Results: 253 people with psychotic conditions were randomised from 4100 people screened: 126 to dose reduction and 127 to maintenance. At 24 months the median dose reduction was 33% in the discontinuation group and 0% in the maintenance group. At 24 month follow up there was no difference in the Social Functioning Scale between the two groups. 25.4% of people in the reduction group had a severe relapse whilst 13.4% did so in the maintenance group. In qualitative interviews, dose reduction patients reported a reduction in negative effects, primarily in mental clouding, emotional blunting and sedation and a positive effect in terms of social functioning and sense of self. They also reported withdrawal effects, symptom recurrence and relapse. Some people experienced an increased sense of empowerment, regardless of the outcome.

Conclusions: Similarly to the previous Dutch trial, there was no difference in social functioning between dose reduction and maintenance at medium term follow-up, and a near doubling in relapse rate. The majority of patients who reduced or stopped medication did not relapse. Longer follow-up is taking place. A more gradual, hyperbolic approach to tapering might improve outcomes. Patients reported a number of subjective and functional benefits to dose reduction.

19.2. 2-YEAR TRAJECTORIES AND OUTCOMES OF GUIDED ANTIPSYCHOTIC REDUCTION TO REACH MINIMUM EFFECTIVE DOSE (GARMED TRIAL) IN PATIENTS WITH REMITTED PSYCHOSIS

Chen-Chung Liu*¹

¹*National Taiwan University Hospital and College of Medicine, National Taiwan University*

Background: Patients in remitted state of schizophrenia face a dilemma whether they could improve their quality of life by reducing antipsychotics or they should maintain on stable dose to prevent from relapse. We tested in real world practice if an operationalized exponential guided-dose-reduction algorithm can help them reach a lower effective dose not at expense of increased risks of relapse. We also depicted and examined dose-tapering trajectories as to explore factors associated with different dose-reduction patterns and provide insights for re-evaluating the risk-to-benefit balance.

Methods: A 2-year open-label randomized prospective comparative cohort trial from Aug 2017 to Sep 2022 in Taiwan. Patients with a history of schizophrenia-related psychotic disorders under stable medications and symptoms were eligible, randomized 2:1 into guided dose reduction group (GDR) versus maintenance treatment group (MT1), together with a group of naturalistic maintenance controls (MT2). We examined if patients of GDR group could have a relapse rate not higher than the other two comparison groups by Kaplan-Meier survival estimates, how much dose they could reduce within 2 years, and if dose reduction correlated with improved functioning and quality of life compared by paired t-test. We also depicted the trajectories of individual GDR patients, grouped them based on dose-tapering patterns, and explored who were more likely to take which tapering strategies by logistic regression analysis.

Results: A total of 96 patients, comprised 51, 24, and 21 patients in GDR, MT1, and MT2 groups, respectively. During 2-year follow-up, 14 patients (14.6%) relapsed, including 6, 4,

and 4 from GDR, MT1, and MT2 (2 GDR and 2MT1 patients confessed discontinuing medications before relapse), statistically no difference between 3 groups. Among the 51 GDR patients, only 18 (35.3%) reduced 4 steps consecutively following the hyperbolic tapering algorithm (sequential reducers, SR, on average 58.5% baseline dose reduced), 14 (27.5%) reduced 1 to 3 steps (modest reducers, MR, 40% dose reduced), 3 (5.9%) re-escalated to previous level (alert reducers, AR, 28.7% dose reduced), 7 (13.7%) returned to baseline level (baseline returners, BR, no dose reduced), 6 (11.7%) relapsed (failed reducers, FR) and 3 (5.9%) withdrew without relapse (early exits, EE). Only SR subgroup of GDR exhibited improved clinical outcomes and endorsed better quality of life. Patients with a history of relapse were strongly correlated to taking a conservative dose-tapering pace, while no variables identifiable for predicting SR or FR.

Conclusions: Guided dose reduction seems to be a feasible approach as the majority of patients successfully tapered antipsychotics to certain extents. However, even though the risk of relapse, 11.8%, is comparable to their maintenance counterparts, in total 25.5% of GDR patients failed to decrease any dose, a fact to be deliberate while trying dose-reduction. Moreover, guided dose reduction comprises dynamic processes with differences between individual trajectories. Longer term observation, more flexible tapering processes, and closer monitoring of factors related to successful or failed tapering, are anticipated to improve outcomes of dose-reduction trials.

19.3. ANTIPSYCHOTIC TAPERING SPEED AS PREDICTOR FOR PSYCHOTIC RELAPSE AFTER FIRST-EPISODE PSYCHOSIS

Shirah Gangadin^{*1}, Franciska de Beer¹, Martijn Kikkert², HAMLETT and OPHELIA consortium³, Iris Sommer¹

¹UMCG, ²Arkin Mental Health Care Amsterdam, ³HAMLETT and OPHELIA Consortium,

Background: The prevention of relapse is a crucial treatment target in first episode psychosis (FEP) patients, as up to 85% of FEP patients experience a psychotic relapse within 5 years of remission from their first episode. Current guidelines recommend continuation of antipsychotic (AP) treatment during the first year after remission to prevent relapse, but patients and clinicians may have prominent reasons to reduce or discontinue AP medication early (e.g., unfavourable side-effects). However, evidence on safe tapering is scarce. Although gradual dose reduction may intuitively reduce relapse risk as compared to rapid discontinuation, this notion has not been supported by a large body of evidence. Therefore, this study will investigate the association between AP tapering speed, the type of AP drug, and psychotic relapse in the first 1.5 years after recovery from FEP in 250 patients.

Methods: We include data from the HAMLETT study (Begemann et al., 2020), a randomised controlled discontinuation trial. Participants were included in the trial when in remission from FEP for 3 to 6 months. Half of the participants is randomised to the continue group, the other half to the dose reduction/discontinuation group. Participants who tapered/discontinued antipsychotic medication, irrespective of randomized group, with available follow-up data for at least 1.5 years were included. We defined relapse as hospitalisation due to worsening of psychotic symptoms, the clinical judgement of the treating psychiatrist, or an increase of ≥ 10 points on the total score of the positive and negative syndrome scale (PANSS). Antipsychotic medication use was based on data from the Dutch Foundation for Pharmaceutical Statistics (SFK). SFK collects dispensation data from community pharmacies in the Netherlands. Tapering speed (in olanzapine equivalents/day) is calculated as the difference of AP dose at remission and at the end of AP discontinuation, divided by the number of days in between. AP

drugs are divided into partial agonists (PA, e.g. aripiprazole) and groups with high affinity (HA, e.g. haloperidol) and low affinity (LA, e.g. olanzapine) D2-receptor antagonism. Data were analysed using binary logistic regression models including AP tapering speed and AP type as predictors for relapse. Covariates were measured at baseline, 3-6 months after remission, and included age, sex, years of education (YOE), and duration of FEP (in months).

Results: The current patient group was on average 28.3 ± 8 years of age at baseline and consisted of 33% females. The average PANSS total score was 43.9 ± 9.4 and GAF score was 66.5 ± 12.4 . Preliminary analyses show that within the first year after recovery from FEP, 50% ($n=78$) experienced a relapse after dose reduction. The average tapering speed of all patients was equivalent to the discontinuation of a daily dose of 10mg olanzapine in 100 days (~ 0.1 olanzapine equivalents/day), starting from an average dose of 12.5 mg olanzapine. Male sex was a significant predictor for relapse $p < 0.05$, but other covariates were not significantly related to relapse.

In a model adjusted for age, sex, years of education and FEP duration, tapering speed was not significantly related to relapse ($OR=2.26$, $p=0.51$). A long total duration of the tapering trajectory ($OR=0.99$, $p=0.001$) and low dose after tapering ($OR=0.86$, $p=0.01$; complete discontinuation was not required) were significant predictors for relapse. AP type might be related to relapse, for which PA users might have a lower risk for relapse compared with HA users ($p < 0.10$).

Conclusions: Preliminary analyses indicate that AP tapering speed may not be related to relapse in patients who have recently recovered from their first FEP. It is important to emphasize that all patients were relatively well functioning individuals that participated in a discontinuation trial and were therefore closely monitored. As a result, all patients tapered off very gradually. A shorter tapering trajectory and lower end dose as significant predictors for relapse are possibly reflections of the protective effects of antipsychotics. In addition, the risk for relapse after tapering may be dependent on specific AP types. Evidence for the relationship between AP tapering speed and psychotic relapse is a valuable addition to current clinical knowledge, since there are still many persistent unknowns regarding AP discontinuation.

19.4. MOTIVATIONAL FACTORS, CLINICAL OUTCOMES, AND MENTAL HEALTH PROFESSIONALS' POSITIONS: RESULTS FROM FOUR DANISH STUDIES ON TAPERING ANTIPSYCHOTICS

Mette Ødegaard Nielsen^{*1}, Helene Speyer², Alexander Nøstdal³, Anne Emilie Stürup², Kickan Roed⁴, Jimmi Nielsen³

¹Copenhagen University Hospital, ²Copenhagen Research Center for Mental Health-CORE; Mental Health Center Copenhagen, Copenhagen University Hospital, ³Psychiatric Centre Glostrup, Mental Health Services in the Capital Region of Denmark, ⁴Centre for Applied Research in Mental Health Care, Mental Health Center, Glostrup, Copenhagen University Hospital - Mental Health Services CPH

Background: The need for lifelong antipsychotic maintenance treatment has been increasingly challenged. Questions have emerged regarding the characteristics of patients who can safely taper off antipsychotic treatment and the most effective way to reduce the antipsychotic dose. However, the idea of tapering antipsychotic medication can be met by negative attitudes among clinical staff.

Methods: In Denmark, three clinical studies on tapering antipsychotics have been conducted during the past 5 years: One randomized controlled study on remitted first-episode patients (n

= 26), one naturalistic study following patients with schizophrenia spectrum disorders who taper their antipsychotics (n=52), and one study on patients with schizophrenia enrolled in a specialized tapering clinic (n=88). Despite different inclusion-criteria and study designs, all projects were challenged in the recruitment of patients. Also, a qualitative study was conducted with 39 mental health staff divided into six focus groups to investigate their accounts of tapering antipsychotics.

Results: For the three clinical studies, 1-year follow-up data showed a total relapse rate of 35%, whereas 45% remained stable on a dosage of LESS THAN 50% of the baseline dosage. In the specialized tapering clinic, motivational factors for tapering were side-effects (71%), thoughts about the continuous need for medication (29%), the feeling of being stigmatized (12%) or disagreeing with the diagnoses (7%). For patients who remained stable, the level of function increased, and the reported side-effects decreased. For patients experiencing a relapse, level of function was stabilized after the relapse. Predictive models were weak but identified higher levels of general symptoms and lower baseline antipsychotic dose as predictors of relapse after one year.

The qualitative study identified three distinctive positions among mental health staff towards tapering antipsychotics, and points to a reluctance among mental health staff to let service users make decisions. This may leave limited possibilities for people with schizophrenia to have their request for tapering of their antipsychotic medication met by mental health staff.

Conclusions: The results from the clinical studies indicate that a significant proportion of patients with a schizophrenia spectrum disorder can benefit from a decreased antipsychotic dose in terms of an improved level of function and reduced adverse effects without a worsening in symptoms. For patients who experienced a relapse, a close monitoring resulted in a relatively swift stabilization of symptoms and level of function. The improved attitude towards antipsychotic medication following a relapse may potentially improve the treatment alliance and future adherence.

The randomized study struggled with recruitment, partly due to unwillingness to let randomization decide. Patients' preference to taper their medicine conflicts with mental health staffs' critical attitude towards tapering and may result in patients quitting the medicine on their own. To date, there are no strong evidence to identify who can safely taper their medication and the most secure method to do so. We argue that, at present, a closely monitored, slowly progressing tapering process based on active shared decision making, stands as the most effective and safe approach to identify individuals who can manage without medication and ensure the minimum necessary antipsychotic dose for those who require continuous antipsychotic treatment.

A limitation of the Danish studies lies in their relatively short follow-up period. It is essential to elucidate the long-term impact of the tapering process on the participants, a task that can, to some extent, be accomplished by examining the Danish registers.

20. NOVEL SOLUTIONS TO OLD QUESTIONS: USING ARTIFICIAL INTELLIGENCE TO PREDICT SEX, DRUGS, AND PSYCHOSIS PREVENTION

Paris Alexandros Lalousis, *Institute of Psychiatry, Psychology, and Neuroscience, King's College London*

Overall Symposia Abstract: Modern psychiatry largely deals with the same questions it did 100 years ago, but our selection of tools to answer them is increasingly growing. The recent Artificial Intelligence (AI) revolution provides hope for innovation and advancement that can

translate into transformative change in patient care. In this symposium, we will present work in which AI techniques have been implemented using biological markers and clinical presentation to improve prediction of sex, treatment response, and psychosis prevention.

In the first talk, Maria Fernanda Urquijo Castro presents work in which she uses machine learning to predict biological sex based on brain structure among patients with psychosis and depression. Drawing insights from the European Personalised Prognostic Tools for Early Psychosis Management (PRONIA) study, this presentation showcases the power of supervised machine learning in forecasting functioning outcomes. Her work showcases the connection between brain structure, sex and clinical trajectories.

In the second talk, Madaliva-Octavia Buciuman shows from resting-state fMRI (rs-fMRI) and their potential as early risk-stratification tools. Using supervised machine learning techniques, the talk explores the predictive value of static and dynamic rs-fMRI metrics, including local fractional amplitude of low-frequency fluctuations and functional connectivity measures. In a second phase, the talk explores the use of semi-supervised clustering methods, particularly Heterogeneity through Discriminative Analysis (HYDRA). These methods unveil transdiagnostic biologically-defined subtypes among clinical high-risk for psychosis, recent-onset depression, and recent-onset psychosis individuals based on rs-fMRI measures. These subtypes offer a deeper understanding of the complexities of these conditions, paving the way for more precise risk-stratification and personalized treatment approaches.

In the third talk, Dominic Oliver explores dynamic risk prediction for psychosis, reimagining how we detect individuals at risk. Utilizing vast patient data from electronic health records, the talk introduces a paradigm shift with time-varying Cox proportional hazards modelling and dynamic survival random forests to capture evolving symptoms over time. By refining a transdiagnostic risk calculator, this research demonstrates how incorporating longitudinal data can transform existing clinical prediction models and approaches to detection.

In the final talk, Paris Alexandros Lalousis presents a comprehensive journey into clinical and biological heterogeneity within depression and psychosis. Using a systematic review of structural neuroimaging studies, we uncover potential transdiagnostic patterns of gray and white matter volume reductions. Leveraging clinical, neurocognitive, and neuroanatomical support vector machine (SVM) learning models, we showcase the separability of depression from psychosis and provide insights into affective comorbidity. Semi-supervised machine learning further identifies distinct clusters of schizophrenia with varying immune signatures, GMV, and neurocognitive function, offering potential for targeted treatments. This work challenges traditional diagnostic boundaries, showcasing the promise for a new era of precise and transdiagnostic approaches to mental health care.

Together, these talks explore uncharted territories in prediction, risk assessment, and patient stratification, offering a glimpse of a future where early detection, dynamic risk prediction, and personalized treatments become the standard of care. Here we provide an overview of the ways that artificial intelligence is redefining our understanding of mental health.

20.1. UNDERSTANDING SEXUAL DIMORPHISM IN EARLY PSYCHIATRIC DISORDERS: A MULTIMODAL MACHINE LEARNING APPROACH

Maria Urquijo*¹, Linda A. Antonucci², Anne Ruef³, Frauke Schultze-Lutter⁴, Anita Riecher-Rössler⁵, Peter Falkai³, Rachele Sanfelici⁶, Lana Kambeitz-Ilankovic⁷, Dominic Dwyer⁸, Nikolaos Koutsouleris³, The PRONIA Consortium⁹

¹*Clinic for Psychiatry and Psychotherapy - LMU Clinic*, ²*University of Bari "Aldo Moro"*, ³*Ludwig-Maximilian-University*, ⁴*University Hospital of Child and Adolescent Psychiatry and Psychotherapy*, ⁵*University of Basel Psychiatric Clinics, Center for Gender Research and Early Detection*, ⁶*Ludwig Maximilian University, Max Planck School of Cognition*, ⁷*University of Cologne*, ⁸*Orygen, University of Melbourne*, ⁹*EU*

Background: Sexual dimorphisms contribute to the heterogeneity observed in psychotic and affective disorders across various disease stages. Despite evident sex-specific patterns in the expression of both disorder groups, prevailing diagnostic and treatment approaches rely on a one-size-fits-all paradigm. This may stem from a limited understanding of the intricate interactions among diverse bio-psycho-social variables that underlie the differences between females and males.

Methods: Here, our objective was to comprehensively investigate sex-related differences in the early stages of psychiatric diseases through a normative modeling lens. We initially constructed models of sexual dimorphism at the neuroanatomical level (BrainSex) and the phenotypical level (PhenotypicSex) using data from healthy individuals (N= 521). Subsequently, we applied these models to data from a total of 994 subjects with Clinical High-Risk (CHR) states for psychosis, Recent Onset Psychosis (ROP), and Recent Onset Depression (ROD) to evaluate whether deviations from the norm were associated with psychopathology. We also combined the initial two models to assess the gains of multimodal data integration.

Results: The BrainSex classifier exhibited a balanced accuracy (BAC) of 85.7% (p < 0.001), the PhenotypicSex model achieved a BAC of 69.6% (p = 0.001), while the multimodal classifier predicted sex with a BAC of 88.9% (p = 0.001). Additionally, when applying the BrainSex model to clinical samples, a gradual decrease in BAC for CHR, ROD, and ROP subjects was observed. In contrast, the PhenotypicSex model demonstrated improved performance in CHR and ROD subjects but not in ROP subjects, indicating a more pronounced influence of sex-related heterogeneity in the latter group.

Conclusions: Our findings affirm the existence of interactions between neuroanatomical and phenotypical patterns related to individuals' sex and psychopathology, even in early stages, with an increasing impact as the illness progresses. Risk stages of psychosis exhibited a marked sex-based dichotomization at the phenotypical level, highlighting the potential for these variables to offer prognostic insights and facilitate better-tailored treatment selection that could delay or even impede disease progression. Moreover, merging the models yielded greater accuracy in characterizing both healthy and clinical populations. These results underscore the imperative need for sex-based stratification in clinical practice for patients even in the early stages of psychiatric disorders as well as the integration of different modalities when aiming for an understanding of their etiopathology.

20.2. RESTING-STATE FMRI METHODS FOR TRANSDIAGNOSTIC PREDICTION OF FUNCTIONING OUTCOMES AND HETEROGENEITY CHARACTERIZATION IN EARLY STAGES OF PSYCHOSIS AND DEPRESSION

Madalina-Octavia Buciuman*¹, Paris Alexandros Lalousis², Shalaila Haas³, Linda A. Antonucci⁴, Lana Kambeitz-Ilankovic⁵, Anne Ruef¹, Stefan Borgwardt⁶, Joseph Kambeitz⁵, Christos Pantelis⁷, Rebekka Lencer⁶, Alessandro Bertolino⁴, Paolo Brambilla⁸, Rachel Upthegrove⁹, Stephen J. Wood¹⁰, Peter Falkai¹, Anita Riecher-Rössler¹¹, Stephan

Ruhrmann⁵, Frauke Schultze-Lutter¹², Eva Meisenzahl¹², Jarmo Hietala¹³, Raimo K.R. Salokangas¹³, Dominic B. Dwyer¹⁰, Nikolaos Koutsouleris¹, PRONIA study group¹⁴

¹Ludwig-Maximilian-University, ²Institute of Psychiatry, Psychology, and Neuroscience, King's College London, ³Icahn School of Medicine at Mount Sinai, ⁴University of Bari Aldo Moro, ⁵University of Cologne, ⁶University of Lübeck, ⁷The University of Melbourne, Melbourne Neuropsychiatry Centre, ⁸University of Milan, ⁹University of Birmingham, ¹⁰Orygen, the National Centre of Excellence in Youth Mental Health, Centre for Youth Mental Health, University of Melbourne, ¹¹University of Basel, ¹²Heinrich-Heine University Düsseldorf, ¹³University of Turku, ¹⁴EU Consortium

Background: Impairments in daily functioning are prevalent in the early stages of psychosis and depression and are of increasing interest as clinical outcome metrics, due to their high impact on patients' quality of life. However, individualized risk stratification of functional outcomes is currently limited and would benefit from the exploration of novel methods and data modalities. In this context, group-level brain functional abnormalities have been extensively reported in psychotic and depressive disorders, but their value as early prognostic tools within the framework of precision psychiatry has been insufficiently explored. Moreover, delineating biologically informed patient subgroups within the highly heterogeneous early illness stages may further aid the development of optimal tools for functional prognosis.

In the current work, we assess the prognostic value of state-of-the-art resting-state fMRI (rs-fMRI) measures for the stratification of functioning outcomes in clinical high-risk for psychosis (CHR) and recent-onset depression (ROD). In the second stage of the project, we explore whether rs-fMRI-based transdiagnostic subgroups within the early stages of psychosis and depression further improve the prediction of functional outcomes.

Methods: A total number of 218 CHR individuals and 197 ROD patients coming from eight European sites within the multi-center European Personalised Prognostic Tools for Early Psychosis Management (PRONIA) study were used for the current analyses. We trained support vector machine classifiers within a leave-site-out nested cross-validated framework to predict functional outcomes at the 9-month follow-up, as well as the persistence of high functioning from the 9-month to the 18-month follow-up based on several rs-fMRI metrics. As sufficient samples were available for the prediction of the 9-month functional outcome, we split our total sample into a model training (N=211) and a model validation (N=204) sample for these analyses, to further assess the generalizability of the models. Functional outcomes were measured using the Global Assessment of Functioning: Disability scale (Pedersen et al., 2007), with high functioning defined as more than 80 points on this scale. The rs-fMRI measures used as predictors were voxel-wise multiband fractional amplitude of low-frequency fluctuations and static and dynamic functional connectivity based on a group-level network model. In the second stage of the project, we plan to use the rs-fMRI metrics to identify transdiagnostic biological subtypes within CHR, ROD, and recent-onset psychosis (ROP) using semi-supervised clustering methods. Lastly, we aim to characterize the obtained subgroups at clinical, cognitive, and genetic levels, and explore their prognostic value for a more precise risk-stratification of functional outcomes.

Results Distributed fALFF and functional connectivity increases/decreases were transdiagnostically predictive of functioning outcomes at the 9-month follow-up above chance level, with a maximal balanced accuracy obtained by stacking the rs-fMRI metrics (Balanced accuracy = 65.8%, Sensitivity = 72.5%, Specificity=59.1%, P LESS THAN .001). Interestingly, the models generalized to the ROD patients in the replication sample, but not to

the CHR individuals, with maximum accuracy for the stacked model combining the different rs-fMRI metrics (BAC = 63.4%, Sensitivity = 72.7%, Specificity = 54%, P LESS THAN .001). Moreover, we found that the persistence of high functioning from the 9-month to the 18-month follow-up point could be predicted with higher performance based on the stacked rs-fMRI metrics (BAC = 71.6%, Sensitivity = 59.3%, Specificity = 84.0%, P LESS THAN .001), with predictive patterns predominantly spanning regions of the default-mode, frontoparietal and salience networks.

Conclusions: We provide evidence that resting-state fMRI measures are predictive of functioning outcomes in prodromal risk syndromes and early depression stages. We highlight the value of transdiagnostic model training for ROD patients and the potential presence of multiple pathways leading to functioning deficits in the CHR state, suggesting the need to further delineate more homogeneous subgroups in terms of risk etiology. Our results open the avenue for the further establishment of the generalizability and complementary prognostic value of rs-fMRI measures to other data domains within multimodal approaches.

20.3. USING DYNAMIC METHODS TO IMPROVE INDIVIDUALISED, TRANSDIAGNOSTIC CLINICAL PREDICTION MODELS FOR ENHANCING PSYCHOSIS PREVENTION

Dominic Oliver^{*1}, Maite Arribas², Kamil Krakowski³, Daniel Stahl⁴, Philip McGuire¹, Paolo Fusar-poli²

¹University of Oxford, ²King's College London, ³University of Pavia, ⁴Institute of Psychiatry, Psychology, and Neuroscience, King's College London

Background: Detection of individuals at clinical high risk of psychosis is sub-optimal and inefficient, limiting the potential of effective primary indicated prevention. To address this, we previously developed and validated a clinical prediction model for individuals at risk of psychosis in secondary mental health care using Natural Language Processing (NLP) symptom and substance use predictors. However, this model can only produce a single risk estimation at baseline, whereas individuals' symptoms and substance use changes over time, and so does their psychosis risk. We therefore aimed to refine our model using dynamic methods.

Methods: We included n=125,855 patients receiving a first index diagnosis of non-organic, non-psychotic mental disorder within the South London and Maudsley NHS Foundation Trust between 1st January 2008 and 10th August 2021. We refined a previously developed static individualized, transdiagnostic risk calculator employing NLP in secondary Electronic Health Records (EHRs) (C-index=0.85). We employed a i) time-varying Cox proportional hazards model; ii) dynamic survival random forest to allow for dynamic/longitudinal representation of predictors to estimate psychosis risk compared to the static model (Least Absolute Shrinkage and Selection Operator (LASSO)-regularized Cox proportional hazards model) according to TRIPOD statement. Performance was assessed via discrimination (C-index) in internal-external validation.

Results: Mean (SD) age was 34 years old (19.5), 48% were female, 66% were of White ethnicity. The most common index diagnostic spectra were anxiety disorders and non-bipolar mood disorders (both 25%). Mean follow up period was 1510 days. The cumulative incidence of psychosis was 0.031 (95% CIs: 0.030-0.033). The time-varying Cox model showed improved discrimination performance (C-index=0.88) compared to the static model (C-index=0.83).

Conclusions: These preliminary findings demonstrate that incorporating longitudinal data on symptoms and substance use substantially improves prediction performance. The study

provides novel evidence for refining detection strategies of individuals at risk of psychosis in secondary mental health care using dynamic prediction models. Further work is needed to mitigate against potential overfitting e.g. incorporating penalisation, test the impact of antecedent features and investigate more complex modelling techniques.

20.4. TRANSDIAGNOSTIC BIOTYPES OF DEPRESSION AND PSYCHOSIS: A MACHINE LEARNING APPROACH

Paris Alexandros Lalouis^{*1}, Lianne Schmaal², Stephen Wood², Renate Reniers³, Raimo Salokangas⁴, Christos Pantelis⁵, Eva Meisenzahl⁶, Paolo Brambilla⁷, Stefan Borgwardt⁸, Dominic Dwyer⁶, Rachel Upthegrove³, Nikolaos Koutsouleris⁶

¹*Institute of Psychiatry, Psychology, and Neuroscience, King's College London*, ²*Orygen, the National Centre of Excellence in Youth Mental Health*, ³*University of Birmingham*, ⁴*University of Turku*, ⁵*Melbourne Neuropsychiatry Centre, The University of Melbourne, VIC, Australia*, ⁶*Ludwig Maximilian University*, ⁷*University of Milan*, ⁸*University of Lübeck*,

Background: Current nosological categories are not reflective of underlying brain pathology. Patients whose symptoms are potentially caused by different biological processes being placed in the same category and patients whose symptoms are potentially caused by same biological processes being placed in different categories with detrimental effects to disease and treatment course prediction. This lack of biological validity is thought to be one of the major reasons for the lack of biomedical translation in psychiatry. Depression and psychosis specifically share hippocampal grey matter volume (GMV) reductions and they have both been found to be pro-inflammatory states with certain cytokines such as IL-6 and CRP detected at elevated levels. This study aimed to identify prototypes of pure depression and pure psychosis to investigate the heterogeneity of depression and psychosis with common, comorbid transdiagnostic symptoms.

Methods: HYDRA (Heterogeneity through Discriminant Analysis) was trained on whole-brain volumetric measures from 577 participants from the discovery sample of the multisite PRONIA study to identify neurobiologically driven clusters, which were then externally validated in the PRONIA replication sample (n = 404) and three datasets of chronic samples (Centre for Biomedical Research Excellence, n = 146; Mind Clinical Imaging Consortium, n = 202; Munich, n = 470).

Results: The optimal clustering solution was two transdiagnostic clusters (cluster 1: n = 153, 67 ROP, 86 ROD; cluster 2: n = 149, 88 ROP, 61 ROD; adjusted Rand index = 0.618). The two clusters contained both patients with ROP and patients with ROD. One cluster had widespread gray matter volume deficits and more positive, negative, and functional deficits (impaired cluster), and one cluster revealed a more preserved neuroanatomical signature and more core depressive symptomatology (preserved cluster). The clustering solution was internally and externally validated and assessed for clinical utility in predicting 9-month symptomatic remission, outperforming traditional diagnostic structures.

Conclusions: We identified two transdiagnostic neuroanatomically informed clusters that are clinically and biologically distinct, challenging current diagnostic boundaries in recent-onset mental health disorders. These results may aid understanding of the etiology of poor outcome patients transdiagnostically and improve development of stratified treatments.

21. LARGE-SCALE COLLABORATIVE NETWORKS TO UNDERSTAND RISK AND RESILIENCE FOR SCHIZOPHRENIA

Gemma Modinos, *King's College London*

Overall Symposia Abstract: Current understanding recognises that schizophrenia spectrum disorders (SSD) exist on a continuum, whose symptoms are distributed from health to (psychotic) illness. Recent large-scale collaborative networks leveraging brain scans from thousands of individuals worldwide across the psychosis continuum are advancing our understanding of the brain mechanisms that predispose to and/or protect from pathophysiology and poor outcomes. This symposium will offer the latest insights arising from such global neuroimaging analyses, across healthy individuals with self-reported schizotypy, individuals at clinical high-risk for psychosis (CHR), those with first-episode psychosis (FEP), and with established SSD. This will be achieved through four inter-related talks, comprehensively characterising brain morphometry across the psychosis continuum to highlight both predictive and protective pathways for the development of adverse clinical outcomes. Matthias Kirschner (Switzerland) will begin by presenting recent work from the global ENIGMA Schizotypy consortium on multiscale differentiation of cortical differences related to positive and negative dimension schizotypy in over 3,000 individuals. The vulnerability for SSD approach will be complemented by Maria Jalbrzikowski (USA), who will describe use of a neuroimaging summary score to detect those at greatest risk for later developing psychosis within the ENIGMA CHR cohort. Next, delving deeper into brain morphometric features with translational potential to predict clinical outcomes at the FEP stage, Dominic Dwyer (Australia) will show how brain risk and resilience biotypes influence prognoses over 5- to 10-year periods. Finally, Ryota Hashimoto (Japan) will present data derived from large-scale mega-analyses of cortical and subcortical structure in SSD and other three major psychiatric disorders. The symposium will conclude with a discussion led by world-leading expert Raquel Gur (USA), who will integrate this set of findings across the psychosis continuum to facilitate a stimulating discussion with the audience. In view of the increasing attention devoted to open science, big data and global collaboration, this timely symposium bringing together large-scale collaborative networks will offer new insights and tools to relevant for the prediction of risk and resilience for SSD from a dimensional perspective.

21.1. MULTISCALE DIFFERENTIATION OF POSITIVE AND NEGATIVE SCHIZOTYPY RELATED CORTICAL SIGNATURES: A WORLDWIDE ENIGMA STUDY

Matthias Kirschner^{*1}, Benazir Hodzic-Santor², Leda Kennedy³, Theo van Erp⁴, Jessica Turner⁵, Paul Thompson⁶, Andre Aleman⁷, Alain Dagher⁸, Stefan Kaiser⁹, Gemma Modinos¹⁰, ENIGMA Schizotypy Working Group¹¹

¹*University Hospitals of Geneva*, ²*Montreal Neurological Institute, McGill University*,

³*University of California - San Diego*, ⁴*University of California Irvine*, ⁵*The Ohio State University Wexner Medical Center*, ⁶*University of Southern California*, ⁷*University Medical Center Groningen*, ⁸*Montreal Neurological Institute*, ⁹*Geneva University Hospitals*, ¹⁰*King's College London*, ¹¹*Worldwide*

Background: Positive and negative schizotypy are associated with impaired neurodevelopment and increased risk for schizophrenia. While cortical alterations have been associated with both schizotypy dimensions, a comprehensive characterization of shared and dimension-specific neuroanatomical signatures is lacking. Here, we present a large-scale meta-analysis of the relationship between positive and negative schizotypy and cortical thickness in

healthy individuals. We further contextualized how these cortical patterns of schizotypy dimensions are shaped by local multiscale variations of brain organization.

Methods: The sample comprised 2,730 unmedicated healthy individuals (12-68 years, 47% male) from 29 cohorts of the worldwide ENIGMA-Schizotypy working group. Cortical effect size maps of positive and negative schizotypy scores were generated using standardized methods. We systematically compared these cortical profiles of schizotypy dimensions to case-control differences in schizophrenia, ADHD, ASD, and 22q11DS-psychosis, as well as microarchitecture, structural connectome measures, and specific neurotransmitter systems.

Results: Higher positive schizotypy was associated with thinner inferior frontal gyrus (pars-opercularis: $r=-.07$, pars-orbitalis: $r=-.06$), while higher negative schizotypy was associated with thicker medial orbitofrontal cortex ($r=.07$), and thicker rostral anterior cingulate ($r=.06$) (all $pFDR$ LESS THAN .05). Cortical maps of positive schizotypy-related cortical profiles were correlated with those of schizophrenia, ADHD and 22q11DS-psychosis. Negative schizotypy-related cortical profiles were correlated with those of schizophrenia, ADHD and ASD (all r GREATER THAN .29, p spin LESS THAN .05). Overall, the cortical profiles of both schizotypy dimensions were better explained by molecular and neurotransmitter features compared to structural connectome measures. In positive schizotypy, variation in gene expression and D1 receptor density, and in negative schizotypy, myelination and histamine receptor density were the best predictors of cortical differences.

Conclusions: This study revealed both shared and unique cortical thickness profiles of positive and negative schizotypy. Cortical pattern similarity of both dimensions with schizophrenia suggests neuroanatomical continuity across the psychosis phenotype, while distinct associations with 22q11DS-psychosis and ASD support additional separate neurodevelopmental pathways in positive and negative schizotypy. Regional facets of microarchitecture, connectomics and neurotransmitter that contribute differently to the cortical profiles of each schizotypy dimension further support distinct neurobiological mechanisms. Altogether, our work yields novel insights in the multiscale differentiation of cortical alterations in positive and negative schizotypy and their relationship to neuroanatomical patterns of related neuropsychiatric disorders.

21.2. NEUROIMAGING SUMMARY SCORES AS AN INDICATOR OF PSYCHOSIS RISK IN THE ENIGMA CLINICAL HIGH RISK FOR PSYCHOSIS COHORT

Maria Jalbrzikowski^{*1}, Rebecca Cooper¹, Rebecca Hayes², Rashmi Sahasrabudhe², Dennis Hernaes³, NA ENIGMA Clinical High Risk for Psychosis Working Group⁴

¹Children's Hospital/Harvard Medical School, ²Boston Children's Hospital, ³Maastricht University, ⁴NA ENIGMA Clinical High Risk for Psychosis Working Group

Background: Structural brain alterations are well-established features of schizophrenia, but do not effectively predict disease or elevated risk for disease. We recently developed a “Schizophrenia Neuroscore” that integrated multifactorial aspects of brain structure and found that this score significantly differentiated schizophrenia cases from controls (Cohen’s d [d]=0.56) to a greater degree than individual brain regions. Analogous to methods used to calculate polygenic risk scores, we created a single neuroimaging score (i.e., the Schizophrenia Neuroscore) by summing the weighted effects of many structural brain regions. Weights were determined via group difference effect sizes from ENIGMA Schizophrenia Working Group publications. The overall pattern of structural brain alterations in individuals at clinical high risk for developing psychosis (CHR) compared to healthy controls is similar to patterns of alterations observed in individuals with schizophrenia; however, the effectiveness of the Schizophrenia Neuroscore has not yet been tested in CHR.

Methods: Cross-sectional T1-weighted magnetic resonance imaging (MRI) data were pooled from a subset of the 32 international sites included in the ENIGMA Clinical High Risk for Psychosis Cohort (26 sites, total N=2681). CHR status was assessed using the Comprehensive Assessment of At-Risk Mental States or the Structured Interview for Prodromal Syndromes, at the baseline assessment and follow-up clinical visits. We processed MRI scans using harmonized protocols. After regressing out the effects of age and sex on each individual brain measure, we z-scored all regions of interest (ROIs) across the entire sample. We then multiplied each ROI by the Cohen's d effect sizes from case vs. control summary-level statistics obtained from ENIGMA Schizophrenia Working Group publications. We then summed the weighted values from all regions to create one cumulative score, with a higher score indicating greater neuroanatomical liability for psychosis. We examined differences in Schizophrenia Neuroscores between individuals at CHR and healthy controls, as well as differences between participants at CHR who later developed a psychotic disorder (CHR-PS+) and those who did not (CHR-PS-). Specifically, we conducted separate linear regressions with Schizophrenia Neuroscore as the dependent variable and group status (CHR vs. healthy controls; CHR-PS+ vs. CHR-PS- vs. healthy controls) as the independent variable. We calculated Cohen's d effect sizes for each group comparison.

Results: Of the 2681 included participants, 1160 (43.3%) were female, and the mean age was 21.5 (SD=5.0; range=9.5-39.9) years. This study included 1516 individuals at CHR and 1165 healthy controls [HC]. Using longitudinal clinical information, 225 individuals were in the CHR-PS+ group, 1074 participants were in the CHR-PS- group, and 217 CHR individuals did not have follow-up data. In comparison to HC, CHR individuals had significantly higher Schizophrenia Neuroscores ($d=0.24$, 95% Confidence Interval [CI]=0.16-0.32, $p=7.5e-10$). Schizophrenia Neuroscores were also associated with psychosis conversion ($F=18.6$, $p=9.5e-09$). In comparison to HC, CHR-PS+ had significantly elevated Schizophrenia Neuroscores ($d=0.31$, CI=0.16-0.45, $p=2.5e-05$). CHR-PS- also had significantly elevated Schizophrenia Neuroscores in comparison to HC ($d=0.22$, CI=0.15-0.31, $p=7.1e-08$). However, CHR-PS+ and CHR-PS- had similar Schizophrenia Neuroscores and did not significantly differ from one another ($d=0.07$, CI=-0.11-0.26, $p=0.28$).

Conclusions: These preliminary results suggest that the development of a cumulative brain-based score of psychosis liability carries potential to identify individuals at clinical high risk for psychosis. Further refinement of such scores could be used in future to accurately predict psychosis onset in individuals at risk.

21.3. THE DISCOVERY OF BRAIN RISK AND RESILIENCE BIOTYPES IN THE PHENOM CONSORTIUM

Dominic Dwyer^{*1}, Ganesh Chand², Junhao Wen³, Alessandro Pigoni⁴, Adyasha Khuntia⁵, Mathilde Antoniades¹⁵, Gyujoon Hwang⁶, Erus Guray³, Jimit Doshi³, Dhivya Srinivasan³, Erdem Varol⁷, Rene Kahn⁸, Stephen Wood⁹, Geraldo Busatto¹⁰, Benedicto Crespo Facorro¹¹, Christos Pantelis¹², Chuanjun Zhuo¹³, Marcus Zanetti¹⁰, Robin Murray¹⁵, Daniel Wolf³, Barnaby Nelson¹⁶, Theodore Satterthwaite³, Raquel Gur³, Christos Davatzikos¹⁷, Nikolaos Koutsouleris¹⁸, Paola Dazzan¹⁵

¹Ludwig Maximilian University, ²Washington University ³University of Pennsylvania, ⁴IMT School for Advanced Studies - Lucca, ⁵Max-Planck Institute of Psychiatry, ⁶University of Pennsylvania, ⁸Columbia University, ⁹University Medical Centre Utrecht, Brain Centre Rudolf Magnus, ¹⁰Orygen, the National Centre of Excellence in Youth Mental Health, ¹¹Universidade De São Paulo, ¹²Hospital Universitario Virgen del Rocio, CIBERSAM, Universidad de Sevilla, IBiS, Sevilla, ¹³Melbourne Neuropsychiatry Centre, The University of

Melbourne, VIC,¹⁴Nankai University Affiliated Tianjin Anding Hospital, Tianjin Medical University,¹⁵Institute of Psychiatry, Psychology, and King's College, London,¹⁶Orygen,¹⁷University of Pennsylvania Perelman School of Medicine,¹⁸Ludwig-Maximilian-University,

Background: Biological heterogeneity underlying psychosis has prevented mechanistic understanding and treatment development. It has also historically led to misdiagnosis with associated morbidity and mortality. Differences in underlying brain morphology have long been suspected, but numerous top-down studies demonstrating associations between brain patterns with diagnoses, illness stages, or symptoms have not resulted in any increases in research or clinical precision. Using machine learning, we recently took a bottom-up approach and decomposed the neuroanatomical heterogeneity of established schizophrenia to discover two volumetric subgroups—a ‘lower brain volume’ subgroup (SG1) and an ‘higher striatal volume’ subgroup (SG2) with otherwise normal brain structure and higher educational attainment. In this presentation, we will report on a series of follow-up studies where aimed to determine if: a) the brain subgroups were present in earlier illness stages; b) they could be found as endophenotypes in the general population. We hypothesised that the brain subgroups may represent brain risk (SG1) and brain resilience (SG2) endophenotypes.

Methods: The work was conducted as part of the PHENOM consortium, consisting of seven international sites in the USA, Europe, South America, and China. We previously created a two-group structural MRI statistical model with participants from USA, Germany, and China in addition to controls from the same sites (n=671). In our follow-up work, we used a first-episode psychosis sample of individuals from Sao Paulo, Santander, London, and Melbourne (n=996). To test endophenotypes, we used population samples from the UK Biobank (n=836) and the Philadelphia Neurodevelopmental Cohort (n=359). We preprocessed all data using a pipeline consisting of multi-atlas segmentation (MUSE) to obtain grey, white, and CSF regional volumes. We also obtained voxel-wise volumetric maps for later comparison of subgroup differences. Our original work in the chronic schizophrenia sample applied a novel semi-supervised learning technique called HYDRA (heterogeneity through discriminative analysis) to cluster brain MRI volume with internal validation to ensure reproducibility of the results (i.e., cross, split-half, and leave-site-out validation). We then applied these models to the first-episode and population samples. We assessed relationships in longitudinal symptoms, functioning, cognition, and genetic risk for schizophrenia (polygenic risk scores).

Results: The SG1 and SG2 subgroup solutions were detected across first-episode psychosis and population samples. In the first-episode sample, SG2 membership was associated with a baseline pattern of higher education, higher positive symptoms, and female sex (p LESS THAN 0.05). During a 5- to 10-year follow-up period, SG2 membership was also associated with higher remission of psychotic diagnoses (SG1, 57%; SG2, 78%; $\chi^2(8)=9.8$, $p=0.02$). In comparing subgroups in population samples, SG2 membership was associated with less incidence of subthreshold psychosis symptoms ($\chi^2=11.67$, $df=1$, p LESS THAN 0.05) and better cognitive performance ($\rho=0.13$, p LESS THAN 0.05). Whereas, SG1 was associated with worse cognitive performance ($\rho=-0.28$, p LESS THAN 10⁻⁴) and increased schizophrenia polygenic risk (Wilcoxon test; $z=2.69$, p LESS THAN 0.05).

Conclusions: Our results challenge common conceptualisations of schizophrenia as a disease involving changes to brain matter volume. Instead, they suggest that a brain risk phenotype is present in the healthy population and is enriched in schizophrenia samples. Such a hypothesis aligns with the concept of clinical risk that occurs along dimensions of severity. For the first time, we also discovered a potential brain resilience subgroup that is present in healthy populations and is associated with less impairment and better long-term outcomes. The results have the potential to lead to precision medicine approaches that employ biological stratification to improve mechanistic understanding and clinical care.

21.4. MEGA-ANALYSIS STUDY OF CEREBRAL CORTICAL AND SUBCORTICAL STRUCTURE IN FOUR MAJOR PSYCHIATRIC DISORDERS AND A DATA-DRIVEN APPROACH FOR CLASSIFICATION

Ryota Hashimoto^{*1}, Naohiro Okada², Junya Matsumoto³, Kenichiro Miura³

¹National Center of Neurology and Psychiatry, ²The University of Tokyo, ³ National Institute of Mental Health, National Center of Neurology and Psychiatry

Background: According to the operational diagnostic criteria, psychiatric disorders such as schizophrenia (SZ), bipolar disorder (BD), major depressive disorder (MDD), and autism spectrum disorder (ASD) are classified based on symptoms. While its cluster of symptoms defines each of these psychiatric disorders, there is also an overlap in symptoms between the disorders. We hypothesized that there are also similarities and differences in cortical structural neuroimaging features among these psychiatric disorders. And the creation of a novel diagnostic system using objective biomarkers using brain structural features is expected to take place the current diagnostic system.

Methods: T1-weighted magnetic resonance imaging scans were performed for over 5500 subjects including SZ, BP, MDD, ASD and healthy subjects recruited from 14 sites. Cortical thickness and surface area and subcortical volumes were calculated using FreeSurfer method. Effect sizes were determined using a linear regression model within each protocol, and these effect sizes were meta-analyzed. The similarity of the differences in cortical thickness and surface area of each disorder group was calculated using cosine similarity, which was calculated from the effect sizes of each cortical regions.

Results: The thinnest cortex was found in SZ, followed by BD and MDD. The cosine similarity values between disorders were 0.943 for SZ and BD, 0.959 for SZ and MDD, and 0.943 for BD and MDD, which indicated that a common pattern of cortical thickness alterations was found among SZ, BD, and MDD. Additionally, a generally smaller cortical surface area was found in SZ and MDD than in BD, and the effect was larger in SZ. The cosine similarity values between disorders were 0.945 for SZ and MDD, 0.867 for SZ and ASD, and 0.811 for MDD and ASD, which indicated a common pattern of cortical surface area alterations among SZ, MDD, and ASD. Patterns of alterations in cortical thickness and surface area were revealed in the four major psychiatric disorders. We demonstrated larger lateral ventricles volume in schizophrenia, bipolar disorder, and major depressive disorder, smaller hippocampus volume in schizophrenia and bipolar disorder, and schizophrenia-specific smaller amygdala, thalamus, and accumbens volumes and larger caudate, putamen, and pallidum volumes. In addition, we observed a leftward alteration of lateralization for pallidum volume specifically in schizophrenia. Moreover, as our main objective, we clustered the 5,604 subjects based on subcortical volumes, and explored whether data-driven clustering results can explain cognitive/social functioning in the subcohorts. We showed a four-biotype classification, namely extremely (Brain Biotype [BB] 1) and moderately smaller limbic regions (BB2), larger basal ganglia (BB3), and normal volumes (BB4), being associated with cognitive/social functioning. Specifically, BB1 and BB2-3 were associated with severe and mild cognitive/social impairment, respectively, while BB4 was characterized by normal cognitive/social functioning.

Conclusions: To our knowledge, this is the first report of a cross-disorder analysis conducted on cortical and subcortical structures of four major psychiatric disorders. Our results may lead to the future creation of novel biological data-driven psychiatric diagnostic criteria, which may be expected to be useful for prediction or therapeutic selection.

22. GLOBAL INEQUITIES IN EXCESS MORTALITY IN SCHIZOPHRENIA: NOVEL PERSPECTIVES TO TACKLE THE INEQUITABLE HEALTH GAP

Jayati Das-Munshi, *Institute of Psychiatry, Psychology and Neuroscience, King's College London*

Overall Symposia Abstract: People with severe mental health conditions, such as schizophrenia and bipolar affective disorders, die on average 15-20 years before the general population. This has been noted across international contexts, has persisted over time and across settings, and may have worsened during the COVID-19 pandemic. Most causes of death are from common preventable physical health conditions, and there is now widespread acknowledgement that a narrow focus on individual health behaviours is inadequate to tackle this inequity.

The aim of this symposium is to bring together research and perspectives from multiple international contexts (UK, Denmark, Ethiopia and Australia), to consider commonalities underlying physical health inequities impacting this group. We will draw upon systems-thinking to consider the role of social determinants and structural inequalities in impacting mortality risks in people with schizophrenia and bipolar disorders. Two of the presentations will consider the impact of the COVID-19 pandemic across different contexts (UK, Ethiopia) to understand how the pandemic may have further magnified inequities in people with schizophrenia.

Dr Ali will present her work which has developed causal loop diagrams to consider how systems-thinking can help inform an understanding of causal relationships, impacting mortality in people with schizophrenia. This will set the context, highlighting the role of stigma, social support and economic disadvantage in impacting physical health in people with schizophrenia.

Ms Chen will present findings from an analysis of whole-population data from Denmark, on the association between schizophrenia and cause-specific mortality with individual-level socioeconomic position data. Her findings suggest that people with schizophrenia experience a shorter life expectancy even compared to the general population in the lowest income bracket.

Dr Mihretu will present findings from a mixed methods study conducted in Ethiopia, which will highlight how the COVID-19 pandemic exacerbated stigma and discrimination towards people with schizophrenia and other severe mental health conditions, having a direct impact on physical health. The talk will reflect on how future emergency responses could prioritise the human rights, health, social and economic needs of people with mental health conditions.

Dr Das-Munshi will present a study of more than 20,000 people in the UK, which assessed mortality trends up to and including the COVID-19 pandemic, in people with schizophrenia and bipolar affective disorders. Mortality risks in this group increased steadily over a 13 year period. Higher mortality was evident in Black Caribbean and Black African people with these conditions, during the pandemic, relative to earlier years. The presentation will consider structural and systemic inequities which accounted for trends. The symposium will be co-chaired by Dr Plana-Ripoll and Dr Das-Munshi. The discussant will be Professor John McGrath, who will draw from his expertise based on many years of research in this area, to consider how we can effectively tackle the gap in life expectancy which continues to impact upon people living with schizophrenia and other severe mental health conditions.

22.1. SOCIOECONOMIC INEQUALITIES IN EXCESS MORTALITY AND LIFE YEARS LOST ASSOCIATED WITH SCHIZOPHRENIA AND OTHER MENTAL DISORDERS: A NATIONWIDE COHORT STUDY IN DENMARK

Danni Chen^{*1}, Linda Ejlskov¹, Julie Werenberg Dreier², Henrik Toft Sørensen¹, Oleguer Plana-Ripoll¹

¹Aarhus University and Aarhus University Hospital, ²National Centre for Register-based Research, Aarhus University,

Background: Schizophrenia and other mental disorders are associated with elevated mortality rates and shorter life expectancy. Although low socioeconomic position (SEP) is associated with both mental disorders and excess mortality, it is unknown to what extent SEP explains the excess mortality among people with mental disorders. Individuals with low SEP may be more often exposed to many risk factors (i.e., poor diet, smoking, alcohol, drugs, obesity, and social exclusion), and have limited access, continuity, and quality of healthcare; therefore, this population may be more sensitive to the adverse association of mental disorders with mortality. Based on our recent literature review, we observed that relative risks for mortality for people with vs. without mental disorders were similar across SEP levels. However, absolute differences in mortality risks between the two groups might differ by SEP, and this information was rarely reported in previous studies. In addition, evidence on specific types of disorders and cause-specific mortality was scarce. This study aims to investigate the associations between schizophrenia and other types of mental disorders with cause-specific mortality according to SEP.

Methods: We designed a cohort study including all individuals living in Denmark on January 1, 2000 (~5.2 millions) and followed them up until December 31, 2020. Information on schizophrenia and other mental disorders was obtained from the Danish Psychiatric Central Research Register, while the date and cause of death were obtained from the Danish Registry of Causes of Death. Individual SEP was defined based on the equated household disposable income as percentile ranks relative to all individuals of the same age and sex. We used Poisson regression models to estimate mortality rate ratios (MRR) comparing people with and without each diagnosis and stratified by SEP. Population attributable fractions (PAF) of all-cause and cause-specific mortality for each diagnosis were also calculated for each SEP stratum. We compared the average life expectancy between people with mental disorders and the general population depending on SEP levels by calculating excess life years lost (LYLs) for all-cause mortality, and for cause-specific deaths. The analysis plan was pre-registered in Open Science Framework (OSF).

Results: In preliminary analyses, we observed that people with mental disorders have higher all-cause and cause-specific mortality rates than those without regardless of SEP level. Specifically, in the bottom SEP quintile, MRR comparing people with and without schizophrenia was 1.96 (95%CI 1.88–2.04) for all-cause mortality, 3.80 (3.31–4.36) for external causes and 1.86 (1.79–1.94) for natural causes, and PAFs were 1.5%, 4.3%, and 1.4%, respectively; whilst the corresponding MRRs in the top SEP quintile were 2.94 (2.65–3.27), 14.92 (11.74–18.97), and 2.43 (2.17–2.73) and PAFs were 0.7%, 4.6%, 0.5%. The gap in average life expectancy between people with schizophrenia and the general population in the top SEP quintile was 11.2 years (73.0 vs. 84.2 years), whereas this difference was smaller in the bottom SEP quintile (9.2 years; 69.9 vs. 79.1 years). For specific causes of death, we found that people with schizophrenia and belonging to the highest rather than lowest SEP quintile lost fewer years due to natural causes, whilst similar LYLs due to external causes. Results for other mental disorders including bipolar disorders showed a similar pattern.

Conclusions: Our study confirms that whereas people in the general population experience a social gradient in mortality risk, people with schizophrenia and bipolar affective disorders experience a substantially shorter life expectancy and elevated mortality, even compared to the general population in the lowest income bracket.

22.2. IMPACT OF THE COVID-19 PANDEMIC ON HEALTH CARE AND PEOPLE WITH SEVERE MENTAL HEALTH CONDITIONS IN ETHIOPIA: THE MASC MIXED-METHODS STUDY

Awoke Mihretu^{*1}, Wubalem Fekadu¹, Azeb Alemu¹, Beakal Amare¹, Eleni Misganaw², Abebaw Ayele³, Ousman Esleman³, Zewdu Assefa⁴, Atalay Alem¹, Graham Thornicroft⁵, Charlotte Hanlon⁵

¹Addis Ababa University, ²Mental Health Service Users Association, Addis Ababa, ³Ministry of Health, Ethiopia, ⁴Ethiopian Public Health Institute, ⁵King's College, London,

Background: The COVID-19 pandemic has had far-reaching effects on the mental health of populations around the world, but there has been limited focus on the impact on people with existing mental health conditions in low-income countries. The aim of this study was to examine the impact of the pandemic on health care and people with severe mental health conditions (MHC), such as Schizophrenia, in Ethiopia.

Methods: A convergent mixed methods study was conducted. We systematically mapped information from publicly available reports on impacts of the pandemic on mental health care. Monthly service utilisation data were obtained from Amanuel Mental Specialised Hospital, the main psychiatric hospital, and analysed using segmented Poisson regression (2019 vs. 2020). In-depth interviews were conducted with 16 purposively selected key informants. Framework analysis was used for qualitative data. Findings from each data source were integrated.

Results: There was low priority given to the overall needs of people with severe MHCs during the COVID-19 pandemic in Ethiopia. Mental health-related stigma and discrimination were evident, complicating care and referrals for pre-existing physical health conditions especially among people with psychoses. People with severe MHCs were reportedly denied COVID-19 treatment because of an attitude from health care providers that they were unpredictable, unreliable and uncontrollable. Scarce mental health service settings were diverted to become COVID-19 treatment centres. Quality of health care was poor due to infrequent visits and follow-up, and there were also suicidal attempts and injuries. Lack of reliable medication supplies increased relapse and the chance of becoming chained at home, abandoned or homeless. At tertiary hospitals, there was a significant reduction in the number of admissions since March 2020. Infection control procedures did not adequately safeguard those with severe MHCs and basic needs were also not fully met. Many people with severe MHCs and their families could not afford to sustainably buy protective equipment due to the impoverishing effects of mental illness.

Conclusions: The COVID-19 pandemic had substantial negative impacts on the lives of people with severe MHCs in Ethiopia. Future emergency response should prioritise the human rights, health, social and economic needs of people with severe MHCs. Integration of mental and physical health care would expand access to care, improve individual outcomes and increase resilience of the mental health system.

22.3. LONG TERM MORTALITY TRENDS IN PEOPLE WITH SEVERE MENTAL ILLNESSES (SMI) AND HOW COVID-19, ETHNICITY AND OTHER CHRONIC

MENTAL HEALTH COMORBIDITIES CONTRIBUTED: A RETROSPECTIVE COHORT STUDY

Jayati Das-Munshi^{*1}, Ioannis Bakolis², Laia Bécaries², Hannah Dasch², Jacqui Dyer³, matthew Hotopf⁴, Rosanna Hildersley¹, Josephine Ocloo², Robert Stewart¹, Ruth Stuart², Alex Dregan¹

¹*Institute of Psychiatry, Psychology, and Neuroscience, King's College London*, ²*King's College London*, ³*NHS England and NHS Improvement (NHS-E/I)*, *Black Thrive Global*,

⁴*Psychological Medicine, Institute of Psychiatry, King's College London*, ,

Background: The COVID-19 pandemic worsened pre-existing inequalities in health outcomes and healthcare access for the most disadvantaged groups, particularly in countries with the highest levels of social inequities. Racialised and minority ethnic communities, and people living with mental disorders, including severe mental illnesses (SMI), such as schizophrenia and bipolar affective disorders, were noted to be at a higher risk of SARS-Cov2 infection and death. Chronic comorbid physical health conditions such as cardiovascular disease and diabetes have been shown to exacerbate mortality following SARS-CoV-2 infection. A growing body of work has also highlighted the additional contributions which long-term mental health conditions play in heightening the risk of death following infection, such as substance use disorders, dementia, anxiety, depression and learning disabilities. The interplay of these comorbidities with other vulnerability factors, associated with a higher risk of death following SARS-CoV-2 infection, in people already living with SMI, remains unclear. In particular, the impact of the COVID-19 pandemic on potentially exacerbating underlying longer-term trends, in addition to exacerbating other inequalities, for example with respect to ethnicity, remains unclear. The aim of this study was to explore longer term trends in mortality in SMI, including over the COVID-19 pandemic period, with a focus on additional vulnerabilities for mortality (psychiatric comorbidities and race/ ethnicity) in this group.

Methods: We conducted a retrospective cohort study using electronic health records from secondary mental healthcare, covering a regional UK catchment of 1.3 million people. Data from adults with clinician-ascribed ICD-10 diagnoses for schizophrenia-spectrum and bipolar disorders were used to assess mortality trends spanning fourteen years, which also included the COVID-19 pandemic period (2020-2021). Parametric regression survival models were used to assess all-cause mortality trends over time, and cause specific mortality was estimated using a competing risks regression model. Age and sex- standardised mortality ratios were estimated for the sample over the pre-pandemic period of 2019 and over 2020 (pandemic).

Results: The sample comprised 22,361 people with SMI, with median follow-up of 10.6 years. Standardised mortality ratios (SMRs) for people with SMI were more than double the population average pre-pandemic, increasing further during the pandemic, with substantial increases in those with mental health comorbidities, particularly in people with SMI and comorbid learning disabilities (SMR: 6.08 (95% CI: 4.13, 8.63) and comorbid substance use disorders (SMR: 6.88 (95% CI: 5.65, 8.31)). All-cause mortality risk was 16% higher (Risk Ratio (RR): 1.16 (95% CI: 1.04-1.29)) in the sample over the first year of the COVID-19 pandemic (2020-2021), compared to reference years (2014-2015). Mortality risk increased steadily among people with SMI and comorbid depression, dementia, substance use disorders and anxiety over a 13-year period, increasing further during the pandemic. Higher mortality was also evident in Black Caribbean (RR: 1.40; 95% CI: 1.11-1.77) and Black African (RR: 1.59; 95% CI: 1.07-2.37) people with SMI during the COVID-19 pandemic years, relative to reference years (2014-2015). During the pandemic period (2020-2021), COVID-19 mortality

was especially elevated in people with SMI and comorbid dementia (sub-Hazard Ratio (sHR): 1.96, 95% CI: 1.26-3.04; p LESS THAN 0.001) and in people with SMI and learning disabilities (sHR: 2.30; 95% CI: 1.30-4.06; p LESS THAN 0.001), compared to people with SMI alone. Deaths from non-COVID-19 causes were also elevated in people with SMI and comorbid dementia (sHR: 2.62; 95% CI: 2.10-3.26; p LESS THAN 0.001) and in people with SMI and comorbid substance use disorders (sHR: 1.31; 95% CI: 1.06, 1.61; p=0.01), over the COVID-19 pandemic period.

Conclusions: Mortality risks have increased over time in people with SMI, with the pandemic exacerbating pre-existing trends. Marked inequities were noted for people with SMI and comorbid conditions, such as dementia and learning disability. A higher risk of death during the pandemic was noted in Black Caribbean and Black African people with SMI, compared to pre-pandemic years. The pandemic may have magnified pre-existing structural inequities. Actionable solutions, focused on structural and social determinants, are needed.

22.4. USING A SYSTEMS THINKING APPROACH TO EXPLORE THE COMPLEX RELATIONSHIPS BETWEEN SCHIZOPHRENIA AND PREMATURE MORTALITY

Suhailah Ali¹, Eryn Wright¹, Fiona Charlson¹

¹*The University of Queensland*

Background: People with schizophrenia have a higher risk of mortality compared to the general population, which has not improved over time. The majority of premature deaths are due to comorbid physical diseases, driven by interrelated factors operating at the individual level, through health systems and influenced by social determinants of health. A holistic understanding of this problem and the causal pathways linking these factors together is lacking.

Methods: This study aims to understand why the mortality gap between people with schizophrenia and the general population is not improving by developing a causal loop diagram (CLD), a systems thinking approach which enables empirical research and theoretical knowledge to be combined into a visual representation of causal relationships and feedback loops. The CLD was constructed using published literature, including both quantitative and qualitative studies, to identify key variables and relationships, and refined through consultation with experts in the topic area.

Results: A total of 21 variables and 68 connections were included in the CLD, with 23 distinct feedback loops identified. Stigma and social support had the most connections, while unemployment was involved in the greatest number of feedback loops. Most feedback mechanisms served to reinforce behavioural risk factors, inadequate healthcare and social disadvantage.

Conclusions: The CLD has created a holistic and dynamic understanding of the causal pathways driving the mortality gap between people with schizophrenia and the general population, providing insights into why it has persisted over time. One of the key findings was the critical role of social determinants in shaping health outcomes, highlighting the need for person-centred models of care and multisectoral government action.

23. SOCIAL DISCONNECTION IN SCHIZOPHRENIA SPECTRUM DISORDERS

Sarah Hope Lincoln, *Case Western Reserve University*

Overall Symposia Abstract: Social connection is important for individuals' mental health. Individuals across the psychosis spectrum experience higher rates of a variety of types of social disconnection, including loneliness, social exclusion, and social isolation. Research on social disconnection could offer new insight into the psychological processes associated with social experiences for individuals across the psychosis spectrum. Additionally, work examining various aspects of social disconnection may identify critical intervention and treatment targets for individuals with schizophrenia spectrum disorders. This symposium brings together four projects focused on social disconnection across a continuum of psychotic experiences.

Examining qualities of embodied loneliness in psychosis, Baxter, Lee, and Park (Vanderbilt University, United States) examine the association among loneliness, hallucinations, and self-disturbances. They find that the embodiment of loneliness is felt in the torso, but the quality of embodiment differs between individuals with schizophrenia and controls, potentially reflecting interoceptive difficulties and degree of self-disturbance in individuals with psychosis.

Furthering our understanding of the role of loneliness and psychosis, Gandhi, Botello, Mueser, and Fulford (Boston University, United States) test a model of the temporal relationships among loneliness and paranoia in 404 individuals with first-episode psychosis. Their work indicates robust associations between loneliness and paranoia across two years. They also find that elevated paranoia may contribute to greater loneliness in the later stages of recovery.

In line with this work, Lincoln, Ward, Laquidara, and Barrick (Case Western Reserve University, United States) investigated the relationship between social isolation and social dysfunction in individuals with schizophrenia and suicidal thoughts and behaviors using self-report, clinical interviews, and ecological momentary assessment. Preliminary results indicate that social isolation and disconnection at baseline is associated with suicidal thoughts and behaviors, and will examine whether these social factors predict suicidal thoughts and behaviors at a 1-month follow-up. These findings may highlight an important target in reducing suicide risk for individuals with schizophrenia spectrum disorders.

Finally, Riehle, Brauer, Lincoln, and Pruessner (Universität Hamburg and Universität Heidelberg, Germany) find in a one-week diary study that young adults with attenuated negative symptoms use less interpersonal emotion regulation strategies in their daily lives than either young adults with attenuated positive symptoms or a control group, and find interpersonal emotion regulation strategies less helpful. These results may further explain emergent and consequential features of social disconnection in individuals with elevated psychosis risk.

Collectively, the work in this symposium furthers our understanding of the experiences, causes, and consequences of social disconnection for individuals with schizophrenia spectrum disorders. This more nuanced understanding of how social disconnection both develops and affects individuals across a continuum of psychotic experiences could inform interventions targeting psychotic symptoms and psychosocial dysfunction.

23.1. EMBODIMENT OF LONELINESS AND SELF-DISTURBANCES IN THE SCHIZOPHRENIA-SPECTRUM

Tatiana Baxter¹, Hyeonseung Lee², Sohee Park²

¹*Vanderbilt University*, ²*Vanderbilt University, Dept of Psychology*

Background: Prevalence of loneliness among individuals with schizophrenia (SZ) is as high as 80% (Badcock et al., 2020). The Social Deafferentation Hypothesis (2007) posits that isolation causes social hallucinations (e.g., felt presence (FP) or hearing voices). Indeed, social isolation is associated with bodily self-disturbances and disembodiment, two core features of SZ. Whilst the negative impact of loneliness on outcome is established, the relationship between loneliness and bodily self-disturbance of SZ remains obscure. The aim of this study was to further elucidate how loneliness, social hallucinations and self-disturbances might be manifested and experienced in the SZ-spectrum conditions.

Methods: Individuals with SZ, matched control participants (CO), people at-risk for psychosis (HR) and those at low-risk (LR) for psychosis participated in visuospatial mapping tasks that required localizing bodily sensations associated with feelings of loneliness (plus 13 emotions) and components of self-disturbances. UCLA Loneliness Scale, Sensed Presence Questionnaire (SenPQ), Body Disturbance Inventory (BODI), and Brief Trauma Questionnaire (BTQ) were administered to assess loneliness, FP, Out-of-Body Experiences (OBE) and trauma, respectively. SANS and SAPS were used to rate the severity of SZ symptoms.

Results: Loneliness was significantly associated with FP and OBE across all groups; self-disturbances were elevated in lonelier participants. Loneliness was embodied primarily in the torso for SZ and CO but there was a noteworthy difference; CO reported deactivation of sensations similar to their map of sadness, but the map of SZ showed activation. In addition, the bodily maps of loneliness differed between the HR vs LR such that the sensations associated with loneliness were distributed more diffusely across the body in the HR. Mapping of sensations associated with self-disturbances revealed that the topography of the core self, voices and FP diverged between SZ and CO, qualitatively and quantitatively. With respect to self-disturbance, the rates of FP and OBE were elevated in SZ and the HR. Among CO, those with both FP and OBE were at the highest risk for psychosis. Lastly, trauma was associated with OBE but not with FP.

Conclusions: We examined embodiment of loneliness and self-disturbances in the schizophrenia-spectrum to document the phenomenology of these experiences and to further elucidate the role of social isolation in self-disturbances. We found that loneliness is felt in the torso, as has been described previously in first-person narratives as a gnawing, hunger-like sensation. However, CO vs. SZ diverged in the quality of the embodiment, which might reflect interoceptive difficulties in the SZ and/or the extent of the self-disturbance. Lastly, embodiment and self-disturbance are rarely considered as treatment-targets, but it would be important to re-evaluate the utility of the core symptoms of schizophrenia as potential targets for intervention.

23.2. INTERPERSONAL EMOTION REGULATION IN YOUNG PSYCHOSIS-PRONE ADULTS: A 7-DAY DIARY STUDY

Marcel Riehle*¹, Saskia Brauer¹, Tania M. Lincoln¹, Luise Pruessner²

¹Universität Hamburg, ²Universität Heidelberg

Background: Emotion regulation difficulties and social disconnect are recognized in psychosis-risk populations. However, little research has been conducted to investigate how psychosis-prone young adults turn to others when regulating their emotions. Such interpersonal emotion regulation (IER) strategies can include contacting others to upregulate positive or downregulate negative emotions. Based on prior research, we hypothesized that young adults with attenuated levels of negative symptoms would make less use of IER strategies and that people with attenuated levels of positive symptoms would use IER strategies more than those

without these symptoms. Our second hypothesis was that people with either attenuated negative or positive symptoms would perceive using IER strategies as less helpful.

Methods: We included three groups of young adults (age 18-29) based on a priori defined psychometric cut-offs for the Community Assessment of Psychic Experiences: psychosis-prone – negative symptoms (PP-NES, $n=37$), psychosis-prone – positive symptoms (PP-POS, $n=20$), and low psychosis proneness (control group, CG, $n=52$). We excluded people with concurrent moderate and concurrent high levels of positive and negative symptoms. Participants provided daily online diary entries in the evenings over one week (min. 3 entries). The diaries assessed the frequency and efficacy of using IER strategies, daily negative symptoms, paranoia levels, and positive and negative affect. Our assessment of IER strategies was based on the Interpersonal Emotion Regulation Questionnaire and included separate measures for regulating positive and negative emotions.

Results: The data were analyzed with multi-level linear models. PP-NES reported using IER strategies for upregulating positive emotions less frequently than both other groups (vs. CG: Cohen's $d = -0.87$, $p < .001$; vs. PP-POS: $d = -0.76$, $p = .017$), and there were no significant group differences in the frequency of using IER strategies for reducing negative emotions. However, the groups differed in their affect levels and after controlling for positive and negative affect, respectively, there were no longer group differences for the upregulation of positive emotions, but PP-NES were found to report using IER strategies to downregulate negative emotions less frequently than both other groups (vs. CG: $d = -0.69$, $p = .003$; vs. PP-POS: $d = -0.63$, $p = .025$). Regarding the efficacy of IER, only PP-NES reported that using IER strategies for positive emotions was less helpful than did controls (upregulating pos. emotions: $d = -0.78$, $p = .005$; downregulating neg. emotions: $d = -0.58$, $p = .018$). Additional analyses showed significant within-person associations, most notably for diary negative symptoms predicting lower scores on all IER variables (i.e., frequency and efficacy).

Conclusions: Our results suggest that young adults with attenuated negative symptoms apply IER strategies less frequently. For upregulating positive emotions this was contingent on low levels of positive affect. For downregulating negative emotions, the effect became only observable after controlling for this group's elevated negative affect levels. Those with attenuated negative symptoms also perceived IER to be less helpful. Particularly the latter may contribute to the social disconnect in this group. The analyses for attenuated positive symptoms were limited by the small group size. Future research should investigate temporal directions of the within-person effects reported here and whether the lower efficacy of using IER strategies in young adults with attenuated negative symptoms has behavioral or psychophysiological correlates.

23.3. SOCIAL ISOLATION AND SUICIDAL BEHAVIORS IN SCHIZOPHRENIA

Sarah Hope Lincoln^{*1}, Madeline Ward¹, Jill Laquidara¹, Elyssa Barrick¹

¹*Case Western Reserve University*

Background: Suicide is the leading cause of premature death in individuals with psychotic disorders, with a lifetime prevalence rate of death by suicide at approximately 4-5% (Palmer et al., 2005). Social isolation, the disruption to or lack of interpersonal interactions, is implicated in both the development of psychotic disorders (van Os et al., 2000) and suicide behaviors (Fisher et al., 2015; Trout, 1980), and thus is a strong candidate mediating the association between psychosis and suicide behaviors. Previous studies have identified social isolation as associated with both self-injurious and suicide behaviors (Endo, et al., 2017), thus social isolation might be a factor in the high rates of suicide behaviors in individuals with schizophrenia. The current research clarifies the association between psychosis and suicide

behaviors by testing a specific mechanism, social isolation, which may explain high rates of suicide behavior in this population.

Methods: Participants, ages 18-30 years old, have been recruited from mental health facilities, community clinics, and online platforms. Inclusion criteria included: 1) United States residents, 2) diagnosis of schizophrenia or schizoaffective disorder (confirmed with clinical interview) (SZ group) or no history of psychiatric diagnosis (HC group), 3) English as a primary language. At baseline, participants complete clinical interviews assessing positive, negative, and disorganized psychotic symptoms using the Psychotic Symptom Rating Scale, Brief Negative Symptom Scale, and the Thought and Language Index, as well as an assessment of suicidal thoughts and behaviors using the Self-Injurious Thoughts and Behavior Inventory (SITBI). Social connection is assessed with several self-report measures focused on social network, perceived social support, and loneliness. Participants then complete five days of ecological momentary assessment assessing symptoms and social connection, and finally complete a 1-month follow-up of psychotic symptoms and suicide behaviors.

Results: Preliminary results indicate that the SZ group reports lower perceived social support, less informational support, and less companionship relative to the HC (ps LESS THAN .05). The SZ group also reports higher endorsement (frequency) of suicidal ideation and suicidal behaviors. Of note, the SZ group also endorses significantly higher rates of depressive symptoms (p LESS THAN .05).

Conclusions: The work of this study thus far supports differences in social behavior (e.g., less effective) and experiences (e.g., lower social support) in individuals with schizophrenia and related disorders relative to healthy controls, as well as demonstrating higher suicide thoughts and behaviors. The interaction of psychological and social factors may contribute significantly to the development of psychiatric symptoms and behaviors in psychosis. Specifically, social difficulties such as exclusion, rejection, loneliness, and isolation may be implicated in risk for suicide behaviors in this population, and could be an important intervention target.

23.4. SOCIAL DISCONNECTION IN SCHIZOPHRENIA: LONELINESS & PARANOIA IN THE YEARS FOLLOWING A FIRST EPISODE OF PSYCHOSIS

Arti Gandhi¹, Renata Botello¹, Kim Mueser¹, Daniel Fulford¹

¹*Boston University*

Background: Loneliness is a common experience in individuals with psychosis and is associated with dire mental and physical health outcomes. Emerging evidence and theories suggest that paranoia plays a key role in the emergence and persistence of loneliness. However, existing research primarily consists of cross-sectional studies in people with chronic psychosis, leaving gaps in our understanding of the early stages of psychosis. This study explores the temporal relationship between loneliness and paranoia over two years in patients with a first episode of psychosis in the United States.

Methods: Four hundred and four people aged 15 to 40 participated in the Recovery After an Initial Schizophrenia Episode-Early Treatment Program (RAISE-ETP), where sites were randomly assigned to either coordinated specialty care, or standard community treatment. Participants completed assessments of psychiatric symptoms and social experiences every 6 months for two years. We calculated a composite loneliness score by averaging four self-report items, including three items from the Well-Being Scale ("I often feel lonely due to a lack of close friends to share my concerns with") and one item from the Stigma Scale ("I often feel alone because of my mental health problems"). We then assessed psychometrics of the scale, including exploratory factor analysis and correlations between loneliness and paranoia (suspiciousness item of the Positive and Negative Syndrome Scale [PANSS]) at each time

point. We analyzed longitudinal associations between paranoia and loneliness using latent growth curve models to understand how changes in paranoia impacted changes in loneliness over time.

Results: Loneliness items exhibited strong internal consistency (omega values = 0.63-0.79) and adequate item loadings (lambda values = 0.41-0.79) across all time points. Self-reported loneliness was moderate across all time points ($M[SD] = 3.52-3.95 [1.22-1.38]$; possible range = 1-7), with the highest levels at baseline, and decreased significantly over time (average loneliness did not differ between groups). We examined trajectories of loneliness and paranoia separately. Both paranoia and loneliness showed significant variability in their intercepts, but only loneliness exhibited variability in the slope. Contemporaneous associations revealed that higher loneliness was related to higher paranoia at 6 ($\beta=0.71$, $SE=0.17$), 12 ($\beta=0.53$, $SE=0.16$), and 18 ($\beta=0.58$, $SE=0.17$) months, but not at 24 months ($\beta=0.04$, $SE=0.18$). Lagged associations showed that increased paranoia at 18 months predicted significantly greater loneliness at 24 months ($\beta=0.64$, $SE=0.19$), but not at previous time points.

Conclusions: Moderate levels of loneliness were observed in patients with a first episode of psychosis, decreasing significantly over time in the context of intervention. Initial severity of loneliness and paranoia varied between individuals. The rate of decline in loneliness differed between individuals while the decline in paranoia was stable. Paranoia and loneliness were related to one-another in the early stages of recovery, which diminished in later stages. Furthermore, elevated paranoia contributed to future loneliness, but only in the later stage of recovery. This study provides evidence that paranoia may lead to greater loneliness, independent of the effect of time, and may have a stronger influence on loneliness in later stages of recovery. In further analyses, we plan to examine these relationships bidirectionally.

24. FROM ALOGIA TO VERBIGERATION: UNDERSTANDING SPEECH AND LANGUAGE DISTURBANCE IN PSYCHOSIS

Sunny Tang, *Zucker Hillside Hospital*

Overall Symposia Abstract: Understanding speech and language disturbances in psychosis and other mental disorders is critical for elucidating key mechanisms underlying these disorders as well as developing novel opportunities to capture objective biomarkers through computational analysis of speech. The objective of this symposium is to discuss current theoretical, trans-nosological, and data-driven understandings of speech and language disturbance in psychosis as part of an international collaborative effort by the DISCOURSE consortium to harmonize the clinical assessment of these phenomena.

Speech and language disturbances are among the canonical features of major psychiatric disorders, particularly including psychosis and schizophrenia-spectrum disorders. The linguistic content of speech and the manner in which it is represented have been interpreted as representing internal thought processes. Disturbances in thought process are related to distinct findings on neuroimaging, poor outcomes and greater disability.

Recent advances in artificial intelligence and natural language processing have launched a wave of new and promising investigations that use computationally derived speech and language features to predict or model key clinical outcomes. For example, natural language processing and acoustic analysis has been used to classify schizophrenia diagnosis relative to individuals with other psychotic disorders, to predict the development of threshold psychotic disorders among youths at clinical high risk, and to model changes in psychosis symptoms over the course of hospitalization.

The DISCOURSE consortium is an international collaboration of researchers studying speech and language in psychosis. This symposium will present ongoing efforts by the consortium to achieve a clinically-informed and evidence-based consensus on how speech and language disturbances should be assessed and understood clinically. First, Dr. Sreeraj will present an overview of clinical and psychometric approaches to describing speech and language disturbances in mental disorders, as well as examining prevalence of different symptom types. Then, Dr. Voppel will use sentence-embeddings from BERT, a large language model, to group and represent rating scale descriptions of speech and language-related symptoms. Next, Dr. Stein will examine factor analysis findings from a large cross-diagnostic sample, along with neurobiological correlates on MRI. Finally, Dr. Tang will relate factor analysis findings based on clinical ratings to computational features derived from acoustic analysis and natural language processing.

24.1. APPROACHES TO CLINICAL CHARACTERISATION OF THOUGHT DISORDER IN SCHIZOPHRENIA

Vanteemar Sreeraj*¹, Kiran Bagali¹, Sonika Nichenametla¹, Nilanjan Datta¹, Swarna Buddha Nayok¹, Venkataram Shivakumar¹, Lena Palaniyappan², Ganesan Venkatasubramanian¹

¹*National Institute of Mental Health and Neurosciences (NIMHANS)*, ²*Douglas Mental Health University Institute*

Background: Thought disturbance is a core symptom dimension of schizophrenia captured by multiple clinical symptom rating scales. However, interoperability/convertibility of thought disorder ratings among the existing assessment scales is necessary to support cross-study comparisons and meta/mega-analysis that are lacking in this domain. The variations in terminology related to thought disturbance pose a challenge. Here, we analyse the definitions of thought disturbance items in different psychopathology rating scales. Further, we estimate the impact of varying definition on the prevalence estimates of thought disorder.

Methods: The clinical rating scales measuring the formal thought disorder in schizophrenia were systematically searched. Individual items of the scales that followed a descriptive psychopathological approach with full texts of descriptions available in the English language were enlisted. The scales' administration methods and item descriptions were collated. Similarities and differences in the item descriptions and their conceptual contexts were evaluated. The items were further rated for their descriptive psychopathological and phenomenological characters. We evaluated the prevalence rates of FTDs in 306 drug-naïve first-episode psychosis (55%males, mean(SD)age=31(7.9)yrs) with SANS/SAPS and 49 schizophrenia patients in remission of positive symptoms (mean illness duration=7.3yrs) using EASE(Examination of Anomalous Self-experience). The impact of differences in item definitions on these ratings was analysed from schizophrenia patients' rating scores.

Results: A total of 15 different scales were identified, 9 of which were used for further item analysis. 72 disjoint items (i.e., minimal conceptual overlapping) were consolidated. The ratings were recommended to be conducted on speech samples from clinical interviews, eliciting speech samples during a conversation, and using neutral and/or standard stimuli. Different technical terms are used to describe similar concepts and vice versa. For eg., the definition of “tangentiality” and “thought block” in the thought language communication (TLC) scale matches that of “cross-talk” and “rupture of thought” in the thought and language disorder(TALD) scale, respectively. Most of these can be construed as positive(n=56), and few

as negative/deficit(n=16) thought disorders. Ten of these items were purely subjective and needed a phenomenological approach to recognise. Nearly 57% of our drug-naïve early schizophrenia cohort had thought disorder. Over 39% of remitted patients had subjective thought disturbance. The prevalence estimates based on the rating scales (TALD vs SAPS-SANS) are being evaluated in a subset of patients with schizophrenia.

Conclusions: The contexts of evaluation and variations in the definitions of terms in rating scales should be considered while comparing scores across studies. Harmonisation of terminology for these symptoms is needed. Theoretical/conceptual backgrounds tended to influence the description of the terms/items in rating scales. Validating the items with objective computational measures may enhance the measurability of thought disorder.

24.2. USING SEMANTIC INFORMATION TO CLUSTER FORMAL THOUGHT DISORDER RATING SCALES

Alban Voppel^{*1}, Lena Palaniyappan²

¹*McGill University*, ²*Douglas Mental Health University Institute*

Background: Schizophrenia-spectrum disorders often involve the manifestation of Formal Thought Disorder (FTD), assessed using clinical rating scales. Scales are designed to capture clinical symptoms associated with the construct of FTD but differ among each other in their approach. Cross-scale analyses using yield variable results; this situation has led to conceptual grouping of symptoms, the most used one being positive (posFTD) and negative FTD (negFTD). Here, we propose a new method to assess on, and expand on this conceptual division. We employ Natural Language Processing (NLP) with semantic models to scrutinize descriptions from commonly used thought disorder rating scales, compare the semantic descriptions to the positive and negative division and to free community detection.

Methods: Using the positive and negative thought disorder symptom division, we assess textual descriptions of formal thought disorder items in multiple clinical rating scales for their semantic content through a transformer model. We compare each semantic item to the description given by Kircher et al. in defining posFTD and negFTD, and thus their semantic relation to the positive and negative division FTD descriptions in the literature. Finally, we perform a conceptually free approach where we use community detection algorithms to detect the most meaningful related groups of symptoms.

Results: Semantic embeddings and their distance to posFTD and negFTD descriptions aligned with 75%+ accuracy with the posFTD and negFTD scales. Antonyms were noted for when alignment was reversed (i.e. “an absence of...”), or referrals to other items within clinical rating scales.

We find four distinct semantically related clusters:

Group 1 features result in muddled communication with some incomprehensible elements. Meaning distortion, word substitution, and weak context association occur; confusion and word sequencing difficulties are associated with group 1.

Group 2 features involve abrupt topic shifts in response to stimuli, repeated words or subjects, speech interruptions, and memory lapses regarding previous speech.

Group 3 features include unfounded conclusions, irrelevant replies, a lack of thought continuity, off-topic wandering, disjointed ideas, and a dearth of meaningful connections, resulting in inconsistent narrative structure.

Group 4 features entail restricted speech, brief concrete answers, omission of additional information, overly concise replies, uninformative or indirect responses with vague, repetitive, or abstract language, hindering meaningful information extraction by interviewers.

Conclusions: From descriptions of clinical rating scales, we were able to replicate the posFTD and negFTD conceptual division, although antonyms in item descriptions muddled the results. Conceptually free community detection algorithms unveiled four distinct clusters of FTD symptoms within item-level descriptions from different scales through the usage of sentence transformers and network community methodologies. Our approach serves as a valuable tool for harmonizing diverse conceptual perspectives and clinical rating scales related to FTD.

24.3. EXPLORING SPEECH AND LANGUAGE DISTURBANCES AND THEIR BRAIN STRUCTURAL CORRELATES IN AFFECTIVE AND PSYCHOTIC DISORDERS

Frederike Stein^{*1}, Tilo Kircher¹

¹*University of Marburg,*

Background: Formal thought disorder (FTD) is highly prevalent in schizophrenia (SZ) and also occurs in in major depressive (MDD) and bipolar disorder (BD). However, the association between alterations in brain structure and FTD across affective and psychotic disorders remains unknown. In two studies, we investigate transdiagnostic symptom dimensions of FTD and their association with both local brain structural alterations and global macroscopic structural brain networks.

Methods: Using FTD symptoms from the SANS and SAPS, we performed exploratory and confirmatory factor analyses in over 1000 patients with MDD, BD, and SZ to identify psychopathological FTD dimensions. Both T1- and diffusion-weighted magnetic resonance imaging were used to investigate local gray matter volume (GMV) alterations, white matter fractional anisotropy (FA) alterations, and structural brain networks being associated with FTD. Interaction analyses were employed to investigate the influence of categorical diagnosis.

Results: Cross-validation factor analyses revealed three psychopathological FTD factors: disorganization, emptiness, and incoherence. Disorganization was negatively correlated with a GMV cluster comprising parts of the middle occipital and angular gyri and positively with FA in the right posterior cingulum bundle and inferior longitudinal fascicle. Emptiness was negatively associated with the left hippocampus and thalamus GMV. Incoherence was negatively associated with FA in bilateral anterior thalamic radiation, and positively with the hippocampal part of the right cingulum bundle. Network-based statistics identified macroscopic subnetworks being associated with the FTD dimensions disorganization and emptiness but not with the FTD dimension incoherence. Confirmatory analyses showed a substantial overlap of nodes from both subnetworks with cortical brain regions previously associated with FTD in SZ. None of the GMV, FA, and macroscopic network associations interacted with diagnosis.

Conclusions: Our results provide a refined mapping of cross-disorder FTD phenotype dimensions, highlighting their neuroanatomical signatures linked to language-related local and global brain structural measures, independent of diagnosis. Our findings open a promising avenue for transdiagnostic, psychopathology-informed, dimensional studies in pathogenetic research.

24.4. DISTINCT RELATIONSHIPS BETWEEN DIMENSIONS OF SPEECH AND LANGUAGE DISTURBANCE AND COMPUTATIONAL FEATURES

Sunny Tang*¹, Amir Nikzad¹, Yan Cong¹, Sunghye Cho², Katrin Hänsel¹, Sarah Berretta³, Leily Behbehani³, Aarush Mehta⁴, Majnu John¹, Sameer Pradhan², Mark Liberman⁵

¹*Zucker Hillside Hospital*, ²*Linguistic Data Consortium*, ³*Northwell Health*, ⁴*Feinstein Institutes for Medical Research*, ⁵*University of Pennsylvania*

Background: Quantitative features derived from speech are increasingly recognized as valuable predictors and objective biomarkers for psychiatric disorders, notably including schizophrenia spectrum disorders (SSD). Significant advancements have been made in SSD to identify clinically relevant speech features, include a wide range of acoustic (e.g., pitch, amplitude), timing (e.g., pauses, speaking rate), lexical (e.g., sentiment, concreteness), syntactic (e.g., parts-of-speech, discourse connectives), and discourse-level measures (e.g., graph analysis, semantic similarity). Presumably, speech features predict clinical characteristics by reflecting speech-related symptoms, but the nature of the relationships are not clear. Here, we identify latent factors for speech and language disturbances which show consistency across language and diagnoses, and describe their distinct relationships to computational speech and language features.

Methods: Clinical ratings for speech and language disturbance were generated across 14 items from the Scale for the assessment of Thought Language and Communication (TLC) and the Scale for the Assessment of Negative symptoms (SANS). We evaluated a cross-diagnostic sample (N=343), including SSD (n=90), individuals with other or unverified psychotic disorders (n=47), those with non-psychotic psychiatric disorders (n=130), and healthy comparison participants (HC, n=76). Participants spoke English proficiently and were ascertained in a diverse area of New York (U.S.A.). Speech features were quantified using an automated pipeline for brief recorded samples of narrative free speech. Factor models for the clinical ratings were generated using exploratory factor analysis, then tested with confirmatory factor analysis in the cross-diagnostic and SSD groups. Correlations and network relationships among factor scores and computational speech features were examined across acoustic, timing, lexical, syntactic, and discourse-level measures.

Results: We found a 3-factor model with good fit in the cross-diagnostic group and acceptable fit for the SSD subsample. The model identifies an impaired expressivity factor and two interrelated disorganized factors for inefficient and incoherent speech. These findings are largely consistent with those of an independent study conducted in German, using the SANS and Scale for the Assessment of Positive Symptoms. We found that incoherent speech was relatively specific to psychosis groups (SSD and other psychotic disorders), while inefficient speech and impaired expressivity showed intermediate effects in people with nonpsychotic disorders compared to HC. Each of the three factors had significant and distinct relationships with speech features. In the SSD group, insufficient speech was most closely related to higher speaking rate ($r=0.63$) and mean age of acquisition ($r=0.54$); incoherent speech was most closely related to decreased positive valence ($r=-0.50$) and greater use of particles ($r=0.41$) and mean speaking rate ($r=0.41$); and impaired expressivity was most closely related to decreased mean pitch ($r=-0.41$) and higher mean turn latency ($r=0.41$).

Conclusions: We identified a 3-factor model that describes speech and language disturbance with good statistical properties in SSD and cross-diagnostically, concordance with an independent study, clinical relevance, and distinct relationships with computational speech and language features. A larger, collaborative effort is underway to replicate and generalize these findings in 700 participants from this site, and several thousand participants internationally.

Plenary Session IV - Oliver Howes: Could the Synaptic Hypothesis Explain All of Schizophrenia?

2:30 p.m. - 3:30 p.m.

25. COULD THE SYNAPTIC HYPOTHESIS EXPLAIN ALL OF SCHIZOPHRENIA?

Peter Falkai, *Psychiatric University Hospital Munich*

25.1. COULD THE SYNAPTIC HYPOTHESIS EXPLAIN ALL OF SCHIZOPHRENIA?

Oliver Howes, *MRC LMS and KCL*

Individual Abstract: The synaptic hypothesis of schizophrenia is one of the leading hypotheses of the pathoetiology of schizophrenia. However, advances in genetics, cellular biology and neuroimaging in the last few years have led to a step change in understanding of the nature and role of synaptic alterations in schizophrenia, their links to symptoms and the mechanisms underlying them. A key advance has been the development of novel neuroimaging techniques that enable synaptic terminal proteins to be measured in vivo in patients. This talk will consider these new lines of evidence and present the latest in vivo neuroimaging data on synaptic terminal markers in people with schizophrenia, and their links to symptoms and glutamatergic function, as well as the effects of antipsychotic treatment. Finally, it will consider the potential of the synaptic hypothesis to explain the cognitive, negative and psychotic symptoms of the disorder, and the implications for pharmacological and psychosocial treatments.

Plenary V - Padmavati Ramchandran: Research to Practice - Understanding the Schizophrenia Conundrum

8:30 a.m. - 9:30 a.m.

26. RESEARCH TO PRACTICE: UNDERSTANDING THE SCHIZOPHRENIA CONUNDRUM

Paola Dazzan, *Institute of Psychiatry, Psychology and Neuroscience, King's College London*

26.1. RESEARCH TO PRACTICE - UNDERSTANDING THE SCHIZOPHRENIA CONUNDRUM

Padmavati Ramchandran, *Schizophrenia Research Foundation, India*

Individual Abstract: The Schizophrenia conundrum remains a management challenge despite the advances in research, globally. However, contemporary expectations of course and outcome of this inherently chronic and deteriorating condition are optimistic given the evidence-based developments in culturally informed intervention across the globe.

The Schizophrenia Research Foundation (SCARF, India) India is a non-governmental, not-for-profit organization that has committed to mental health care and research over the past 4 decades. Forging national and international collaborations, SCARF has consciously focussed

on the translation of research findings to practice. In this process we have tried to make sense of the condition, especially to understand the interplay between culture and psychosis.

Our research over 40 years has encompassed epidemiology, untreated illness, course and outcome, untreated psychoses, and understanding the patient/family perspectives of psychoses. An example of the Madras Longitudinal study, carried out over 35 years when compared with other longitudinal studies has emphasized the multifaceted role of culture. A series of studies have examined schizophrenia under the lens of gender, marriage, employment, and stigma. Genetic research of studies has helped understand some facets of the condition. Over one and half decades of research with a population of persons with a first episode of psychoses has informed the development of protocols for interventions at the clinics. Research on metabolic comorbidity has contributed to the understanding of lifestyles of the persons with schizophrenia and the effects of antipsychotic medications. The lessons learned informed an appropriate re-orientation of psychosocial interventions whether in the facility-based setting or the community. The use of technology in testing a low-cost app-based intervention using the DIALOG + and online compensatory cognitive interventions is currently under investigation. More recent investigations have included persons with lived experience, the research establishing the acceptability and feasibility of peer support volunteer programs. On a broader scale, recognising the need for appropriate sharing of information, SCARF's public awareness programs have systematically included the findings of research, through the past 4 decades.

This talk will discuss challenges in providing equitable mental health care across diverse cultural contexts will be critically examined, emphasizing the importance of dismantling cultural barriers to accessing appropriate and effective treatments. The presentation advocates for a global mental health perspective that recognizes and respects the diversity of cultural narratives surrounding mental illness.

Concurrent Symposia

10:00 a.m. - 12:00 p.m.

27. NOVEL PSYCHOLOGICAL TREATMENTS FOR PSYCHOSIS – CURRENT EVIDENCE, LIMITATIONS, AND FUTURE IMPLICATIONS

Kerem Böge, *Charite CBF*

Overall Symposia Abstract: Psychosis is considered one of the most impairing mental health disorders worldwide, with significant major long-term consequences on individuals' psychological and physical health, relationships, and employment. National and international clinical guidelines recommend cognitive behavioral therapy, next to psychopharmacology, as a treatment of choice for psychosis. However, the effect sizes of these interventions are still limited to the medium range. Moreover, they do not reach all patients because they either do not have access to care with psychotherapy in the face-to-face setting or because the available treatments are not sufficiently adapted to the cultural and ethnic background of those affected. Together, this underscores the dire need for novel interventions with improved efficacy that are accessible to a broader range of consumers and that can be adapted to the individual and cultural needs of the patients. Therefore, this symposium aims to showcase new research and treatment developments to improve the psychological treatment of patients with psychotic disorders. Alexandra Moussa-Tooks (Indiana University Bloomington) will discuss and address current developments and outcomes from the cultural adaptation of CBT, particularly for Black Americans. She will give novel insight into the role of systematic racism in the

therapy process and treatment gaps for minority populations throughout series of cases. Louise Birkedal Glenthøj (University of Copenhagen) will present new outcomes from a randomized controlled trial (N=239) on Virtual-Reality-augmented CBT (VR-CBT) compared to CBT for the treatment of paranoia. Tania Lincoln (University of Hamburg) will discuss the findings of the RELATE trial (N=85) testing a new behavioral intervention aiming to reduce voice-related distress compared to the current mental health care system in Germany (treatment-as-usual) in a multicenter randomized controlled trial. Geraldine Pijnenborg (University of Groningen) will expand the focus to new technologies such as VR-assisted psychotherapy and present findings of a randomized controlled trial (N=81) examining therapeutic potentials on social functioning but also discuss limitations and future implications. Accordingly, she will present novel developments in the field of VR for psychosis, focusing on the quality of social contacts, leisure activities, and overall participation in society. Together, the speakers in this symposium will provide insight into novel developments in the psychological treatment of people with psychotic disorders. We will discuss implications as well as directions for future research building up on these findings.

27.1. BEING ASSERTIVE TO DISTRESSING VOICES? FEASIBILITY AND PRELIMINARY EFFICACY OF ADDING RELATING THERAPY TO STANDARD CARE. FINDINGS FROM THE RELATE TRIAL

Tania Lincoln^{*1}, Björn Schlier¹, Mark Hayward², Rebecca Müller¹, Thomas Lang³, Gonther Uwe⁴, Cornelia Exner⁵, Kerem Böge⁶, Jürgen Gallinat⁷, Candalaria Mahlke⁷, Antonia Zapf⁷, Annika Buchholz⁷, Katharina Stahlmann⁷, Matthias Pillny¹

¹University of Hamburg, Institute of Psychology, ²School of Psychology, University of Sussex, ³Jacob University Bremen, ⁴AMEOS Klinik, Bremen, ⁵Universität Leipzig, ⁶Charité – Universitätsmedizin Berlin, Campus Benjamin Franklin, ⁷University Medical Center Hamburg-Eppendorf,

Background: Auditory verbal hallucinations (AVH) such as hearing voices are a common and distressing experience in psychotic disorders. Accordingly, patients report the reduction of voice related distress amongst their most important treatment goals for AVH. However, available treatment options show only limited efficacy on AVH related distress. Relating Therapy (RT) is a novel translational approach that tackles the distress related psychological mechanisms by exploring the experience of hearing voices within interpersonal frameworks and by rebalancing the hearer-voice relationship through the development of assertive responding.

Methods: We conducted a multi-centered and randomised-controlled pilot feasibility trial that aimed to evaluate the feasibility of trial procedures and to examine effect-size estimates of a 16-session RT module compared with Treatment-as-usual (TAU) in different German mental healthcare settings. Single-blind assessments were done at baseline, post-treatment at five months (T1) and at nine months follow-up (T2). Primary outcome was the distress factor score of the AVH subscale of the Psychotic Symptoms Rating Scale at T2 adjusted for the baseline value. Secondary outcomes included change in depressive symptoms, quality of life, daily-life activity engagement as well as relating to voices and to other people.

Results: From October 2020 to April 2022, 85 patients with persistent distressing AVH were included in the trial. Of these, 43 received either 16 sessions of RT plus TAU and 42 received TAU only. 82% of the participants completed the primary outcome assessment at 5 and 86% at 9 months. Of those participants assigned to RT, 88% received the pre-specified minimum

treatment dose of at least 8 sessions. The rating of therapist adherence with the RT protocol reached the predefined quality criterion in 98% of the rated therapy audio tapes. The number of reported adverse events did not differ between the conditions. Auditory-related distress decreased after 9 months in both conditions, with a non-significant trend towards greater improvement in the RT plus TAU condition (PSYRATS AVH distress $b=-2.40$ (1.52), $p = 0.121$, (-4.94 to 0.15). The effect size of this difference remained stable with significant confidence intervals in two of four sensitivity analyses. Descriptive changes on all but one of the secondary outcomes were in the expected direction.

Conclusions: We conclude that adding a RT module to standard care is feasible and well accepted by patients and has the potential to lead to reduced hallucination related distress. Further research should examine the benefit of RT compared to TAU in a full-scale trial using a mixed method approach by adding a qualitative assessment of the consumer's experiences with RT. This would add substantially to our understanding of the positive and adverse effects associated with RT.

27.2. VIRTUAL REALITY-BASED CBT VS. CBT FOR PARANOIA: PRELIMINARY FINDINGS FROM THE FACEYOURFEARS RANDOMIZED CLINICAL TRIAL

Ulrik Nykjær Jeppesen¹, Ditte Lammers Vernal², Anne Sofie Due³, Mariegaard Lise⁴, Amy Pinkham⁵, Mads Juul Christensen², Wim Velting⁶, Merete Nordentoft⁷, Louise Birkedal Glenthøj^{*8}

¹Copenhagen Research Center for Mental Health (CORE), , ²Aalborg University Hospital, Psychiatry, Research Unit for Child and Adolescent Psychiatry, ³Mental Health Centre Copenhagen, University of Copenhagen, ⁴Copenhagen Research Center for Mental Health - CORE, VIRTU Research Group, ⁵The University of Texas at Dallas, ⁶University Medical Center Groningen, ⁷Mental Health Centre Copenhagen, ⁸Mental Health Centre Copenhagen University of Copenhagen

Background: Paranoia is a frequently occurring symptom in schizophrenia spectrum disorders (SSD). While cognitive behavioral therapy (CBT) has proven small to moderate effect in alleviating this symptom, there is a need to advance therapy approaches stressing the behavioral component of CBT. Virtual reality (VR)-based therapy offers the potential of exposing the individual to paranoid inducing situations in a safe and controlled manner and may hold great potential in increasing CBT benefits.

Methods: The FaceYourFears trial is a randomized, single-blind, clinical trial allocating 256 patients with SSD to either 10 sessions of CBT or 10 sessions of virtual reality-based CBT (VR-CBT) for paranoia. Assessments are carried out at baseline, at treatment cessation, and at 9-months post-baseline. Primary outcome is ideas of persecution and secondary outcomes: ideas of reference, social anxiety, safety behavior, emotion recognition, and daily life-functioning. Additionally, health economic analyses will elucidate cost-effectiveness of the interventions.

Results: A total of 239 participants have been included in the study. Participant enrollments will be completed in November 2023, and 9-months follow-up data are expected in August 2024. Data on baseline characteristics of the study sample along with data on feasibility and acceptability (drop-out rate, adverse events etc.) of both interventions will be presented at the conference. Additionally, this presentation will elucidate patients' experiences with the interventions at a case level.

Conclusions: The FaceYourFears trial will elucidate whether VR-CBT can enhance therapy efficacy for paranoid ideations in a cost-effective manner. This may guide the possible

dissemination and implementation into clinical practice. Within this scope, it is essential to outline the acceptability and safety of the intervention. In a long term perspective, VR-based CBT may be the preferred non-pharmacological treatment option for paranoia.

27.3. CONCEPTUALIZING AND INTEGRATING CULTURE INTO CONTEMPORARY COGNITIVE-BEHAVIORAL THERAPIES FOR PSYCHOSIS

Alexandra Moussa-Tooks*¹, Julia Sheffield², Daniel Freeman³, Aaron Brinen²

¹*Indiana University Bloomington*, ²*Vanderbilt University Medical Center*, ³*University of Oxford*

Background: Racial threat (RT) is increasingly recognized as a critical factor in the diagnosis, assessment, and treatment of psychosis. Threat-based worry and hypervigilance in Black Americans and other minoritized individuals is higher due to systemic racism, which has a long-standing history in the United States. RT has been associated with increased risk for psychopathology like clinically significant paranoia. Although there has been a rise in the accessibility of CBT for psychosis (CBTp), there have been no adaptations of cognitive-behavioral therapies for Black Americans with psychosis. These interventions are needed to address the unique challenges associated with experiences of RT, to increase engagement from clients and enhance the impact of the intervention.

Methods: We present the first step towards developing an adapted cognitive-behavioral intervention for Black and minoritized Americans with psychosis. The case is of a Black American man diagnosed with schizoaffective disorder. He enrolled in a clinical trial of a worry intervention for persecutory delusions. This adaptation of an empirically supported worry-based treatment for persecutory delusions was accomplished by comprehensive conceptualization and integration of how systemic racism and minoritization drive the prevalence and perception of threats. This contrasts with conceptualizing racism-related hypervigilance and cognitions as worry or ignoring these critical experiences altogether, which is invalidating and neglects optimal identification and intervention on behavioral targets. He was assessed for change in persecutory beliefs, worry, and activity engagement at various timepoints including baseline, mid-way through the intervention (4 weeks), end of the intervention (8 weeks), and a 24-week follow-up.

Results: At the onset of establishing the therapy rationale, we intentionally acquired information about the role of RT in daily life on worry. Using a validating and normalizing approach, the individual was able to identify how frequent threats related to systemic racism resulted in increased worry, vigilance, and distress. We were careful to conceptualize these experiences as threats, not worry behaviors or thoughts. Over the course of the intervention, we saw a clinically meaningful improvement in worry that persisted to follow-up (Reliable Change Index = 2.29-8.64). He also exhibited improvement in delusional content per self- and clinician-report with distress, conviction, and preoccupation all trending downward (RCI = 3.95-7.77). He reported improved self-efficacy and treatment satisfaction during the therapy.

Conclusions: By identifying and intervening on the perception of threat and associated worry, the individual engaged in more helpful responses to the threat, which in turn increased participation in more meaningful activities and reduced worry and clinical paranoia. This case illustrates how accurate conceptualization clarifies behavioral targets and increases patient engagement, which together enhance the effectiveness of the intervention for minoritized individuals. This case also provides a path towards improving the conceptualization of culture in treatment models and increasing adaptations across groups and interventions.

27.4. VR TREATMENT FOR IMPAIRED SOCIAL FUNCTIONING IN PSYCHOTIC DISORDERS

Marieke (Gerdina) Pijnenborg*¹, Saskia Nijman², Ivo Meins¹, Dauw Muijsson³, Elisabeth van der Stouwe³, Wim Veling³

¹University of Groningen, ²GGZ Drenthe, ³University Medical Center Groningen

Background: Social functioning is often impaired in psychotic disorders while effective treatment options are few. Virtual Reality (VR) may be an ecological valid tool for practicing social interactions. Currently, several new treatments are being evaluated.

Methods: In this presentation two VR interventions targeting social functioning in psychotic disorders. First, results of an RCT on DISCOVR (social cognition training in VR, n=81) will be discussed. Second, we will present the outline of VR SOAP. This brandnew VR intervention offers various modules that contribute to improving the amount and quality of social contacts, leisure activities and participation in society.

Results: DISCOVR was compared to an active control condition, and appeared not more effective in improving social cognition or social functioning than the control condition, probably because the intervention was not realistic enough to improve emotion perception and mindreading in real life. However, learning did occur, as participants did demonstrate within session improvement on emotion recognition in VR. Pilot data (n=5) show that VR SOAP was acceptable and beneficial by therapists and participants.

Conclusions: Although VR has the potential to contribute to the treatment of people with psychotic disorders, it is critical to evaluate what can and cannot be trained in VR.

28. ETHICAL CONSIDERATIONS ON THE USE OF AI IN MENTAL HEALTH

Sophia Frangou, *Icahn School of Medicine at Mount Sinai*

Overall Symposia Abstract: This proposal has been put together by the Ethics Committee of SIRS to stimulate ethical scrutiny of the increasing use of algorithmic and data-driven technologies, commonly grouped under the term artificial intelligence (AI), in mental health research and clinical care. Properly designed AI solutions securely utilized can improve mental health research and service delivery, improve patient engagement and well-being, and allow more flexible allocation of resources. Conversely, the potential risks are undeniable such as breaches of therapeutic records, and algorithms that may discriminate or disadvantage specific patient populations to mention two examples. Concerns also arise, not necessarily from the misuse or malfunctioning of technologies, but from their intended operations that may have intrinsic harmful potential such as technologies that implement extensive observation, recording, digitization, and prediction of human behaviour. The four speakers of the proposed symposium are thought leaders in the field of AI ethics and bring a range of perspectives given their diverse and multi-disciplinary backgrounds. Each presentation will focus on different aspects of ethical challenges impacting policies, new forms of embodied AI treatment options, and research integrity and will also discuss how and who could potentially act to regulate AI use in mental health.

28.1. THE ETHICS OF MACHINE LEARNING APPLICATIONS AND BIG DATA IN MENTAL HEALTHCARE

Giovanni Rubeis*¹

Background: Machine learning techniques commonly referred to as AI in combination with big data approaches offer a wide spectrum of possibilities for mental healthcare. These technologies enable the integration and modelling of multimodal data from different sources, e.g. combining patient data from electronic health records and diagnoses with behavioral and environmental data form

self-reports and monitoring via sensors (either wearable or stationary). By using data mining technologies, analyzing this data may enable a better risk assessment, stratification and predication, tailoring of treatment to the individual needs of each patient, preventing the onset of episodes or symptoms, and empowering the patient's self-management. Focusing on the complex connections between individual symptoms and behavior with specific situations and environment of patients may furthermore help to understand the specific needs of groups and individuals with a complex help-seeking behavior that are otherwise under-served. Hence, the use of AI and big data may support decision-making and the personalization of treatment.

Methods: Narrative synthesis of the existing research literature in the ethics of AI and big data in mental healthcare.

Results: The intensive use of highly sensitive data from various sources as well as the operational logic of machine learning algorithms pose several ethical risks. I will discuss three types of risks, namely security risks like data safety and privacy protection, epistemological risks such as digital positivism and reductionism, and risk for the therapeutic alliance, namely overstraining autonomy and reduced personal contact.

Conclusions: Realizing the potential of AI and big data for accuracy, efficacy, and personalization requires combining the skills of care givers for building a meaningful, patient-centered therapeutic alliance that centers around the uniqueness of the patient.

28.2. THE USE OF GENERATIVE LARGE LANGUAGE MODELS LIKE CHATGPT AND BARD FOR CITATION SEARCH AND LITERATURE REVIEW: THE PROBLEM OF ACCURACY

Alessia McGowan¹, Yunlai Gui¹, Matthew Dobbs¹, Sophia Shuster¹, Alexandria Selloni¹, Matthew Cotter¹, Marianne Goodman¹, Agrima Srivastava¹, Guillermo A. Cecchi², Cheryl Corcoran*¹

¹Icahn School of Medicine At Mount Sinai, ²IBM, Thomas J. Watson Research Center

Background: Large language models such as OpenAI's ChatGPT (Generative Pre-Trained Transformer) and Google's Bard are neural networks that have learned information and patterns of language use from the internet. These language models are generative in that they can respond to queries in a conversational manner. They have been identified as having several uses, including the provision of companionship and assistance in the writing of music, code, and text, including essays, protocols and even jokes. However, there are concerns that such models may replace jobs and even lead to catastrophic consequences (through scams and misinformation). Also, several ethical concerns have been identified, including with respect to security, privacy, copyright (plagiarism), bias and accuracy. Here we describe our experience in using ChatGPT and Bard to identify references relevant to a literature review for a manuscript on the linguistic correlations of suicidal behavior in spontaneous spoken language in individuals at clinical high risk for psychosis, highlighting the problem of accuracy.

Methods: In March 2023, we queried ChatGPT 3.5 for citations relevant to a literature review in preparation of a manuscript on linguistic correlations of suicidal behavior in individuals at clinical high risk (CHR) for psychosis. Our initial query was "What has been published regarding suicidal behavior in individuals at high risk for psychosis?", followed by requests to list specific papers that used NLP (natural language processing). Citations provided by ChatGPT were compiled and verified for accuracy. In June 2023, we again similarly queried ChatGPT, and as it no longer provided references or citations, we then queried Google's Bard 2.0, using the same prompt as was used in March 2023, also verifying produced citations for accuracy. Error patterns were characterized for output from ChatGPT in March 2023 and from Bard in June 2023.

Results: In March 2023 ChatGPT provided 35 citations after a series of prompts/queries. Of these, only 2 (6%) were accurate. Of the 33 inaccurate citations, 12 had titles that were "near-matches" for existing real articles, whereas 21 could not be readily linked to any real manuscripts. For the 12 "near-matches", 9 listed incorrect first authors, 10 listed incorrect years of publication, and 4 listed incorrect journal names. A common error pattern was that for titles, original terms (e.g. "bipolar disorder") were replaced with terms from our queries ("clinical high risk for psychosis"; "suicidal ideation"). In June 2023, ChatGPT no longer provided citations, writing "Unfortunately, as an AI language model, I don't have direct access to databases or the ability to perform real-time searches". However, in June 2023, Bard 2.0, in response to the same query "What has been published regarding suicidal behavior in individuals at high risk for psychosis?", responded "Talk to someone now", providing a number for a suicide crisis hotline. It then generated 8 references, none of which were accurate. Of these, 5 were "near-matches" for real articles (1 with an erroneous title; 4 with incorrect authors) and 3 could not be matched to any real articles. Overall, the accuracy for provided citations was low for ChatGPT in March 2023 (2/35 or 6%) and for Bard in June 2023 (0/8 or 0%), and error patterns were similar.

Conclusions: While it is now more widely known that programs like ChatGPT and Bard can be highly inaccurate, nonetheless the assured tone of language they produce can be misleading. For example, in response to our query for a list of relevant papers, ChatGPT provided citations, adding "While this list is not necessarily exhaustive, it is a comprehensive sample of existing research in this field". Similarly, Bard generated 8 citations (none of which were accurate), adding "I hope this is comprehensive and exhaustive!" Our research team assiduously spent hours looking for citations and manuscripts they assumed to be real, until they had an "aha" moment when they realized ChatGPT was fabricating citations - pastiches of real titles and authors and journals. But not all users will be so diligent. For example, two lawyers used ChatGPT to find cases and citations for a legal brief which was then submitted unchecked, resulting in fines and public castigation by a judge (<https://www.nytimes.com/2023/06/22/nyregion/lawyers-chatgpt-schwartz-loduca.html>). Overall, our experience suggests caution in using these models in research, where accuracy is paramount.

28.3. CONSIDERATIONS FOR EMBODIED AI AND MENTAL HEALTH CARE

Amelia Fiske^{*1}, Peter Henningsen¹, Alena Buyx¹

¹*Technical University of Munich*

Background: Research in embodied artificial intelligence (AI) has increasing clinical relevance for therapeutic applications in mental health services. With innovations ranging from 'virtual psychotherapists' to social robots in dementia care and autism disorder, to robots for sexual disorders, artificially intelligent virtual and robotic agents are increasingly taking on

high-level therapeutic interventions that used to be offered exclusively by highly trained, skilled health professionals. In order to enable responsible clinical implementation, ethical and social implications of the increasing use of embodied AI in mental health need to be identified and addressed.

Methods: Based on a thematic literature search and established principles of medical ethics, an analysis of the ethical and social aspects of currently embodied AI applications was conducted across the fields of Psychiatry, Psychology, and Psychotherapy. To enable a comprehensive evaluation, the analysis was structured around the following three steps: assessment of potential benefits; analysis of overarching ethical issues and concerns; discussion of specific ethical and social issues of the interventions.

Results: From an ethical perspective, important benefits of embodied AI applications in mental health include new modes of treatment, opportunities to engage hard-to-reach populations, better patient response, and freeing up time for physicians. Overarching ethical issues and concerns include: harm prevention and various questions of data ethics; a lack of guidance on development of AI applications, their clinical integration and training of health professionals; ‘gaps’ in ethical and regulatory frameworks; the potential for misuse including using the technologies to replace established services, thereby potentially exacerbating existing health inequalities. Specific challenges identified and discussed in the application of embodied AI include: matters of risk-assessment, referrals, and supervision; the need to respect and protect patient autonomy; the role of non-human therapy; transparency in the use of algorithms; and specific concerns regarding long-term effects of these applications on understandings of illness and the human condition.

Conclusions: Embodied AI is a promising approach across the field of mental health; however, further research is needed to address the broader ethical and societal concerns of these technologies to negotiate best research and medical practices in innovative mental health care. I conclude by indicating areas of future research and developing recommendations for high-priority areas in need of concrete ethical guidance.

28.4. ETHICAL CONSIDERATION OF NORMATIVE MODELING OF BRAIN IMAGING DATA

Sophia Frangou*¹

¹*Icahn School of Medicine at Mount Sinai*

Background: Neuroimaging offers a unique window into the living brain but its translational application of neuroimaging to mental health has been minimal, largely due to the lack of normative reference frameworks for neuroimaging measures. This contrasts with other medical fields where diagnosis and prognosis are aided by criteria on how biological measures deviate from established normative ranges (e.g., height, weight, blood glucose). However, determination of "normality" in terms of brain structure is philosophically and ethically complex because it is intrinsically linked with societal concepts of the ideal human.

Methods: We developed CentileBrain, a normative model of brain morphometry and brain-age-gap-estimates (brainAGE) that belongs to the category of standard life charts; it is derived from a large, international, and diverse pool of healthy individuals and thus represents the healthy pattern of age-related brain changes. CentileBrain currently contains lifespan charts of measures of regional cortical thickness, surface area, and subcortical volumes and brainAGE derived from neuroimaging data of 37,407 healthy individuals (53.33% female; aged 3 to 90 years) collated from 86 international MRI datasets

Results: CentileBrain was generalizable to different ethnoracial groups but the predictive value of brain morphometry and brainAGE for behavioural and cognitive outcomes in healthy individuals was limited. Normal variation in these measures was very wide.

Conclusions: These findings argue for a "soft normativism" in terms of neuroanatomical features. Soft normativism comes with a moderate degree of relativism, and argues that normative models have a role to play as they enrich our understanding of processing models but should not be used to inform idealistic notions of human beings.

29. PREVENTING PSYCHOSIS IN LOW RESOURCE SETTINGS: UNIQUE PERSPECTIVES FROM ULTRA-HIGH RISK FOR PSYCHOSIS RESEARCH IN LOW- AND MIDDLE-INCOME COUNTRIES

Alexandre Loch, *University of Sao Paulo*

Overall Symposia Abstract: Given the social and economic burden associated with psychotic illnesses, research efforts have increasingly focused on early stages of the disorder. In this sense, the ultra-high risk for psychosis (UHR) criteria were created to identify subjects before they developed their first psychotic episode. Despite the many advances made in the field, most data come from high-income countries.

A recent systematic review (Loch et al., 2023) showed this discrepancy, with only 112 articles on UHR coming from low- and middle-income countries (LAMIC), as compared with more than 500 for manuscripts on UHR in more developed countries. This review identified obstacles in the conduction. of prospective UHR research in LAMIC, including mainly lack of funding, and cultural issues and stigma. However, data collected in such scenarios, in face of these adversities, is of utmost importance as they can bring up unique perspectives such as inovative screening methods and new insights into the psychosis continuum.

In this symposium, we will address examples of country-specific experiences in UHR research, including in Brazil, Turkey and Tunisia, that may be common to other LAMIC countries, or in some cases different. We describe challenges and obstacles, as well as success in overcoming these, to provide important data on UHR from LAMIC that will complement that from more developed countries. We hope this will generate a lively discussion in the audience as to experiences in other LAMIC countries as well.

First, in Brazil, we will show how technology can help in the identification of UHR individuals at the population level. Alexandre Loch will present data that shows that automated facial expression analysis can be used to identify UHR individuals, as compared to healthy individuals, and to predict transition from the UHR state to psychosis and psychiatric illnesses in general. Research was conducted with non-help seeking, medication-naïve individuals from an epidemiological general population sample from Sao Paulo, Brazil.

Second, Ruben Valle will present a systematic review of multicomponent interventions available for LAMIC. He will show how antipsychotic medication, psychoeducation, family support and cognitive behavioral therapy are used in LAMIC.

Third, Gresshma Mohan, from India, will explain the components about first episode psychosis services from the Indian SCARF project. She will discuss which aspects of this innovative project can be used in other high-income and LAMIC countries.

Finally, Feten Fekih-Romdhane will present results from a Tunisian initiative to prevent psychosis, showing the challenges and facilitative factors in implementing a psychosis prevention service in a low-resource setting.

With this symposium, we wish to bring new data on this under researched area. We also wish to discuss new ideas to conduct research in this scenarios, and how data from these different settings might shed light into psychosis prevention initiatives across the world.

29.1. USING MACHINE LEARNING ENSEMBLES AND FACIAL FEATURES TO DETECT INDIVIDUALS AT ULTRA-HIGH RISK FOR PSYCHOSIS AND PREDICT THEIR OUTCOME

Alexandre Loch^{*1}, João Medrado Gondim², Ana Caroline Lopes-Rocha³, Felipe Argolo⁴, Anderson Ara⁵

¹*University of Sao Paulo*, ²*Federal University of Bahia*, ³*Institute of Psychiatry, Laboratory of Neuroscience (LIM 27), University of Sao Paulo*, ⁴*Universidade de São Paulo (USP)*,

⁵*Federal University of Paraná*

Background: Detection of individuals at risk for psychosis and outcome prediction poses a great challenge for several reasons. First, very long interviews by trained mental health professionals are resource consuming. This is particularly critical in low resource settings such as low and

middle-income countries, where there is an insufficient regular mental healthcare delivery. Second, there is a help-seeking barrier, given that these are psychotic phenomena which are intrinsically related to lack of judgement and insight. Third, transition to psychiatric illnesses among those at risk is erratic, with heterogeneous transition rates observed across studies. Taking all that into account, our study aimed to develop two machine learning ensembles. The first was intended to distinguish subjects at "ultra-high risk for psychosis" (UHR) from control subjects from the general population based on facial data extracted from short video-recordings. The second was developed to predict transition from the UHR state to psychosis and/or general psychiatric illnesses using the same approach.

Methods: 58 non-help-seeking medication-naïve UHR and 70 healthy subjects were screened from a representative general population sample. At-risk status was assessed with the Structured Interview for Prodromal Syndromes (SIPS). Presence of psychiatric disorder was evaluated with the Structured Interview for DSM-5 diagnosis (SCID-5). Two videos of the participant's interview were recorded at baseline. The first consisted in the "Subject's Overview" section of the SIPS (3-5 min), in which participants were asked to talk about their relationship with their parents during their childhood. The second video was recorded during a memory recall free speech task, in which

individuals were asked to talk about a recent dream, an old dream, and to tell stories based on three positive affective pictures. Several features were extracted, e.g., eye and mouth aspect ratio, Euler angles, coordinates from 51 facial landmarks. This elicited 649 facial features, which were further selected using Gradient Boosting Machines (AdaBoost combined with Random Forests). The selected features entered a first machine learning model to discern UHR from control subjects. Data was split in 70/30 for training, and Monte Carlo cross validation

was used. UHR subjects were then followed-up for two years and assessed for transition to psychosis or any psychiatric disorder. After this period, 51 UHR subjects could be reassessed, of whom 9 converted to psychosis, and 21 to other psychiatric diagnosis. The same procedures were made for a second machine learning model, to predict transition from the UHR state to psychiatric disorders.

Results: The first model, to detect UHR, reached 83% of mean F1-score, and balanced accuracy of 85%. Mean area under the curve for the receiver operator curve classifier was 93%. Convergent validity testing showed that two features included in the model were significantly correlated with Avolition (SIPS N2 item) and expression of emotion (SIPS N3 item). The second model, to predict conversion among UHR subjects, reached 82% of mean F1-score, and balanced accuracy of 85%. Sensitivity of the classifier was of 79%, and specificity was of 84%. Convergent validity testing showed that features included in the model were significantly correlated with Avolition (SIPS N2 item) and ideational richness (SIPS N5 item).

Conclusions: Our model capitalized on short video-recordings from individuals recruited from the general population, effectively distinguishing between UHR and controls, and predicting their

transition to psychiatric diagnoses, including psychosis. Results are encouraging for large-screening purposes in low-resource settings.

29.2. MULTICOMPONENT INTERVENTIONS IN EARLY PSYCHOSIS AVAILABLE IN LOW- AND MIDDLE-INCOME COUNTRIES: A SYSTEMATIC REVIEW

Ruben Valle^{*1}, Nora Morrison¹, Srividya Iyer¹

¹*McGill University*

Background: Early intervention in psychosis (EIP) is a multicomponent intervention aimed at identifying and treating psychotic symptoms in their early phases. EIP services have been well-established in high-income countries. However, EIP services in low-and middle-income countries are still in their infancy. Most EIP services in those countries were adapted from high-income countries to fit with the available local resources. Although we are aware of the existence of EIP services in low-and middle-income countries, the components offered and their efficacy when used within such services is unknown. The present systematic review seeks to determine the multicomponent interventions offered to individuals at clinical-high risk and with first-episode psychosis in low-and middle-income countries; and determine the efficacy of these interventions when used in these settings.

Methods: We conducted a systematic review in PsycInfo, Embase, and Medline from inception until February 2023. We included search terms such as: prodromal phase of psychosis, first-episode psychosis, early intervention in psychosis services and low-and middle-income countries. Records of studies which were: conducted in low-and-middle income countries, provided multicomponent interventions to people at clinical high risk or with first episode psychosis, reported on at least one EIP component in addition to assessment of individuals with first episode psychosis and antipsychotic medication, reported at least one EIP component beyond clinical assessment of individuals at clinical high risk, and reported on the long-term provision of such multicomponent interventions, were included in the review. Data on the number and name of components provided and the efficacy of such components was synthesized.

Results: We identified 110 records across 15 low-and middle-income countries. Most EIP services were located in tertiary health facilities located in urban areas, with only a single site per country. Multicomponent interventions for individuals with first-episode psychosis comprised a mean of 4.6 components provided over 23 months, most commonly including clinical assessment, antipsychotic medication, patient psychoeducation, family education and support and cognitive-behavioral therapy. Multicomponent interventions for individuals at clinical-high risk included a mean of 4.4 components provided over 19 months, namely clinical assessment, evaluation by a specialist, monitoring by a specialist, and interventions for health problems. Multicomponent interventions were found to be beneficial in many clinical and functional outcomes for people with first-episode psychosis from low-and middle-income countries. Three randomized clinical trials showed multicomponent intervention is more effective than standard treatment in first-episode psychosis.

Conclusions: Multicomponent interventions for early psychosis in low- and middle-income countries closely mirror high-income country models in the number and type of EIP components offered. Also, multicomponent interventions for early psychosis are also effective in improving outcomes. However, most of these interventions are offered within short-term research studies rather than integrated into routine care and have limited cultural adaptation. Specifically, for individuals with first-episode psychosis, it's noteworthy that first-generation antipsychotics are commonly used and cognitive behavioral therapy is moderately applied. Also, for those at clinical high risk, antipsychotic medications are prominently featured, while cognitive behavioral therapy is less frequently utilized. Leveraging the review's findings, this presentation will highlight implications for further development and scale-up of EIP in low-and middle-income countries.

29.3. EARLY PSYCHOSIS SERVICES: AN INDIAN PERSPECTIVE

Greeshma Mohan*¹, Rangaswamy Thara², R Padmavati², Swaran Singh³, Ashok Malla⁴, Srividya Iyer⁵

¹Schizophrenia Research Foundation, India and University of Warwick, ²Schizophrenia Research Foundation, ³University of Warwick, ⁴McGill University, ⁵McGill University and Douglas Hospital Research Institute

Background: FEP in the Indian Context: India has a large pool of undetected and untreated patients with psychosis and a treatment gap exceeding 75%. Evidence-based packages of care have been piloted, but delivery of interventions still remains a challenge. Even when patients access treatment, there is minimal to no continuity of care. Much of the data and experience from India is provided from the First Episode Psychosis (FEP) program at Schizophrenia Research Foundation (SCARF) located in the Southern state of Tamil Nadu, India. Collaboration with PEPP, Montreal: The FEP program at SCARF was initiated in 2003 as a research collaboration with the Prevention and Early Intervention Program for Psychoses (PEPP), affiliated with McGill University, Montreal. A series of collaborative studies was carried out from 2003-2017 which focused on patients with previously untreated FEP who received clearly defined and similar treatment for two years. Partnering with the WIC group: While the collaboration with PEPP, Montreal furthered understanding of the nature of early psychosis presentation in India and the impact on patients and their families, a need was felt to develop culturally-sensitive interventions that could expand mental health services to communities that currently have no access in India. This brought together four internationally recognized institutions with a single aim – to develop protocol for management of first episode psychosis, thereby reducing burden of psychotic disorders. Partners included University of

Warwick (Coventry, UK); All India Institute for Medical Sciences (New Delhi, India); McGill University (Montreal, Canada) along with SCARF; collectively called the WIC group. During this presentation, we will describe the main findings resulting from both collaborations. To identify and discuss the components of FEP services in India that are best suited to wider implementation.

Methods: The first half of the presentation will focus on the outcome indicators and distinct characteristics of the FEP patients in India. The second part of the presentation will highlight the core components of FEP services in India with an emphasis of emerging symptoms, care pathways and duration of untreated psychosis based on 283 participants who were recruited as part of research collaborations.

Results: Our unique findings will be presented (eg., very low to no service disengagement, relatively high rates of medication discontinuation with maintained symptom remission, no delay in overall DUP when first contact is with healer as compared to other sources of help). We will also discuss the core components that provide a foundation for broader implementation and provide an evidence-based understanding.

Conclusions: Our unique findings will be presented (eg., very low to no service disengagement, relatively high rates of medication discontinuation with maintained symptom remission, no delay in overall DUP when first contact is with healer as compared to other sources of help). We will also discuss the core components that provide a foundation for broader implementation and provide an evidence-based understanding.

29.4. CHALLENGES OF IMPLEMENTING AN EARLY PSYCHOSIS INTERVENTION PROGRAMME IN TUNISIA

Feten Fekih-Romdhane*¹

¹*Tunis El Manar University*

Background: In Tunisia, psychiatric healthcare has long been mainly hospital-based and secondary care, with no community-based care or rehabilitation and recovery services available for youth with mental health problems. During the last decade, the public mental health strategy was approved, particularly with the adoption of the 2013 Tunisian National Strategy for the Promotion of Mental Health. Since then, a specific emphasis has been placed on mental health prevention efforts. This presentation seeks to describe the structural characteristics of a new early intervention in psychosis service in a real-world low-resource setting in Tunisia, i.e. the Tunisian Center of Early Intervention in Psychosis (TCEIP) program, and to discuss the benefits and challenges of implementing an early psychosis intervention programme in Tunisia within the local economic, social, and cultural context.

Methods: A literature review was undertaken.

Results: The Tunisian Center of Early Intervention in Psychosis (TCEIP) program has been created in 2017 in response to a lack of policies, staff training, and specialized early intervention services in the country. It is located at the Razi Psychiatric Hospital, and integrated into an existing service structure. The TCEIP was implemented with the financial support of civil societies, as well as the support and encouragement of the Ministry of Health. To the best of our knowledge, it is, so far, the first early detection and intervention in psychosis center based in Tunisia and the Middle East-North Africa region. The TCEIP targets individuals between the ages of 16 and 35 years, who are considered at risk for developing psychosis or presenting with a first episode of psychosis. It offers extensive clinical assessment and evidence-based interventions. However, there exists important barriers and challenges to be currently considered for the functioning, strengthening and sustainability of the TCEIP,

including a substantial burden of chronic underfunding of public mental health services, resource scarcity, financial obstacles to staff recruitment, lack of availability of and recurrent shortages in psychotropic medications, stigma toward the psychiatric hospital, and poor communication/collaboration with primary health care providers.

Conclusions: Because of the economic, social and cultural peculiarities, simply translocating early intervention programs previously implemented and tested in the Western, high-income world to the Tunisian context may be inappropriate.

30. RACISM AND PSYCHOSIS: FUTURE DIRECTIONS

Hans Oh, *University of Southern California*

Overall Symposia Abstract: Racism and psychosis: Future directions In a rapidly changing world where systemic inequities adversely affect population health, people of color are disproportionately impacted and appear to have higher psychosis risk. Race is a social construct used to categorize people based on secondary physical characteristics, such as skin tone, hair texture, and facial features. Historically, the concept of race was erroneously used to infer biological, genetic, and essential differences across groups; and as such, race has served as the basis of marginalization and oppression. Like in other mental health fields, psychosis researchers have treated ethnicity and race without proper contextualization, namely, without acknowledgement of racism –the complex system of oppression that operates through multiple pathways, including structures, institutions, culture, and interpersonal interactions to privilege the dominant (white) group while disadvantaging people of color. By and large, the field of psychosis research has employed underdeveloped conceptualizations of race and racism. Thus, we begin with an overview of anti-racist praxis when examining race and ethnicity in research to properly establish race as a proxy for exposure to racist experiences. Dr. Els van der Ven will present data from a meta-analysis showing ethnoracial risk variation across multiple psychosis outcomes, calling attention to diagnostic biases and systemic influences such as structural racism. Ms. Katrina Rbeiz will then present data from the US showing psychosis risk within the Middle Eastern/North African population, which is often treated as a monolith, with little regard for the socio-cultural variability in terms of exposure to discrimination and presence of resilience. Dr. Benson Ku will present data from the US showing associations between neighborhood racial diversity, peer victimization, perceived racial discrimination, and attenuated positive symptoms among youth at Clinical High Risk for Psychosis, shedding light on the social determinants of psychosis and stimulating discussion on potential early interventions for schizophrenia. Dr. Frederike Schirmbeck will present findings from the Netherlands, showing significantly longer time-to-treatment interval for ethnic minorities when compared with their white counterparts. Finally, Dr. Srividya Iyer will synthesize the presentations and share her thoughts on implications for service delivery and population health. Those in attendance will come away with greater awareness of racialization, race and ethnic minority status and racism in relation to psychosis, and hopefully become inspired to interrogate studies that make claims about race or ethnicity, adopt more measures of racism in data collection, and uphold antiracist practices in research to address racial disparities in psychosis.

30.1. ETHNORACIAL RISK VARIATION ACROSS THE PSYCHOSIS CONTINUUM IN THE UNITED STATES: A SYSTEMATIC REVIEW AND META-ANALYSIS

Els van der Ven*¹

¹*Vrije Universiteit Amsterdam*

Background: Studies suggest higher risk of schizophrenia diagnoses in Black versus White Americans, yet a systematic investigation of disparities that include other ethnoracial groups and multiple outcomes on the psychosis continuum is lacking. The objective of this study was to identify ethnoracial risk variation in the U.S. across three psychosis continuum outcomes (ie, schizophrenia and other psychotic disorders, clinical high risk for psychosis [CHR-P], and psychotic symptoms [PS] and experiences [PE]).

Methods: PubMed, PsycINFO and EMBASE were searched up to December 2022. Observational studies on ethnoracial differences in risk of three psychosis outcomes were selected. Data extraction and synthesis were conducted following the Preferred Reporting Items for Systematic Reviews and Meta-analyses (PRISMA) guidelines. Using a random-effects model, estimates for ethnoracial differences in schizophrenia and PS/PE were pooled and moderation by sampling and setting was determined, along with the assessment of heterogeneity and risk of bias. Main outcomes included risk of schizophrenia and other psychotic disorder, CHR-P and conversion to psychosis among CHR-P, and PS/PE.

Results: Of 32 studies on schizophrenia, 3 on CHR-P, and 29 on PS/PE included in the systematic review, 47 were included in the meta-analysis. Compared to White individuals, Black Americans had increased risk across two outcomes, ie, schizophrenia (pooled odds ratio [OR], 1.80 [95% CI, 1.36-2.38]) and PS/PE (pooled standardized mean difference [SMD], 0.10 [95% CI, 0.03-0.16]), Latinx individuals for PS/PE (pooled SMD, -0.15 [95% CI, -0.22-0.08]), and individuals classified as ‘Other’ ethnoracial group for schizophrenia (pooled OR, 1.81 [1.31-2.50]). The results regarding CHR-P studies were mixed and inconsistent. Sensitivity analyses showed elevated odds of schizophrenia in Asian individuals in inpatient settings (pooled OR, 1.84 [95% CI 1.19-2.84]) and increased risk of PE among Asian compared to White individuals specifically in college samples (pooled SMD, 0.16 [95% CI, 0.02-0.29]). Heterogeneity across studies was high and there was substantial risk of bias in most studies.

Conclusions: Findings suggest widespread ethnoracial risk variation across multiple psychosis outcomes. In addition to diagnostic, measurement and hospital bias, systemic influences such as structural racism should be considered as drivers of ethnoracial disparities in outcomes across the psychosis continuum in the U.S.

30.2. NAVIGATING DISCRIMINATION AND BUILDING RESILIENCE: INSIGHTS FROM MIDDLE EASTERN AND NORTH AFRICAN POPULATIONS IN THE U.S.

Katrina Rbeiz*¹, Sohee Park¹

¹*Vanderbilt University*

Background: Ethnic identity plays a significant role in people's psychological outcomes, experiences of discrimination, and the coping mechanisms that may emerge from these negative experiences. This study aims to delve into the emotional experiences, ethnic identity, and resilience of people from Middle Eastern and North African (MENA) populations. MENA individuals are among the most vulnerable populations, as they have been historically understudied due to the erasure of representation in key demographic questionnaires (i.e., the U.S. Census) as well as in psychological research, leading to major gaps in the literature regarding the culturally specific discrimination and ethnic trauma they endure. Even less is known about the development of psychotic experiences in MENA populations.

Methods: Participants will include community-dwelling adults from MENA backgrounds living in the United States. Using bivariate correlations and t-tests, we investigated whether ethnic and religious identity, immigrant status, gender, social defeat (via SDS), and everyday experiences of discrimination (via PDS) were associated with higher reports of psychosis-risk (via PQ-16), trauma (via BTQ), psychological distress (i.e., depression, anxiety, and stress; via DASS-21), as well as resilience (via BCRS) and belongingness (via CSBS). Further, categories within the PDS were created to measure race-, religion-, and gender-based discrimination, to investigate their associations with outcomes.

Results: We hypothesize that lower income and education will be associated with increased reports of trauma. We also predict that US-born MENA populations will report higher psychosis-risk, discrimination, social defeat, trauma, and psychological distress. We believe that ethnic and religious identity and feelings of belongingness will also serve as protective factors against trauma and psychosis-risk, and that these will be correlated with higher scores of resilience. All categories of discrimination (including total scores) will predict higher psychosis-risk, trauma, and psychological distress.

Conclusions: MENA populations are often treated as a monolith, with little regard for the socio-cultural variability that exists within them. We urge future researchers to use intersectional frameworks to explore MENA identities and experiences, such as immigrant status, race-, religion-, and gender-based discrimination, and their relationships to adverse psychological outcomes (i.e., psychosis-risk, trauma, distress), as well as resilience. This may address a public health concern by promoting inclusivity in research and clinical work for an understudied ethnic identity group, who are unlikely to access mental health resources to promote resiliency and protection.

30.3. THE RELATIONSHIPS OF NEIGHBORHOOD RACIAL DIVERSITY, PEER VICTIMIZATION, DISCRIMINATORY EXPERIENCES, AND POSITIVE SYMPTOMS AMONG YOUTH AT CLINICAL HIGH RISK FOR PSYCHOSIS

Benson Ku^{*1}, Emerald Yuan¹, Regine Haardorfer¹, Jean Addington², Carrie Bearden³, Kristin Cadenhead⁴, Tyrone Cannon⁵, Barbara Cornblatt⁶, Benjamin Druss⁷, Matcheri Keshavan⁸, Daniel Mathalon⁹, Diana Perkins¹⁰, William Stone¹¹, Scott Woods⁵, Elaine Walker¹, Deidre Anglin¹²

³University of California, Los Angeles, ⁴University of California, San Diego, ⁵Yale

University, ⁶The Zucker Hillside Hospital, ⁷Emory University Rollins School of Public

Health, ⁸Harvard University, ⁹University of California, San Francisco, ¹⁰University of North

Carolina At Chapel Hill, ¹¹Harvard Medical School / Beth Israel Deaconess Medical Center,

¹²The City College of New York (CCNY)

Background: Racial diversity is an important factor in promoting inclusivity, productivity, and wellness. Greater racial diversity in schools has been associated with less bullying. Neighborhood-level factors including ethnoracial minority density and social fragmentation have been shown to be important in the development of psychosis. However, the relationships between neighborhood-level racial diversity and psychosis have yet to be investigated. In this study, we hypothesize that greater neighborhood-level racial diversity will be associated with lower psychotic symptoms among youth at clinical high risk for psychosis (CHR-P). In addition, we hypothesize that this relationship will be explained by less peer victimization and discriminatory experiences.

Methods: Data is collected at baseline from North American Prodrome Longitudinal Study Phase 2 (NAPLS-2) among youth at CHR-P. Neighborhood racial diversity was constructed using the Simpson Index using participants' census tract characteristics derived from their baseline addresses. The Simpson Index measures the probability that two racial groups randomly selected from a census tract will belong to different racial groups. The value of this index ranges between 0 and 1, the greater the value, the greater the sample diversity. Peer victimization was derived from the Life Event Stress Scale: (1) were bullied/got in a fight; (2) were excluded from a peer group and (3) were the subject of a cruel rumor. Discriminatory experiences included having experienced discrimination in their lifetime due to (1) skin color; (2) ethnicity; and (3) appearance. Both peer victimization and discriminatory experiences were constructed with the specified items above as latent variables. Attenuated positive psychotic symptoms were derived from the SOPS. Structural equation modeling (SEM) was employed to assess serial mediation of peer victimization and discriminatory experiences in the relationship between neighborhood racial diversity and attenuated positive symptoms. All models have been clustered by sites and adjusted for the following covariates: age, sex, neighborhood-level poverty, and depressive symptoms. Subgroup analyses explored whether the relationship of these variables differs based upon the racial minority status of the participant.

Results: The study included 437 participants at CHR-P. The median age was 18.0, 57.9% were male. The median neighborhood racial diversity index was 0.46. Median neighborhood poverty was 6.6%. All models reported had adequate model fit statistics. The final main model showed that greater neighborhood racial diversity was associated less attenuated positive symptoms (Std. Est = 0.28, 95% CI = 0.10 to 0.47, $p = 0.003$). This relationship was serially mediated by less peer victimization (Std. Est. = -0.14, 95% CI = -0.24 to -0.03, $p = 0.017$) and less discriminatory experiences (Std. Est. = 0.45, 95% CI = 0.26 to 0.63, $p < 0.001$), both of which explained 16.67% of the relationship between neighborhood racial diversity and positive symptoms. In subgroup analyses, the relationships between these variables were statistically significant among racial minorities, but not among white non-Hispanic participants.

Conclusions: This study demonstrates the associations between neighborhood racial diversity, peer victimization, perceived racial discrimination, and attenuated positive symptoms among youth at CHR-P. These findings help us better understand the social determinants of psychosis, which also shed light on potential early interventions for schizophrenia.

30.4. RISK CLUSTERS OF MULTIPLE SOCIAL DETERMINANTS IN THE PREDICTION OF DURATION OF UNTREATED PSYCHOSIS

Hannah Edelhoff^{*1}, Frederike Schirmbeck², Ulrich Reininghaus¹, GROUP Investigators³

¹*Central Institute of Mental Health, Mannheim*, ²*AMC, University of Amsterdam*, ³*GROUP*

Background: A longer duration of untreated psychosis (DUP) is associated with several short-term and longer-term negative outcomes, including higher symptom severity, longer time until remission, poorer overall functioning and quality of life. Despite efforts to implement early-intervention services and specialized care, DUP are still considerably long. Improving our understanding of predictors and barriers for a delay to adequate care for a first episode psychosis (FEP) may display important targets for intervention. Studies investigating individual and environmental factors influencing DUP, highlighted associations with several social determinants such as ethnoracial group, education, premorbid social, and academic functioning. Instead of focussing on single factors recent findings propose to use multiple characteristics of social determinants to identify potential clusters of risk/privilege. In addition,

potential barrier to care, measured at first contact might shed light on important variables on the pathway to treatment initiation.

Methods: In a cohort studies of recent onset psychosis (n=447) sociodemographic characteristics on gender, ethnicity, employment status, living arrangement, education, urbanicity, cannabis use and proportion of unmet needs were collected and included in latent class analysis to identify clusters of individuals based on these variables. Subsequently, differences in outcome (DUP) were compared with ANOVA and post-hoc comparisons.

Results: Preliminary analysis revealed 4 clusters. Cluster 1 was the largest cluster (31.1%) of individuals characterized as being predominantly white, male, living alone, being employed, with high educational degree and no cannabis use over the last 12 months. Cluster 2 (27,7%) differed from Cluster 1 by frequent cannabis use and a higher proportion of unmet needs. Cluster 3 (23.5%) consisted of predominantly female, white, more often being married or living together, not using cannabis and reporting little unmet needs. Finally, cluster 4 (17,7%) was characterized as male, non-white individuals with lower educational degree, higher proportion of unemployment, living in urban regions and reporting several unmet needs. Between cluster comparisons with regard to the DUP revealed significant longer time-to-treatment interval for individuals in cluster 4 compared with individuals in cluster 1 and 3.

Conclusions: Preliminary findings suggest that duration of untreated psychosis differs between clusters combining several social determinants. Accounting for their combination and potential interaction might increase early detection of subjects most vulnerable for a delay to adequate care.

31. ENVIRONMENTAL RISK FACTORS AND PSYCHOPATHOLOGIC DOMAINS: FROM MOLECULAR MECHANISMS TO THERAPEUTIC INTERVENTION

Marco Andrea Riva, *University of Milan*

Overall Symposia Abstract: A strong relationship exists between psychiatric disorders, such as schizophrenia, and disturbances of neurodevelopment. Indeed, a derangement in the maturational pattern of specific cellular subtypes, because of a genetic predisposition or exposure to adverse life events, may lead to alterations in brain circuits critical for the manifestation of key psychopathologic domains. With this respect, a better understanding of the relationship between early life adversities, psychopathologic domains, and key neurobiological mechanisms is crucial to identify potential targets for pharmacological intervention. Our symposium will summarize and discuss authoritatively important recent findings in this field by integrating basic and clinical research to highlight key molecular mechanisms and circuits that will ultimately guide future research efforts toward better phenotyping of ‘at risk’ individuals as well as for the identification of novel therapeutic strategies intervention.

At the preclinical level, Marco A. Riva (Italy) will discuss how stress exposure during gestation leads to vulnerability or resilience for specific behavioral constructs in adolescence, which are associated with altered function and responsiveness of selected brain circuits. He will also discuss the contribution of neuronal plasticity and immune mechanisms and the role of pharmacological intervention. Considering the relevance of adolescent experiences for disease susceptibility, Felipe V. Gomes (Brazil) will focus on the effects produced by stress exposure during this critical time frame and how such experience leads to impaired sociability and cognitive deterioration with significant changes in excitatory/inhibitory (E/I) balance due to oxidative stress (OxS) and altered mitochondrial function. Moreover, he will show how

treatment with N-acetylcysteine (NAC) may be able to prevent and/or attenuate the schizophrenia-related changes caused by stress exposure.

The central role of OxS in mediating the etiopathological role of genes and environment will be further addressed by Danielle Dwir (Switzerland) using a translational approach both in animal models and in early psychosis patients (EPP). She will show how OxS may interact with inflammation to produce long-term dysfunction of parvalbumin interneurons. She will also show how EPP with a genetic vulnerability to OxS, may display alteration of redox markers in plasma that are associated with reduced prefrontal GABA levels, potentially predicting a central E/I imbalance. Interestingly, sub-chronic NAC treatment may counteract such changes leading to an improvement in cognition and clinical symptoms.

Lastly, considering that a dysfunction of the hypothalamic-pituitary axis represents a key element in stress response and may also interact with some of the mechanisms discussed above, Alexis E. Cullen (Sweden) will focus on cortisol abnormalities among individuals with psychotic disorder and those at high-risk for the disorder. She will show data from five unique cohort studies conducted in the UK and she will discuss how cortisol measures may indeed show robust association with established psychosis and psychosis high-risk status thus providing useful information for a better characterization of affected individuals.

Together with the discussant (Marta Di Forti; UK), this expert panel of speakers will discuss how these findings can advance the understanding of etiological mechanisms for schizophrenia toward the identification of novel and more targeted strategies for preventive and therapeutic interventions.

31.1. VULNERABILITY AND RESILIENCE TO PRENATAL STRESS EXPOSURE IN RODENTS AT ADOLESCENCE: FROM BRAIN MECHANISMS AND CIRCUITS TO PSYCHOPATHOLOGIC DOMAINS.

Marco Andrea Riva*¹

¹*University of Milan*

Background: Exposure to adverse conditions early in life represents an important risk factor for the onset and development of mental disorders, including schizophrenia. Adverse perinatal events are indeed associated with profound changes in the progeny, which often become manifest at the transition between adolescence and adulthood. With this regard, animal models are particularly useful to investigate the molecular and functional mechanisms that are persistently affected after exposure to stressors early in life (ELS). The characterization of the timing for such alterations is instrumental in developing pharmacological interventions aimed at normalizing or preventing the behavioral consequences associated with ELS exposure. In our studies, we employed the prenatal stress model (PNS) in rats to investigate the behavioral and molecular alterations that develop because of this adverse experience in adolescent rats, also considering sex differences.

Methods: Pregnant rats were exposed to the prenatal stress (PNS) paradigm, consisting of 3 daily sessions of immobilization for 45 minutes from gestational day 14 to birth, while control dams were left undisturbed. During adolescence, the behavior of male and female offspring was investigated to analyze psychopathologic domains, including sociability, anhedonia, and anxiety, that are shared across different mental disorders. Following sacrifice, transcriptomics as well as candidate gene analyses were performed in different brain regions to identify

mechanisms that may be relevant for the behavioral phenotypes observed in animals exposed to PNS. Furthermore, a subgroup of animals was exposed to a 5 min of forced swim before sacrifice to investigate the differential responsiveness to the acute challenge.

Results: We found that PNS exposure produces emotional dysregulation in male and female adolescent offspring, including anhedonia, anxiety, and impaired sociability. Based on a two-step cluster analysis of the behavioral data, we identified 30% of PNS animals as resilient (PNS-res), whereas the remaining 70% were classified as vulnerable to PNS exposure (PNS-vul). At the molecular level, we found that such behavioral patterns were associated with selective changes in the expression of activity-dependent genes as well as of immune-related mechanisms in different brain regions, which are known to play a crucial role in emotional regulation. Moreover, while control or PNS-exposed rats show a similar activation of different brain structures following an acute stress in adolescence, some differences were found in the prefrontal cortex with an imbalance between excitatory and inhibitory circuits.

Conclusions: Overall, we showed that stress exposure during gestation produces emotional dysregulation only in a sub-group of adolescent male and female offspring. The characterization of the neurobiological mechanisms contributing to resilience or vulnerability to stress will be instrumental in identifying mechanisms that may be targeted by therapeutic approaches to counteract specific pathologic domains of mental disorders, including schizophrenia.

31.2. SCHIZOPHRENIA-RELATED HIPPOCAMPAL EXCITATORY/INHIBITORY IMBALANCE CAUSED BY ADOLESCENT STRESS: INVOLVEMENT OF REDOX DYSREGULATION AND MITOCHONDRIAL DYSFUNCTION

Felipe Gomes^{*1}, Thamyras Santos-Silva¹, Icaro Freitas¹, Caio Lopes², Doğukan Ülgen³, Francisco Silveira Guimaraes¹, Luciane Alberici², Carmen Sandi³

¹Ribeirao Preto Medical School, University of Sao Paulo, ²Ribeirão Preto Pharmaceutical Sciences School, University of São Paulo, ³Brain Mind Institute, École Polytechnique Fédérale de Lausanne

Background: The developing adolescent brain is highly susceptible to social experiences and environmental insults, influencing how personality traits emerge. We previously found that adolescent stress leads to long-lasting behavioral changes and excitatory/inhibitory (E/I) balance dysregulation in the ventral hippocampus (vHip) associated with neurodevelopmental disorders, including schizophrenia. The neurobiological mechanisms of psychiatric disorders have been linked with oxidative damage and reduced antioxidant capacity in the brain. However, the impact of severe stressors during adolescence, a critical neurodevelopmental period, on mitochondrial function, redox balance, and their functional consequences are not completely understood. We hypothesized that mitochondrial respiratory function and redox homeostasis in the vHip are affected by adolescent stress, leading to behavioral and electrophysiological changes associated with schizophrenia.

Methods: First, we performed a behavioral characterization during late adolescence (postnatal day, PND 47 – 50), including naïve animals and animals exposed to stress from PND 31 until 40 (10 days of footshock and 3 restraint sessions) by assessing sociability (social interaction test) and cognition function (novel-object recognition test). Then, we uncovered changes in E/I balance by analyzing the activity of glutamate pyramidal neurons, and the number of parvalbumin (PV)-containing GABAergic interneurons and their possible association with oxidative stress. To address the dynamic impact of stress on mitochondrial redox homeostasis, we performed high-resolution respirometry, DHE staining, MitoSox™ and AmplexRed® assays one (PND 41) and ten days (PND 51) after stress protocol. Also, we evaluated

glutathione (GSH) and glutathione disulfide (GSSG) levels at PND 51. We also assess the genome-wide transcriptomic signature of vHip of stressed animals by performing bulk RNA-sequencing following the behavioral tests. Finally, we tested whether the treatment with the antioxidant N-acetylcysteine (NAC) would attenuate the deleterious impact of adolescent stress.

Results: One week after stress, adolescent-stressed animals exhibited: loss of sociability and cognitive impairment; enhanced vHip pyramidal neuron activity; and reduction in the number of PV-positive cells and their associated perineuronal nets. These changes were associated with an increase in 8-oxo-DG, a marker of oxidative stress, in the vHip that was co-localized with PV interneurons. By performing high-resolution respirometry analysis, we found that stress impacted mitochondrial uncoupled efficiency (PND 41) and the phosphorylation capacity (PND 51). In addition, stressed animals displayed long-lasting redox dysregulation in the vHip, as revealed by molecular analysis. GSSG levels were increased in the vHip and serum of stressed animals and negatively correlated with social and cognitive performance, indicating that GSH was previously oxidized by ROS in stress conditions, and may affect behavioral phenotype. In another cohort of animals, we identified three cluster subgroups by performing a principal component analysis of behavioral assessment: naïve higher-behavioral z-score (HBZ), naïve lower-behavioral z-score (LBZ), and stressed animals. Genes encoding subunits of oxidative phosphorylation complexes were significantly down-regulated in both naïve LBZ (Cox7c) and stressed animals (Coa5), while the Txnip gene that encoded thioredoxin-interacting protein was up-regulated in stressed animals and negatively correlated with behavioral performance. The treatment with NAC during adolescent stress attenuated the behavioral and electrophysiology abnormalities caused by adolescent stress.

Conclusions: Our results identify mitochondrial genes associated with distinct adolescent behavioral phenotypes and highlight the negative impact of adolescent stress on vHip mitochondrial respiratory function and redox regulation, in which are partially associated with E/I imbalance and behavioral abnormalities related to schizophrenia. In addition, redox dysregulation and mitochondrial dysfunction may be potential targets to prevent and/or attenuate schizophrenia-related changes caused by stress.

31.3. MMP9/RAGE AS A COMMON MECHANISM INDUCED BY ENVIRONMENTAL RISK FACTORS IN THE DEVELOPMENTAL PSYCHOPATHOLOGY OF SCHIZOPHRENIA: A PROMISING TARGET FOR EARLY INTERVENTION IN EARLY PSYCHOSIS PATIENTS.

Daniella Dwir^{*1}, Jan Harry Cabungcal¹, Basilio Giangreco¹, Lijing Xin², Enea Parietti¹, Larissa Allgäuer¹, Catherine Yzydorczyk³, Raoul Jenni¹, Philippe Conus⁴, Michel Cuénod¹, Paul Klauser¹, Pascal Steullet¹, Kim Q. Do¹

¹Center for Psychiatric Neuroscience, Lausanne University Hospital, ²Center for Biomedical Imaging (CIBM), Ecole Polytechnique Fédérale de Lausanne, ³, ⁴Service of General Psychiatry, Lausanne University Hospital, Switzerland

Background: The complexity of SZ comes from its multifactorial origins, involving both genetic and environmental factors. Environmental stressors occurring during gestation, at birth or during childhood increase the risk for SZ. The interaction between environmental risk factors and a genetic background of vulnerability converges to increased oxidative stress (OxS) and inflammation during early brain development, which may affect the proper maturation of cortical circuitry, specifically the highly metabolically active PVI, as a hallmark of SZ. In a translational approach both in animal models and in early psychosis patients (EPP), we aimed (1) to identify a precise mechanism induced by environmental stressors and leading to the

interaction between OxS and neuroinflammation, affecting PVI, and (2) to interfere with the proposed mechanism by using the antioxidant N-acetyl-cysteine (NAC) and environmental enrichment (EE) to rescue PVI maturation.

Methods: This study was conducted on three rodent models of environmental stressors with relevance for SZ: the transgenic GSH deficit (GCLM KO) model with an additional OxS during childhood, the gestational methylazoxymethanol acetate (MAM) model and the intrauterine growth restriction (IUGR) model. The animal findings were then validated in a well-characterized cohort of EPP. A rescue experiment was conducted on the GCLM-KO+GBR mice with NAC and EE during juvenile/adolescent period and morphological/functional analysis were conducted on adult animals. EPP underwent blood sampling, magnetic resonance spectroscopy (MRS) and clinical assessment. This cohort is composed of N=68 healthy controls (37% females; 14.7% ethnic minority) and N=111 EPP (25% females; 30% ethnic minority). A part of this cohort joined a double-blind, randomized, placebo-controlled clinical trial of NAC supplementation for 6-months and underwent blood sampling, MRS and clinical assessment at baseline and after treatment. This cohort is composed of N=16 placebo (44% females; 31% ethnic minority) and N=15 NAC (14% females; 26% ethnic minority).

Results: In the three rodent models with an environmental stressor, we identified a mechanism that maintained a feedforward loop of increased OxS and neuroinflammation, leading to PVI impairments. This mechanism involved the activation of MMP9, leading to the cleavage of the extra- and intra- cellular domains of RAGE (RAGE shedding). The intracellular domain of RAGE translocated to the nucleus, leading to the activation of NFkB, and further pro-inflammatory cytokines and microglia activation. These effects were completely reversed by the combination of NAC treatment and EE in the GCLM KO+GBR mice. This recovery was mediated by NAC, possibly via the inhibition of OxS induced MMP9/RAGE pathway, interrupting this deleterious feedforward mechanism, and allowing PVI maturation. A subsequent EE during adolescence promoted the final maturation of PVI, providing a long-term neuroprotection to PVI network. The fast-rhythmic oscillations reflecting neuronal synchronization of PVI was decreased in the GCLM KO+GBR, and recovered by NAC/EE. In EPP with a genetic vulnerability to OxS, an increase in RAGE shedding, measured as soluble form of RAGE (sRAGE) in the plasma, was associated with low prefrontal GABA levels, potentially predicting a central inhibitory/excitatory imbalance, in line with our preclinical model. Interestingly, 6-month NAC treatment decreased RAGE shedding in the plasma of EPP, in association with increased prefrontal GABA level, improvement of cognition and clinical symptoms, suggesting similar neuroprotective mechanisms.

Conclusions: MMP9/RAGE pathway represents a key regulatory mechanism by which OxS interacts with neuroinflammatory conditions, which is particularly damaging to PVI. The long-lasting effects on PVI can be reversed by a combined NAC/EE, even after the challenge. In analogy, patients carrying genetic risks to redox dysregulation potentially vulnerable to early-life insults could benefit from a combined pharmacological and psycho-social therapy. Our translational study establishes sRAGE as a peripheral marker for CNS inhibitory circuit impairments. The activation of MMP9 by OxS, on its redox-sensitive site, represents a mechanism-based peripheral proxy for brain neuroinflammation and OxS. Our findings highlight the MMP9/RAGE pathway as a promising target for novel drug development in psychiatry.

31.4. CORTISOL MEASURES ACROSS CLINICAL STAGES OF PSYCHOSIS: AN INDIVIDUAL PATIENT DATA (IPD) META-ANALYSIS

Senta Haussler¹, Uzma Zahid¹, Mahnoor Hassan¹, Fern Day², Simone Ciufolini¹, Natalia Petros¹, George Gifford¹, Luis Alameda³, Diego Quattrone¹, Kareen Heinze⁴, Helen Fisher¹,

Kristin Laurens⁵, Marta Di Forti⁶, Stephen Wood⁷, Robin Murray⁶, Philip McGuire¹, Valeria Mondelli¹, Alexis Cullen*⁸

¹*Institute of Psychiatry, Psychology, and Neuroscience, King's College London*, ²*South London and Maudsley, NHS Foundation Trust*, ³*Institute of Psychiatry, Psychology and Neuroscience, King's College London/South London and Maudsley*, ⁴*University of Birmingham, UK*, ⁵*Queensland University of Technology/University of New South Wales*, ⁶*Institute of Psychiatry, Psychology and Neuroscience, King's College London, UK*, ⁷*University of Melbourne*, ⁸*Karolinska Institutet*

Background: Studies conducted over the past five decades have provided evidence of cortisol abnormalities (indexing hypothalamic-pituitary axis dysregulation) among individuals with psychotic disorder and those at high-risk for the disorder. However, attempts to synthesise evidence from these studies indicate that findings are extremely heterogeneous. There are several factors that may explain this heterogeneity, including diversity in the cortisol measures, variable approaches accounting for potential confounders, and differences in illness stages across study populations. To address these issues, we will conduct an individual participant data (IPD) meta-analysis to examine five distinct cortisol measures across psychosis clinical stages. Our primary aim is to identify cortisol measures that differ in established psychosis and high-risk populations relative to controls. Our secondary aim is to conduct subgroup analyses comparing cortisol measures across clinical stages of psychosis.

Methods: As our aim is to harmonise and pool data across cohorts that had adopted similar methods of data acquisition, we have not conducted a systematic review to identify all studies reporting cortisol measures in psychosis/high-risk populations, but instead included a reasonably representative sample of studies that employed similar protocols and were accessible to us through existing consortia. Studies are required to (a) have measured cortisol in either saliva or hair using a clearly-defined protocol, (b) have data on a minimum set of potential confounders (age, sex, ethnicity, tobacco use, cannabis use, psychotropic medication), (c) have clinical data, obtained using a validated/reliable instrument, to determine illness stage, and (d) included at least one psychosis clinical stage and a healthy control group. Clinical stages are defined as mild psychotic symptoms and/or depression anxiety (stage 1a), clinical high-risk for psychosis (stage 1b), first-episode of psychosis (stage 2), relapsing/remitting illness (stage 3), or chronic illness (stage 4). A two-stage IPD meta-analysis will be conducted using the 'ipdmetan' package in Stata 17. In the first stage, correlational analyses will be used to investigate the relationship between potential confounders and cortisol measures within each cohort. Linear regression models will then be performed in each cohort to obtain standardised beta coefficients (StB), adjusted for potential confounders, representing the difference in cortisol measures between each clinical stage and healthy control group. In the second stage, StB's will be pooled using random effects meta-analyses.

Results: We have obtained six datasets from five unique cohort studies conducted in the UK. From the available datasets, we derived four salivary cortisol measures and a single measure of hair cortisol (indexing chronic HPA axis function). The number of cohorts and total sample size (N) for each cortisol measure is as follows: awakening response (5 cohorts, N=794), basal cortisol (5 cohorts, N=623), diurnal slope (5 cohorts, N=581), overall daytime cortisol release (5 cohorts, N=761), and hair cortisol (4 cohorts, N=255). We are currently performing stage 1 of the IPD meta-analysis, in stage 2 we will first compare healthy controls with all high-risk groups (stages 1a and 1b) and all individuals with established illness (stages 2, 3, and 4). Subgroup analyses will then be used to compare individual stages with healthy controls. The results from this analysis will be presented at the meeting.

Conclusions: Based on the results of the study, we will identify the cortisol measures that are the most robustly associated with established psychosis and psychosis high-risk status and provide recommendations for advancing scientific research in this field.

32. NEW FRONTIERS FOR PSYCHOSIS PREDICTION AND PREVENTION IN CHILDREN AND ADOLESCENTS

Ian Kelleher, *University of Edinburgh*

Overall Symposia Abstract: This symposium will explore new approaches to identifying risk for psychosis, in particular in childhood and adolescence.

Dr Kelleher will begin by discussing the current state of the art with regard to psychosis prediction research, especially for children and adolescents.

Dr Jalbrzikowski will then discuss new U.S. research looking at risk for psychosis in young people who have been followed up for 5 years+ after presenting to clinical services with self-harm. Her findings will demonstrate that this is a group at significantly elevated risk for later psychosis.

Dr Healy will discuss his research on risk for psychosis associated with 2 different approaches: (1) the classic Familial High Risk approach, looking at offspring of parents with a history of psychosis, and compare this to (2) offspring of parents who have attended specialist mental health services for any reason (not limited to psychosis). He will compare data on both the absolute risk of psychosis in each of these two groups but also on the total proportion of cases of psychosis that are captured by each of the two approaches.

Dr Lang will discuss data from Finland looking at risk of psychosis in young people who have attended adolescent psychiatry services who are followed into adulthood. She will demonstrate that this is a high risk group for later psychosis and present data on additional variables that help to identify subgroups of adolescent psychiatry patients who are at particularly high risk.

Dr O'Hare will present UK biobank data on risk for psychosis among young people who have attended child and adolescent mental health services (CAMHS). She will also present data on risk factors within these patients that predict a higher risk of later psychosis.

Dr Moriyama will summarise the four talks and lead our discussion, including discussing global health implications of the findings.

32.1. LEVERAGING ELECTRONIC HEALTH RECORDS TO IMPROVE RISK PREDICTION FOR PSYCHOSIS AND BIPOLAR DISORDER

Maria Jalbrzikowski*¹, Rashmi Sahasrabudhe²

¹*Children's Hospital/Harvard Medical School*, ²*Boston Children's Hospital*

Background: Psychosis and bipolar disorder are debilitating psychiatric disorders that prevent individuals from reaching their optimal level of functioning and are associated with significant economic and medical burden in society. Currently established risk prediction models for psychosis or bipolar disorder were built using specialized, costly, help-seeking samples and are focused on a single psychiatric disorder. While these approaches are valuable, only ~4-13% of individuals who present with first episode psychosis to mental health care centers were

previously seen through these programs prior to diagnosis. Furthermore, early diagnoses of psychosis and bipolar disorder are often unstable, suggesting that a transdiagnostic approach may be more effective. A recent study used data from a Finland registry to find that hospital presentation with self-harm was an indicator of elevated risk for later development of psychotic or bipolar disorder. Among children and adolescents who presented with self-harm, ~20% later received a diagnosis of psychosis or bipolar disorder. Yet, such an approach has not been validated in the United States of America (USA). Electronic Health Records (EHRs) offer a unique opportunity to assess self-harm presentation as a marker of psychiatric risk in the USA primary health care system.

Methods: We extracted EHR records from Boston Children's Hospital (Oct 2015-August 2023) on individuals 6-28 years old at the first incidence. After excluding individuals with less than 2 years of active diagnostic records, and those missing ICD-10-CM information, our final sample consisted of 157,708 individuals (mean age (SD)=12.98 (3.89) years, 52.5% female). We used ICD-10-CM diagnosis codes to identify records of presentation with self-harm and first diagnoses of psychotic and bipolar disorder. We conducted Cox proportional hazard analyses, to assess the relationship between hospital presentation with self-harm and receiving a diagnosis of psychotic or bipolar disorder. We also examined presentation with self-harm to any type of medical center (including outpatient settings) as a possible predictor. We then examined the ability of other known risk factors for psychosis and bipolar disorder (e.g, post-traumatic stress disorder, childhood maltreatment) to predict these outcomes. Covariates for all models included race, ethnicity, and birth year.

Results: Hospital presentation with self-harm was associated with a greater likelihood of developing a psychotic or bipolar disorder (hazard ratio [HR]=9.1, 95 % Confidence Interval [CI]=5.0-16.5, $p=2.9\text{e-}13$). 11% of individuals who presented with hospital presentation of self-harm went on to receive a diagnosis of a psychotic or bipolar disorder. This association between hospital presentation of self-harm and psychotic/bipolar disorder remained present (HR=2.9, CI=1.6-5.2, $p=5.2\text{e-}04$) when we included an ICD-10 diagnosis of a depressive disorder in the model (HR=6.5, CI=5.8-7.3, $p=5.8\text{e-}239$). With hospital presentation of self-harm also included in the model as a predictor, other notable predictors of psychotic or bipolar disorder included anxiety disorders (HR=5.8, CI=5.2-6.4, $p=4.1\text{e-}214$), attention-deficit hyperactivity disorder (HR=4.2, CI=3.8-4.7, $p=1.6\text{e-}143$), post-traumatic stress disorder (HR=7.8, CI=6.6-9.3, $p=1.6\text{e-}121$), obsessive-compulsive disorder (HR=4.3, CI=3.4-5.4, $p=1.6\text{e-}36$), childhood maltreatment (HR=3.4, CI=2.0-5.6, $p=4.4\text{e-}06$). Presentation to any type of medical center with self-harm was also associated with increased likelihood of developing a psychotic or bipolar disorder (HR=4.3, CI=2.9-6.4, $p=6.6\text{e-}13$).

Conclusions: This study adds to the building body of research showing that individuals with hospital presentation of self-harm are at significantly elevated risk for developing a diagnosis of psychotic or bipolar disorder. This research highlights the need to monitor and provide treatment to this high-risk group. Furthermore, to our knowledge, this is the first documentation of this relationship in a U.S. cohort and shows that this relationship is not restricted to European registry samples. In the future, we plan to look at the ability to improve our risk prediction model by including all significant univariate predictors combined. We also plan to test how our ability to predict those at greatest risk improves when we use natural language processing models to gather self-harm information from clinical notes.

32.2. CAPACITY FOR PSYCHOSIS PREDICTION USING THE FAMILIAL HIGH RISK APPROACHES: A FINNISH TOTAL POPULATION STUDY

Colm Healy*¹

¹University College Dublin

Background: Psychotic disorders have a strong hereditary component. Children who have a parent with a psychotic disorder have an increased risk of developing psychosis themselves. However, despite many studies demonstrating this increased risk, no research to date has quantified what proportion of all psychosis cases in the population are captured by this familial high-risk (FHR-P) approach. This is essential information for prevention research and health service planning, as it tells us the total proportion of psychosis cases that this high risk approach stands to prevent if we were to identify an effective treatment. Beyond this, we also wished to assess the same questions using a broader familial risk approach: looking at psychosis risk in individuals who have a parent who has attended mental health services for any mental disorder (not just psychosis), FHR-MD.

Methods: Data linkage from multiple Finnish registries were used to; 1) identify all individuals born between 1987-1992 (the index children); 2) examine their history of non-affective psychosis and schizophrenia based on a secondary care registry with inpatient and outpatient data; and 3) examine their parent's history of mental disorder which was based on inpatient registries. FHR-P and FHR-MD were defined as a parental diagnosis that occurred prior to the index child's 13th birthday and were based on a harmonized grouping of ICD-8, 9 and 10 codes. Outcome diagnoses in the index children, by ages 25-30, of non-affective psychosis and schizophrenia were defined using ICD 10 coding (F2X and F20, respectively).

Results: Of the index children (n=384,549), 1.5% (n=5,754) had FHR-P and 10.2% (n=39,313) had FHR-MD. By their late 20s, 1.7% (n=6,333) of the index children had been diagnosed with non-affective psychosis and 0.5% (n=1,799) had been diagnosed with schizophrenia. Of all non-affective psychosis cases in the index children, 5.3% (n=333) were captured by FHR-P and 20.4% (n=1292) were captured by FHR-MD. Of all schizophrenia cases in the index children, 6.4% (n=114) were captured by FHR-P and 21.5% (n=386) were captured by FHR-MD. The absolute risk of non-affective psychosis in the index children with FHR-P or FHR-MD was 5.8% and 3.3%, respectively. The absolute risk of schizophrenia in the index children with FHR-P or FHR-MD was 2.0% and 1.0%, respectively. Sensitivity analysis indicated that the absolute risk and capacity from FHR-P and FHR-MD were equivalent in mothers and fathers of the index children.

Conclusions: The FHR-P approach captures only a small proportion of all future psychosis cases but this is similar to the proportion of cases captured with the Clinical High Risk approach. The FHR-MD approach captures a substantially larger proportion of future psychosis cases. The absolute risk for non-affective psychosis from both FHR approaches was low but additional factors may improve prediction precision of these approaches and may ultimately aid in the prevention of psychosis.

32.3. PREDICTING PSYCHOTIC DISORDERS WITHIN ADOLESCENT PSYCHIATRY SERVICES – NATIONWIDE REGISTER-BASED STUDY

Ulla Lång*¹

¹*Finnish National Institute of Health and Welfare*

Background: We recently showed that as many as half of all psychotic disorders in the population emerge in individuals who have attended child and adolescent psychiatry services. There are, therefore, enormous opportunities for psychosis prediction and prevention within these services. In the current study, we wished to assess whether it is possible to stratify the level of risk among subgroups of patients attending adolescent psychiatry services.

Methods: Finnish healthcare registers capture extensive data on population healthcare usage, including all contacts with specialist mental health services. We linked Finnish population wide health care register data for all individuals born in 1987-1992 who had attended adolescent

psychiatry services between ages 13-18 years (N=26,195). Using logistic regression models, we assessed whether psychotic disorders after age 18 were predicted by 1) adolescent mental disorder diagnoses and 2) other clinical and demographic factors, including sex, season of birth, personal history of inpatient psychiatric treatment in adolescence, parental history of psychosis, and mother's education level.

Results: Of all individuals who had attended adolescent psychiatry, 9.8% (N=2,556) went on to be diagnosed with a psychotic disorder in adulthood. Looking at adolescent mental disorder diagnoses as risk factors for later psychosis, risk was broadly distributed across diagnoses. However, being assigned diagnoses from multiple mental disorder categories in adolescence was associated with higher risk of adult psychosis. The absolute risk of psychosis was 7.8% in individuals who left adolescent psychiatry services (at age 18 years) with 1 mental disorder category, 12.4% for 2 mental disorder categories, and 20.0% for 3 or more mental disorder categories. Higher risk of adult psychosis was predicted by (1) inpatient psychiatric treatment in adolescence (OR 2.0 95% CI 1.8-2.1), (2) parental history of psychosis (OR 1.7 95% CI 1.4-2.1), and (3) lower socio-economic status (OR 1.3 95% CI 1.0-1.5), but not by sex, season of birth or mother's education level. The absolute risk of psychosis among adolescent psychiatry patients varied from 4.7% for those who did not have an inpatient adolescent psychiatry admission, had no parental history of psychosis, and had the highest socioeconomic status to 28.7% for those who had one or more inpatient adolescent psychiatry admission, had a family history of psychosis, and were in the lowest socioeconomic status group.

Conclusions: Our findings show that there are important opportunities to identify risk for psychosis in young patients attending adolescent psychiatry services and highlight the need for research on psychosis prevention within this clinical population.

32.4. RISK FACTORS FOR LATER PSYCHOSIS IN INDIVIDUALS WHO ATTENDED CHILD AND ADOLESCENT MENTAL HEALTH SERVICES IN THE UNITED KINGDOM

Kirstie O'Hare*¹

¹*University of Edinburgh*

Background: Recent findings indicate that a large proportion of psychosis diagnoses occur in individuals who had attended Child and Adolescent Mental Health Services (CAMHS) earlier in life. CAMHS therefore appears to represent a high-risk, high-capacity system for identifying individuals at risk of psychosis. The ability to further refine prediction of psychosis within a CAMHS sample could facilitate the delivery of preventative interventions to those most at risk. Our aim was to examine whether sociodemographic and clinical factors could be used to enhance the prediction of psychosis within a CAMHS sample.

Methods: Using data from the UK Biobank, we investigated whether a range of risk factors were associated with lifetime diagnoses of psychosis within a sample of individuals who had attended CAMHS at least once. Risk factors included: male sex, ethnicity, immigrant status, age at first CAMHS attendance, season of birth, low birthweight, maternal smoking, educational achievement, cigarette smoking, self-harm, cannabis use, and adverse childhood experiences. Univariate and multivariate logistic regression was used to examine associations between these risk factors with lifetime diagnoses of psychosis (including non-affective psychosis and bipolar disorders).

Results: Of all individuals who had attended CAMHS, 10.3% had a lifetime diagnosis of psychosis. In univariate models male sex, minority ethnic group, a first CAMHS attendance in adolescence, not having a secondary school qualification, and self-harm, were all associated

with an increased risk of psychosis. In multivariate models only male sex, minority ethnic group, and a first CAMHS attendance in adolescence were associated with a diagnosis of psychosis. The absolute risk of psychosis ranged from 4.7% for individuals who were female, belonged to a white ethnic group, and had first attended CAMHS during childhood, through to 35.7% for individuals who were male, belonged to a minority ethnic group, and had first attended CAMHS during adolescence.

Conclusions: A small number of sociodemographic and clinical factors that are readily available to clinicians may be useful for aiding in the identification of individuals at a very elevated risk of psychosis.

Plenary Session VI - Jari Tiihonen: Antipsychotic Treatment of Schizophrenia: Real-World Evidence from National Cohorts

2:00 p.m. - 3:00 p.m.

33. ANTIPSYCHOTIC TREATMENT OF SCHIZOPHRENIA: REAL-WORLD EVIDENCE FROM NATIONAL COHORTS

Laila Asmal, *University of Stellenbosch*

33.1. ANTIPSYCHOTIC TREATMENT OF SCHIZOPHRENIA: REAL-WORLD EVIDENCE FROM NATIONAL COHORTS

Jari Tiihonen, *Karolinska Institutet*

Individual Abstract: The current treatment guidelines are largely based on randomized controlled trials (RCTs), but also observational studies have provided substantial contributions to evidence-based medicine. RCTs provide information on the efficacy of treatments in standardized settings in selected patient populations, i.e. they tell us if the treatment can work in optimal conditions. Well-conducted observational studies can inform us about the effectiveness of drugs, indicating whether or not these treatments actually work in a real-life setting. Both of these approaches have their pros and cons. In RCTs, randomization eliminates the selection bias, which is a problem in observational studies. On the other hand, highly selected patient populations, limited number of participants, and relatively short follow-up periods in RCTs make it very difficult to study relatively rare outcomes such as death, suicide, or severe adverse effects of medications. Using large unselected nation-wide patient cohorts can overcome these obstacles. Nordic countries with comprehensive nation-wide registers provide good possibilities for pharmacoepidemiological research. During the last decade, within-individual analysis has been utilized increasingly to eliminate selection bias related to time-invariant characteristics, such as sex, genetics, and initial severity of illness. This research has increased the knowledge on the effectiveness of the pharmacological treatments in schizophrenia, and has contributed to national treatment guidelines in several countries. This lecture will review how the big data have provided new insights to the associations between antipsychotic treatments and mortality, risk of relapse, risk of long-term adverse effects such as breast cancer, hematological cancer, and general physical morbidity, dopamine supersensitivity and breakthrough psychosis, and occupational functional outcome among patients with schizophrenia. Development of new methodological tools has enabled also modelling of dose-response effects of medications with these outcomes.

Concurrent Symposia

3:00 p.m. - 5:00 p.m.

34. APPROACHES TO IMPROVING THE QUALITY OF EARLY PSYCHOSIS INTERVENTION SERVICES

George Foussias, *Centre for Addiction and Mental Health*

Overall Symposia Abstract: Early psychosis intervention (EPI) offers timely, comprehensive treatment for young people with psychosis and their families. While it has been widely implemented, there is a high degree of variation in how the model is delivered. Furthermore, models have failed to improve psychosis recovery rates and functional outcomes at the population level. Increasingly, evaluation mechanisms are being implemented to help to ensure model fidelity, quality, and access with the aim of improving outcomes in EPI. This symposium will examine some of the mechanisms being used to improve EPI service delivery and outcomes. First, N. Kozloff (Ontario, Canada) will present the “EPI-SET” study, which implemented the NAVIGATE model of coordinated specialty care in 6 EPI programs in Ontario, Canada. She will present on the primary objectives at one year, including fidelity, individual-level outcomes, and youth and family engagement. M. Ferrari (Quebec, Canada) will present the 3-year implementation evaluation of “SARPEP,” the first rapid learning health system for first-episode psychosis in Canada. I. Bello (New York, USA) will present the development of a data visualization dashboard to support OnTrackNY, a state-and federally funded learning healthcare system for early psychotic disorder. N. Stefanis (Greece) will discuss his experience leading the first system-wide implementation of EPI services in Greece. L. Dixon, who directs the Center for Practice Innovations (CPI) at the New York State Psychiatric Institute which oversees OnTrackNY as well as a range of other evidenced based practices for persons diagnosed with serious mental illness, will highlight key themes across these efforts to improve EPI service delivery and lead a discussion to help attendees consider application to their local contexts. The highlighted research initiatives advance EPI service delivery and evaluation with the potential to improve patient and family experience and outcomes and clinician experience related to this population.

34.1. IMPROVING OUTCOMES IN EARLY PSYCHOSIS INTERVENTION THROUGH NAVIGATE IMPLEMENTATION: ONE-YEAR FINDINGS OF THE ONTARIO “EPI-SET” STUDY

Nicole Kozloff¹, George Foussias¹, Marleine Saliba¹, Emily Panzarella¹, Rakshita Kathuria¹, Kiran Jassal¹, Rsha Soud¹, Augustina Ampofo¹, Lillian Duda¹, Alexia Polillo¹, Janet Durbin¹, Paul Kurdyak¹, Sanjeev Sockalingam¹, Aristotle Voineskos¹

¹*Centre for Addiction and Mental Health*

Background: While Ontario has a relatively well-developed system of over 50 early psychosis intervention (EPI) programs delivering care informed by a set of program standards, surveys and fidelity reviews suggest that programs struggle to consistently deliver evidence-based, recovery-oriented services. NAVIGATE is a manualized model of coordinated specialty care integrating evidence-based interventions for early psychosis. NAVIGATE was implemented in 6 geographically diverse EPI programs across Ontario starting in 2019 in the “Early Psychosis Intervention: Spreading Evidence-based Treatment (EPI-SET)” study. The primary

objectives of this implementation-effectiveness study were to 1) assess implementation of NAVIGATE and whether this leads to improvement in fidelity to the EPI standards; 2) determine longitudinal change in functioning and symptoms among individuals receiving NAVIGATE; 3) evaluate youth and family member engagement in the study; 4) compare system-level outcomes (i.e. health service utilization, suicide attempts, mortality and system costs) associated with receipt of NAVIGATE. One-year results were measures for the first 3 objectives.

Methods: We assessed fidelity to EPI standards using the First Episode Psychosis Services Fidelity Scale (FEPS-FS; Addington et al, 2020), with 31 items rated on a scale from 1 (not implemented) to 5 (fully implemented). Trained assessors conducted baseline assessments prior to NAVIGATE implementation (T1) and a second assessment 20 months later after most clients had at least one year of exposure to the model (T2). Fidelity ratings were based on staff interviews, administrative data and client chart data. We calculated mean T1 and T2 fidelity scores at the item, domain and total scale levels. For the individual-level outcomes, we recruited 100 participants ages 14 to 35 years who met criteria for a DSM-5 schizophrenia spectrum disorder, substance-induced psychotic disorder, or mood disorder with psychotic features and had received less than 2 years of services in an EPI-SET site prior to enrolment between 2020-2022. Participants complete outcome measures at baseline and every 6 months over 2 years, including the Quality of Life Scale (QLS), the Social and Occupational Functioning Assessment Score (SOFAS), the World Health Organization Disability Assessment Schedule 2.0 (WHODAS), and Brief Psychiatric Rating Scale (BPRS). Change in outcome measures over the first 12 months was evaluated using linear mixed models. Youth advisors completed the modified Public Patient Engagement Evaluation Tool (PPEET) tool every 3 months and family advisors completed the tool monthly (their preferred frequency) to measure their experience of engagement. We administer the PPEET to YAC members every 3 months and FAC members monthly as recommended by participating advisors. Responses are rated on a scale from 1 (strongly disagree) to 5 (strongly agree). Percentage who rated each item at least 4 were calculated for each advisory group for each year of the study.

Results: The mean fidelity score across the 6 EPI-SET sites increased from 3.82 to 4.05 from T1 to T2. At the domain level, mean ratings increased for team practice (4.14 to 4.45) and psychosocial treatments (2.79 to 3.77). Participants were a mean age of 22.7 ± 4.2 years, 58% were male, 62% identified as White, and 33% were unemployed and not in school. Participants exhibited a significant improvement in QLS scores ($F(82.2,2) = 13.129$, $p < .001$), and SOFAS score ($F(53.9,1) = 47.890$, $p < .001$). There was also a trend for improvement in overall symptoms as measured by the BPRS ($F(87.6,2) = 2.802$, $p = .066$). There were no significant changes over time in WHODAS scores. Percentage of youth advisors with a favourable response to the engagement items ranged from 84-87% in the first year and 93-96% in the third year of the study. Eighty-three to eighty-six percent of family advisors in year 1 and 82-87% in year 3 had favourable responses to the engagement items.

Conclusions: Early data following the implementation of the NAVIGATE model of coordinated specialty care in Ontario EPI programs suggest that it was associated with improvements in fidelity to the EPI standards and patient outcomes. Youth and family advisors were highly engaged in the project. Evaluation at the study endpoint at 2 years is required to inform efforts aimed at sustaining quality of services and positive outcomes over the long term.

34.2. DEVELOPMENT OF DATA VISUALIZATION TO IMPROVE THE DELIVERY OF ONTRACKNY EARLY INTERVENTION SERVICES

Iruma Bello^{*1}, Ana Stefancic², Igor Malinovsky¹, Marleen Radigan³

¹*College of Physicians and Surgeons, Columbia University*, ²*Columbia University Medical Center*, ³*New York State Office of Mental Health*

Background: OnTrackNY (OTNY) is a state-and federally funded learning healthcare system (LHS) providing specialized early intervention services to adolescents and young adults with early psychotic disorder across New York state. It was awarded funding by the National Institute of Mental Health to become a regional hub within the Early Psychosis Intervention Network (EPINET), a national LHS for young adults with early psychosis. OTNY consists of 28 CSC teams receiving support from an intermediary organization, OnTrack Central, on CSC model implementation. OnTrack Central is supported by the New York State Office of Mental Health as an intermediary purveyor organization. It oversees the implementation of the OTNY model through the delivery of training and technical assistance, data collection, and fidelity assessments. Programmatic and outcome data for all OTNY participants are submitted by primary clinicians on a quarterly basis using standardized admission, follow-up, and discharge forms. OnTrack Central coordinates with OMH to aggregate de-identified participant and program data and provides monthly reports to teams for quality improvement. However, to impact individual-level care, the OTNY LHS recognized the need have providers access participant-level data. This presentation will describe the process for developing a data visualization dashboard that provides teams with participant-level data that can be utilized to guide treatment decisions and model implementation.

Methods: A User-Centered Design framework, Discover, Design, Build and Test (DDBT) was used to maximize key stakeholder engagement at each phase of the project. The Discover phase involved 12 provider key informant interviews (KII) eliciting feedback on key data elements to include. Findings were shared with OnTrack Central, who identified additional data elements in response to provider feedback. Design and Build Phases: A 10-member key stakeholders committee (KSC) met monthly for one year, to discuss the feedback received and design a dashboard in Tableau. An iterative process was used to inform the KSC that included two focus groups (FGs) and a survey with a total of 11 stakeholders and five cognitive walk throughs for usability testing.

Results: The Discover phase indicated that providers preferred a dashboard that was accessible to different team members, depicting outcomes that were important to participants, and could be connected to fidelity indicators, to guide model implementation. During the Design and Build phases, feedback from the FGs and interviews highlighted the need to use clear language and formatting to facilitate understanding of data represented. Providers emphasized the need to be provided with flags and suggestions related to data trends. Overall, the survey data indicated consensus (100% of 11 respondents) that the content of the dashboard was useful to the work.

Conclusions: The use of data to guide treatment decisions could be facilitated by a visualization dashboard that reflects the priorities of program participants and providers. Results indicate that to increase the usability of a dashboard, it needs to be easily accessible, the data need to be presented in an intuitively clear format and represent key elements and outcomes of CSC. Connecting the dashboard to data collection process by including reminders and fidelity indicators was also deemed very important by providers. The next phase of this project will consist of piloting the dashboard with all teams throughout the network and creating mechanisms for feedback within the LHS to understand how it is being used to make individual level care decisions and whether it can impact the implementation of OTNY to fidelity.

34.3. IMPLEMENTING A RAPID-LEARNING HEALTH SYSTEM IN EARLY INTERVENTION SERVICES FOR PSYCHOSIS IN QUÉBEC, CANADA: REFLECTING ON INDICATORS AND TECHNOLOGIES

Manuela Ferrari^{*1}, Marc-André Roy², Srividya N. Iyer³, Camille Arbaud⁴, Annie LeBlanc⁵, Amal Abdel-Baki⁴

¹*McGill University and Douglas Mental Health Institute*, ²*l'Université Laval, Institut Universitaire en Santé Mentale de Québec, Centre de Recherche de l'Institut Universitaire en Santé Mentale de Québec*, ³*McGill University; Douglas Mental Health University Institute*, , ⁴*Centre Hospitalier de l'Université de Montréal*, ⁵*Université Laval*

Background: Psychosis typically emerges during the major developmental period between ages 15-30, with profound personal, family and socio-economic impacts, and has a lifetime prevalence of 3%-3.5%. The risks are high for social and vocational difficulties, long-term disability, and tragic outcomes like violence or suicide. Early intervention services (EIS) are the treatment of choice for psychosis in Québec/Canada, Australia, the US, and Denmark. More effective than routine care, EIS respond to problems of treatment delay and challenges arising in the first crucial 2-5 years, like poor service engagement and medication nonadherence. EIS for psychosis have operated for over 20 years in Canada, with Québec, British Columbia, Nova Scotia, and Ontario leading the creation of guidelines. Yet, similar to experience elsewhere, EIS implementation in Canada shows a lack of standards in some jurisdictions. Systematic monitoring of quality indicators and outcomes is lacking, and problems persist in integrating essential organizational components, despite the availability of fidelity measures. Rapid learning health systems (RLHS) embed data collection in clinical settings for real-time, problem-focused learning and continuous quality improvement. SARPEP (Système Apprenant Rapide pour les Programmes de Premiers Épisodes Psychotiques), the first rapid learning health system for first-episode psychosis in Canada, was designed and implemented to test the feasibility and acceptability of the new RLHS, bridging the gap between evidence and practices.

Methods: The first 3-year implementation of the SARPEP project, which involved 11 early intervention services (EIS) from urban, semi-rural, and rural areas, was evaluated using a mixed method design grounded in the Reach, Effectiveness, Adoption, Implementation, Maintenance (RE-AIM) framework. Six focus groups were conducted with participants (n=24) from different stakeholder groups (two with service users, and one each with family members, psychiatrists, managers, and team leaders) who shared their experiences with the implementation of the RLHS.

Results: All invited EIS agreed to participate in the RLHS and completed all components (systematic monitoring of program and patient-level indicators; capacity-building activities). Study participants confirmed the value of introducing a standardized, measurement-based, digital system through SARPEP for routine collection and sharing of program-level data. Reach: SARPEP recruited 11 clinics, 90+ healthcare professionals, 33 psychiatrists, 12 team leaders, five patient and four family partners. All invited EIS agreed to participate in the RLHS and completed all components (systematic monitoring of program and patient-level indicators; capacity-building activities). The 11 SARPEP clinics currently care for 2,050+ active patients, adding 734 new cases per year. Effectiveness: key program indicators improved (e.g., time from referral to first contact, continuing education, patient-to-provider ratios), informing the revision of provincial standards. Adoption: all EIS monitored program indicators every 4 months, gradually improving data completion and accuracy. Participation in satisfaction questionnaires by youth and family members remained low, but varied across programs. Stakeholders (n=20-35) attended capacity-building events (knowledge exchange,

implementation meetings). Implementation: the completion time for data collection decreased over the study period from 10 to 3 weeks, as the REDCap system underwent continuous adaptation, creating tools and rapid supports for team leaders. Maintenance: all EIS pledged to maintain their participation and 9 new EIS joined SARPEP after completion of the study.

Conclusions: Implementing SARPEP proved feasible and successful, reaching targeted EIS/participants, who adopted and maintained the RLHS, improving in key program indicators despite the pandemic, and providing a new Québec database of quality care indicators.

34.4. NATIONWIDE COVERAGE OF EARLY INTERVENTION SERVICES FOR PSYCHOSIS IS UNDERWAY IN GREECE

Nikos Stefanis*¹

¹*National and Kapodistrian University of Athens*

Background: What can only be described as an unprecedented thrust in mental health reform is currently underway in Greece. Responding to the recommendation from the Ministry of Health, the Ministry of Finances announced in March 2022 the allocation of considerable funds drawn from the Recovery and Resilience Facility of the European Commission (RRF) for the establishment and operation of initially eight Early Intervention Services for Psychosis (EISP) providing nationwide coverage. Consequently, the Ministry of Health in August 2022 announced a tender in which local mental health Non-Government Organisations could apply either as a single entity or forming partnerships with public mental health institutions, such as University Departments, to claim the establishment of community-based EISP in eight predetermined major cities of the country. The final eight winners of the bid were announced in early December 2022 with an allocated budget of 500,000 Euros per year per service and a mandate to deliver operational services by late 2023. This fortunate development is the accumulation of combined efforts on the one hand by numerous colleagues and stakeholders who have tirelessly advocated for Mental Health Reform in Greece, and on the other a receptive Ministry of Health who responded favorably to public demand.

If one was to trace the origins of the effort, one would probably date it back to 2015, when the Athens First Episode Psychosis (FEP) research study was launched by the A' Department of Psychiatry in Athens, consequently evolving in the first prospective study of FEP in the country. The study provided much-needed local information on clinical outcomes such as the high one-year relapse/readmission rates after initial hospitalization under the existing “treatment as usual” model. This was a prominent argument utilized in consequent debates over the necessity of establishing such community-based EIP services and a sign for a change in policy to occur. Consequently, a committee under the Ministry of Health was formed in late 2018 with a mandate to examine the legal and organizational framework for the implementation of EISP. The current government adopted the recommendations of the committee and proceeded to bring the legislation to Parliament (Official Government Gazette of the Hellenic Republic, A 256 - 23.12.2020) thus establishing EISP as a legal entity within the NHS. Public awareness amongst colleagues and mental health professionals grew even further thanks to the highly successful international WPA Thematic Congress on Early Intervention in Psychiatry, held in Athens in June 2022 (www.wpathematic.org) under the auspice of the Greek Psychiatric Association, the University of Athens, and the Early Intervention in Mental Health international Network (IEPA).

Methods: NONE

Results: NONE

Conclusions: As of October 2023, six such EISP are operational. Even though there is still much to be done, such recent advances raise justified optimism for a new era of reform in community mental health in Greece. However, complacency is unwarranted. The sustainability of government-based funding should be secured in the long run and integration of EISP with existing mental health services may prove to be a challenging process. Nevertheless, it is now undisputed, Greece joins the selected few countries that provide government-based and nationwide coverage of EISP.

35. DECONSTRUCTING THE NEGATIVE SYMPTOM CONCEPT

Emilio Fernandez-Egea, *University of Cambridge*

Overall Symposia Abstract: The reborn interest in the negative symptoms of schizophrenia has led to new assessment tools, large epidemiological studies, new cognitive paradigms.... and the perennial lack of novel and effective interventions. Increasingly, some researchers are moving away from considering negative symptoms a single entity but a construct with at least two dimensions, loosely defined as experiential (motivation) and expressive (emotion), or even five different domains. This is not a semantic discussion as the two dimensions (or five domains) might have distinct pathophysiology and, crucially, treatment. This symposium will explore recent work in against (and in favour) an unitary view of the negative symptoms (Prof Mucci and Dr Fernandez-Egea's talks). Then, we will explore two different approaches to negative symptoms: as a transdiagnostic dimension, with shared pathophysiology in affective, psychotic and neurodegenerative disorder (Dr Robert's talk) or as a specific symptom in schizophrenia, by exploring the clinical and imaging predictors of the primary negative symptoms (Dr Mane talk). We hope this symposium will stimulate a debate about how should negative symptoms be reconceptualised in order to progress in our understanding and treatment.

35.1. EXTERNAL VALIDATION OF NEGATIVE SYMPTOM DOMAINS WITH COGNITIVE AND FUNCTIONING-RELATED VARIABLES IN SUBJECTS WITH SCHIZOPHRENIA

Armida Mucci¹, Giulia Maria Giordano¹, Francesco Sanmarchi², Paola Rucci², Paola Bucci¹, Paola Rocca³, Alessandro Rossi⁴, Alessandro Bertolino⁵, Silvana Galderisi¹, Mario Maj¹

¹*University of Campania Luigi Vanvitelli*, ²*University of Bologna*, ³*University of Turin*,

⁴*University of L'Aquila*, ⁵*University of Bari*

Background: Recent confirmatory factor-analytic studies suggested that the bi-dimensional model (Motivational Deficit-MAP and Expressive Deficit-EXP) may not capture the complexity of negative symptoms (NS) structure, and a 5-factor or a hierarchical model, in which the five NS domains are the first-order factors, and MAP and EXP the second-order factors are proposed. A validation of these models is needed to define the structure of NS.

Methods: To evaluate the validity and temporal stability of the five-factor or the hierarchical structure of the Brief Negative Symptom Scale (BNSS) in individuals with schizophrenia (SCZ), exploring associations between these models with cognition, social cognition, functional capacity, and functioning at baseline and at a four years follow-up.

Clinical variables were assessed using state-of-the art tools in 612 SCZ at two time points. The validity of the five-factor and the hierarchical models was analyzed through structural equation models.

Results: The two models had both a good fit and showed a similar pattern of associations with external validators at the two time points, with minor variations. The five-factor solution had a slightly better fit. The associations with external validators favored the five-factor structure.

Conclusions: Our findings suggest that both the five-factor and the hierarchical models provide a valid conceptualization of NS in relation to external variables and that the 5-factor solution provides the best balance between parsimony and granularity to summarize the BNSS structure. These findings have implications for the study of pathophysiological mechanisms to develop new treatments for negative symptoms.

35.2. CASES: A EUROPEAN STUDY USING DIFFERENT MEASURES OF APATHY AND NEGATIVE SYMPTOMS.

Emilio Fernandez-Egea^{*1}, Stefan Kaiser², Anna Mane³, Armida Mucci⁴, Silvana Galderisi⁴, Gabriel Robert⁵, Philippe Robert⁶

¹*University of Cambridge*, ²*Geneva University Hospitals*, ³*Hospital del Mar*, ⁴*University of Campania Luigi Vanvitelli*, ⁵*University of Rennes*, ⁶*Université Côte d'azur*

Background: Apathy is a quantitatively reduction of goal-directed activity either in behavioural, cognitive, emotional or social dimension in comparison to person's previous level of functioning in these areas. Apathy is prevalent across many neurodegenerative, neurological, and psychiatric disorders. However, the definition and terminology employed to refer to apathy can vary in the context of different conditions and specialties and the diagnostic criteria have evolved overtime and little progress has been achieved in assessing the validity of the same construct across different disorders (eg.

neurodegenerative disorders, schizophrenia or affective disorders). The first diagnostic criteria for apathy (DCA) in neuropsychiatric disorders were published in 2009

(Robert et al. 2009) A group of experts reached a novel consensus in 2018 using Delphi panel methodology (Robert et al. 2018). The validity of this new consensus has yet to be assessed among all relevant populations. This Multicentre PanEuropean study had two aims: The first aim of the present multicenter survey was to test the prevalence of apathy, measured with the 2018 DCA, in patients diagnosed with schizophrenia. The second aim will focus on the relationship between DCA and other measures of apathy and negative symptoms in schizophrenia.

Methods: Cross sectional assessment of schizophrenia patients (18-60 years old) stable on medication from six different centres in France (Rennes and Nice), Switzerland (Geneva), Italy (Naples), Spain (Barcelona) and UK (Cambridge). Sociodemographic and clinical data was collected, as well as structured psychometric scales including: 1) 2018 DCA: Diagnostic criteria for apathy (Robert et al. 2018); 2) PANSS: positive and negative symptoms scale (Kay et al. 1987); 3) BNSS: brief negative symptoms of schizophrenia (Kirkpatrick et al. 2011); 4) AMI: apathy and motivation index (Ang et al. 2017); 5) PSP: Personal and social performance scale (Morosini et al. 2000); 6) BACS: brief assessment of cognition in schizophrenia (Keefe et al. 2004); 7) CDS: Calgary depression scale (Addington et al. 1993); 8) SHRS: St. Hans Rating Scale for extrapyramidal symptoms (Gerlach et al. 1993); 9) M.I.N.I: Mini International Neuropsychiatric Interview (Sheehan et al. 1998).

Results: The study recruited between April 2021 and March 2023, with data consolidated in August 2023. A total of 151 cases were recruited (107 males and 44 female) in all six sites (ranging from 5 to 38 per site) with a mean age of 39.8 years old (SD 11.2). Ninth-one out of the 151 met criteria for apathy using the DCA. Further analysis of the relationship between the DCA, BNSS and AMI will be unveiled at the meeting.

Conclusions: It is crucial that neurology, geriatry and psychiatry find a common lexicon to describe the decrease of goal directed activity. Here, we compared three different system: dichotomic (DCA), clinician rated (BNSS and PANSS) and patient-rated (AMI). DCA might represent a first step towards the convergence of the three fields.

35.3. APATHY AS A TRANSDIAGNOSTIC SYNDROME IN CENTRAL NERVOUS SYSTEM DISEASES AND DISORDERS: WHAT ARE THE FACTS?

Gabriel Robert^{*1}, Jean-Charles Roy¹, Dominique Drapier¹

¹*Rennes University*

Background: Apathy is one of the dimension or facet of negative symptoms in schizophrenia. It is frequently described across central nervous system diseases and disorders (CNS-DD) and iteratively associated with pejorative outcomes, independently of the underlying CNS-DD. Therefore, it raises the question of a trans-diagnostic syndrome. However, it is still unclear how cognitive and cerebral correlates of apathy overlap and what are the differences across and within CNS-DD. Our overarching goal is to systematically identify the cognitive and cerebral correlates of apathy in schizophrenia and other CNS-DD. The secondary goal is to identify the clinical (age, medication, disease duration, socio-educative level) factors that best explain the heterogeneity of cognitive and cerebral correlates of apathy.

Methods: A systematic review following the PRISMA guidelines will be performed using the following term (apathy [title] OR motivation [title] OR goal-oriented [title/abstract]) AND (cogni* [title/abstract] OR neurocogni* [title/abstract] OR dementia [title/abstract] OR schizo* [title/abstract] OR Parkin* [title/abstract] OR alzhei* [title/abstract] OR vascular [title/abstract] OR small vessel [title/abstract] OR lewy [title/abstract] OR depress* [title/abstract]) AND (imaging [title/abstract] OR MRI [title/abstract] OR PET [title/abstract] OR EEG [title/abstract] OR MEG [title/abstract] OR SPECT [title/abstract]) in MEDLINE, EMBASE, PsycINFO, The Cochrane Library, Health Technology Assessment Database, and Web of Science. Two independent reviewers will select the articles and a third will choose for inclusion when conflictual situations. The review is registered in Prospero, currently under review.

Results: The analysis has not been performed yet and following are only preliminary findings. Our search a total of 373 articles have been retrieved, after excluding doubles. However, based on our previous knowledges about apathy cognitive and cerebral correlates, we expect some general findings. Goal-oriented behaviors and cognition, anchored in computational decision making field as well as the executive system, with planning and anticipating positive outcomes, are the two cognitive pillars of apathy in schizophrenia, which are also found in degenerative and major depression disorders. From the cerebral literature, the dopamine-dependent ventral striatum and its projection to the medial prefrontal cortex is also found across CNS-DD, including in schizophrenia. The anterior cingulate and its role in effort devaluation seems also to contribute to apathy pathophysiology in schizophrenia. From a network perspective, the interplay between the central executive, the salience and the default mode networks is also described in schizophrenia. However, other cerebral structures are less robustly found such as the hippocampus and the cerebellar basal ganglia projections. The

systematic review will be able to provide a comprehensive view of the moderating effect size of the clinical factors (age, medication, disease duration, socio-educative level).

Conclusions: The literature of apathy in schizophrenia suggest that there might be cognitive and cerebral correlates across CNS-DD and the vision of a trans-diagnostic apathy syndrome is very appealing. However, some cerebral structures are less robustly found and within and between CNS-DD that influences the results are not known. Additionally, the mechanistic explanations that disrupt these cerebral pathways and cognitive functions vary across CNS-DD, thereby reducing trans-diagnostic therapeutic approaches.

35.4. CAN NEUROIMAGING DETECT THE VULNERABILITY TO PERSISTENT NEGATIVE SYMPTOMS?

Anna Mane*¹, Laura García-Blanco¹, Alba Toll¹

¹*Hospital del Mar,*

Background: Negative symptoms remain a major unmet therapeutic need for people with schizophrenia. Epidemiological studies suggest an increase of the severity of negative symptoms over time. Still, it is unclear whether these are primary negative symptoms or secondary to other factors (psychosis, depression, etc..). In this study, we aimed to predict the presence of persistent negative symptoms after a year of the onset of the disorder, using a multimodal approach of neuroimaging and peripheral biomarkers.

Methods: We recruited 50 drug-naïve patients with first-episode psychosis and 50 age- and sex-matched healthy controls to study brain volumes. We performed univariate and multiple and logistic regression analyses to determine the association between baseline clinical and neurobiological variables, score on the PANSS negative subscale and persistent negative symptoms after 1 year of follow-up.

Results: Low baseline serum BDNF levels ($p = 0.011$), decreased left amygdala relative volume ($p = 0.001$) and more severe negative symptomatology ($p = 0.021$) predicted the severity of negative symptoms at 1 year, as measured by the PANSS negative subscale. Low baseline serum BDNF levels ($p = 0.012$) and decreased left amygdala relative volume ($p = 0.010$) predicted persistent negative symptoms at 1 year.

Conclusions: This study shows that a set of variables at baseline, including low BDNF levels, smaller left amygdala relative volume and score on the PANSS negative subscale are significant predictors of outcome in first-episode psychosis. These findings might offer an initial step for tailoring treatments in first-episode psychosis

36. PROMISES AND PITFALLS OF CLINICAL TRIAL DESIGN: HOW CAN WE BETTER EVALUATE NOVEL TARGET ANTIPSYCHOTICS?

Anthony Grace, *University of Pittsburgh*

Overall Symposia Abstract: Clinical trials are an essential means to evaluate clinical efficacy of new medications. However, many agents that appeared to be highly effective in preclinical studies and early stage evaluations failed in the multi-center trials. This could be due to several factors, including the lack of efficacy across a broad population, or a trial design that is ineffective at identifying novel target compounds. These limitations could prevent the entry of more effective medications that may be highly beneficial to the patient populations. For example, it may be that some medications are only effective in subgroups of patients, and denying their entry would limit the ability of these patients to receive effective treatment. The other issue is the trial design itself. Thus, many clinical trials for e.g. antipsychotic drugs have

relied on the principle that once a drug is washed out of the system over a 1-2 week period, a new medication can be introduced. While this has been effective in identifying “me-too” D2 antagonist antipsychotic drugs, there is the strong potential that the drug that the patient had been given for long periods of time has altered the system in such a way that only another drug of the same class can be effective. Indeed, in preclinical studies it has been shown that the D2 supersensitivity induced by 3 weeks of treatment with the D2 antagonist haloperidol interfered with the efficacy of a novel GABAergic drug that was found to be highly effective in non-pre-exposed animal models. In this panel, we will discuss the potential limitations of current clinical trial design, and how these shortcomings may be circumvented. Dr. Ines Khadimallah will present data showing that the antioxidant N-acetyl cysteine is only effective in patients in the early phase psychosis showing high oxidative status and mitochondrial impairments. In a randomized double blind clinical trial with supplementation of NAC, patients’ subgroup with high baseline plasma exosomal levels of microRNA-137, the key regulator of mitochondrial oxidative stress, showed significant improvements of cognitive and functional outcomes. The latter was associated with a reduction in exosomal microRNA-137 levels. Dr. Stefan Gold will present the EU-PEARL project, an IMI-funded private-public partnership that jointly developed an adaptive platform trial for treatment resistant depression and how this may serve as a blueprint for clinical trials that can increase efficiency, speed, comparability, and patient-centricity in mental health. Dr Stephen Wood will discuss the benefits of clinical trials networks as platforms for delivering rapid, high quality trials of novel treatments, with a particular focus on the Australian early psychosis network. Dr. Anthony Grace will present preclinical data showing that drugs such as pomaglumetad, which failed in large multicenter trials, was highly effective in reversing the pathophysiology in a developmental disruption model of schizophrenia. A reason for this discrepancy is suggested by his studies showing that prior exposure to D2 antagonist antipsychotic drugs interfere with potential therapeutic actions of a novel target compound, a GABA A alpha 5 PAM. He will also present a unique approach for investigating novel target antipsychotic drugs without extended withdrawal periods. Dr. Pat McGorry will then provide an integration and describe how trial designs may be modified to more effectively test novel compounds for efficacy.

36.1. N-ACETYL-CYSTEINE (NAC) INTERVENTION AND MITOCHONDRIAL MECHANISMS IN EARLY PSYCHOSIS: COGNITIVE AND FUNCTIONAL IMPROVEMENTS

Ines Khadimallah^{*1}, Martine Cleusix², Raoul Jenni¹, Paul Klauser¹, Kim Do³, Philippe Conus², Luis Alamedad²

¹*Center for Psychiatric Neuroscience, Lausanne University Hospital*, ²*Service of General Psychiatry, Centre Hospitalier Universitaire Vaudois (CHUV) and University of Lausanne (UNIL)*, ³*Lausanne University*

Background: Schizophrenia (SZ) is associated with neurocognitive dysfunction already in the early phase of the disease. However, cognitive impairments are poorly treated by pharmacological interventions, leaving severe problems in functioning (Green et al., 2000). Redox dysregulation and oxidative stress emerge as a central pathological mechanism underlying schizophrenia (Cuenod et, 2023). Individuals with SZ show increased oxidative damage and reduced antioxidant capacity. Impairments of fast-spiking GABA parvalbumin interneurons (PVI), leading to cortical excitatory-inhibitory imbalance, underlie cognitive deficit. A variety of models relevant to SZ and psychotic disorders, converge on oxidative

stress induced PVI integrity impairment as a common underlying pathway (Steullet and Cabungcal et al, 2017). In a proof-of-concept trial in patients with early psychosis (EPP), the antioxidant N-acetyl-cysteine (NAC) increased prefrontal glutathione levels in a small subgroup of patients, thus suggesting target engagement. NAC improved moderately processing speed (Conus et al., 2017) with no effect on other clinical symptoms. However, in a subgroup of patients with high blood oxidative markers at baseline, NAC improved positive symptoms, in parallel with changes in peripheral redox status, (Conus et al., 2017).

To search for biomarkers capturing circuitry dysfunction needed for patient stratification, we have identified a molecular mechanism linking mitochondria and oxidative stress induced PVI impairments. Oxidative stress upregulates the microRNA miR-137 in PVI, a gene strongly associated with SZ (Ripke et al., 2011), leading to decreased COX6A2, a subunit of cytochrome c oxidase complex IV specific to PVI, and impaired mitophagy with mitochondrial damage accumulation (Khadimallah et al., 2022). In EPP, high miR-137 and low COX6A2 plasma exosomal biomarkers allow to select with high accuracy patients with worse psychopathological status and neurocognitive performance, and impaired global and social functioning. We now aim to compare the effect of NAC between subgroups of patients with and without mitochondria dysfunction.

Methods: The study was a 6-month, double-blind, randomized, placebo-controlled trial of NAC supplementation (2700 mg/d) to standard medications. Sixty-one patients (31 NAC, 30 placebo) with a diagnostic of psychotic disorder and less than 12 months of antipsychotic treatment were enrolled. We assessed and compared in NAC and placebo groups at baseline and at the end of treatment: 1) Neurocognition using with the MATRICS Consensus Cognitive Battery (MCCB) (Nuechterlein et al., 2008). b) Global assessment of functioning (GAF), c) Brain-derived exosomal levels of miR-137 and COX6A2.

Results: Patients with high baseline plasma exosomal miR-137 levels in the NAC group showed significant improvements in processing speed, attention/vigilance, and GAF. The amelioration in processing speed within the NAC group was inversely correlated with exosomal miR-137 levels. Moreover, an improvement of GAF was positively linked to higher COX6A2 exosomal levels in both NAC and placebo groups.

Conclusions: The addition of NAC significantly improved neurocognition and functional outcome in early psychosis patients, particularly in those with mitochondrial dysfunction, in parallel with associated biomarkers miR-137 and COX6A2. If replicated in larger studies, in particular with treatment focusing on mitochondrial mechanisms, our results would open the way for personalized and mechanistically guided treatments.

36.2. THE EU-PEARL INTEGRATED PLATFORM TRIAL FOR MAJOR DEPRESSION

Stefan Gold*¹

¹*Charite University Medical Center Berlin*

Background: Clinical trials are at the core of evidence-based medicine. However, in psychiatry, the trials conducted often fail to inform clinical practice because many are underpowered. Moreover, the available treatments only work for a subset of patients and the number of new regulatory approvals in psychiatry has consistently lagged behind other areas of medicine, such as oncology, infectious diseases, or neurology. Thus, there is an urgent need for a more efficient, faster and more collaborative way of evaluating the safety and efficacy of new and repurposed drugs as well as comparative effectiveness data for medications already in use.

Traditionally, treatments are evaluated in individual trials, with participants randomized to the intervention or a control group, each trial conducted in a specific setting and requiring its own infrastructure, which is dismantled after completion of the trial. This approach is slow, not very efficient, and limits comparability across trials. In contrast, a platform trial uses a shared infrastructure for many treatments, a shared control group, and allows new treatments to be added over time. Importantly, platform trials also require fewer participants overall and fewer participants will receive control/placebo treatments in this setting. This approach can thus increase the speed at which data on safety and efficacy are obtained, reduce operational costs and participant burden, and increase statistical power and comparability. Platform trials have successfully been used in fields like oncology, and – more recently – during the COVID pandemic.

Methods: The EU-PEARL project, an EU-funded public private partnership, has thus developed a similar approach for the mental health field by building a reusable multinational infrastructure, operated by an open collaborative consortium, to run an integrated platform trial for new and repurposed treatments for depression.

Our integrated platform trial (IPT) consists of 3 components: A trial site network, a longitudinal observational cohort (LOC), and the platform trial itself. The platform trial will evaluate investigational (new as well as repurposed) drugs for treating treatment-resistant depression (TRD) in a proof of concept (PoC) / phase 2 setting.

Results: This IPT has been co-designed with lived experience experts and informed by extensive trial simulations to test the efficacy and safety of combination or augmentation strategies over a 6-week period with long-term follow-up within the observational cohort. The trial can accommodate different routes of administration (“domains” of the trial) and the protocol allows for flexibility in the samples size of each arm (ranging from N=40 to N=120), with blinding ensured and controls shared within each domain (but not across domains).

Conclusions: In this presentation, I will describe the development of this platform trial and discuss its advantages and challenges for accelerating evidence generation in mental health.

36.3. CLINICAL TRIALS NETWORKS AS PLATFORMS FOR DELIVERING BETTER TRIALS: THE AUSTRALIAN EARLY PSYCHOSIS COLLABORATIVE CONSORTIUM

Stephen Wood*¹, Patrick McGorry², Michael Berk³, Sue Cotton², Eóin Killackey², Barnaby Nelson², Alison Yung³, G Paul Amminger², Brian O'Donoghue⁴, Aswin Ratheesh², Mario Alvarez-Jimenez², Deborah Rickwood⁵, Andrew Thompson²

¹University of Melbourne, ²Orygen; The University of Melbourne, ³Deakin University,

⁴University College Dublin, ⁵Headspace

Background: Although early intervention services for psychosis now have Cochrane level 1 evidence for their effectiveness for many outcomes, real-world outcomes at a population level such as quality of life, cognitive and physical health impairments, and social and occupational disability for many young people could be improved. Trialling new interventions in early psychosis populations can be challenging because of the large number of young people required for eligibility screening to secure suitable study-specific clinical trial participation, especially for important sub-groups such as those with delayed recovery. There are similar challenges in the area of indicated prevention for psychosis and the Ultra High Risk paradigm which has also developed rapidly over the last few decades. Whilst profiling risk and new treatments have

emerged, no first line treatment has been firmly established and larger trials and co-ordinated monitoring of outcomes are needed to further progress the field.

Methods: One option to significantly enhance the depth, breadth, and quality of the evidence base is through a Clinical Trials Network (CTN). CTNs bring together clinicians, primary healthcare, and research professionals to design and conduct clinical trials that provide high-level evidence about which treatments work and are most cost-effective in clinical practice and other real-world practice settings. CTNs provide access to multiple health service centres, a myriad of healthcare practitioners and academic professionals, and thousands of participants/patients. In addition, through the establishment of standard training, processes and research operational documents, CTNs reduce the variation between health services, clinical trials sites, and jurisdictional requirements while streamlining budget and governance negotiations in order to shorten start up times and reduce duplication of resource effort.

Results: In Australia we have set up a CTN for early psychosis as part of the Australian Early Psychosis Collaborative Consortium (AEPCC). Australia is already a world leader in the design and conduct of high impact clinical trials across the investigator-initiated and commercial sectors, a reputation which is built on a strong, collaborative foundation of CTNs. We particularly wanted our CTN to have a strong translational role and therefore have intentionally labelled ourselves as a Clinical Trials and Translation Network (CTTN), and have adopted a “Facilitating Network” organisational model in which the network facilitates the set-up, national reach and delivery of clinical trials but does not conduct them.

Conclusions: CTNs can provide leadership for world-class, large, and cost-effective multicentre trials answering the key clinical research questions relevant to schizophrenia. They can optimise value for research investment by ensuring the most important questions are prioritised and also develop ‘living’ systematic reviews and guidelines, implement and evaluate uptake of Clinical Care Standards and facilitate closer collaboration with our stakeholders, to ensure evidence is more rapidly taken up into practice, policy and education curricula. Through training and mentoring of clinicians and researchers at all career stages they can also enable the next generation to continue this work.

36.4. PRECLINICAL STUDIES OF STANDARD AND NOVEL TARGET ANTIPSYCHOTIC DRUGS IN ANIMAL MODELS OF SCHIZOPHRENIA: INSIGHTS INTO WHY CLINICAL TRIALS MAY HAVE FAILED TO RECAPITULATE PRECLINICAL FINDINGS

Anthony Grace^{*1}, Daniela Uliana¹, Susan Sonnenschein¹

¹*University of Pittsburgh*

Background: Accumulating evidence suggests that the DA system is not the primary driver of pathology in schizophrenia. Instead, substantial research has focused on hippocampal dysregulation driving the DA dysfunction underlying psychosis and contributing to cognitive and negative symptoms. However, several agents that target normalization of the hippocampal circuit, while showing promise in preclinical studies and in early clinical trials, have failed in large multicenter studies. However, we posit that classic clinical trial design may not be effective at evaluating novel target agents. Indeed, we found that pomaglumetad was highly effective in developmental disruption and prepubertal stress models of schizophrenia in its ability to normalize hippocampal function and reverse the hyperdopaminergic state, but despite showing early promise in initial trials, this drug also failed in large clinical trials. Based on evidence presented here we posit that prior treatment of patients with D2 antagonist antipsychotic drugs, by inducing D2 supersensitivity, obscured the potential therapeutic actions

of these novel compounds. We then examined if there was a way in which we can circumvent the confound of prior drug administration when testing the actions of novel target compounds.

Methods: Pregnant Sprague Dawley rats were administered with MAM (20mg/kg) at gestational day 17 and the male offspring were tested as adults. We tested the effects of acute and repeated (3 weeks) treatment with pomaglumetad or a novel GABA A alpha 5 positive allosteric modulator (PAM) on DA and hippocampal neuron activity. In another cohort of rats, we examined the impact of aripiprazole vs olanzapine on DA neuron activity. DA neuron population activity was assessed by making 9 electrode tracks through the ventral tegmentum and assessing number of DA neurons active, firing rate and pattern.

Results: We found that MAM-treated offspring showed increased activity in the limbic ventral hippocampus and an increase in the number of DA neurons spontaneously active, consistent with studies in schizophrenia patients. Acute administration of the GABA A alpha 5 PAMs (2 types) consistently reversed hippocampal hyperactivity and normalized DA neuron firing as well as amphetamine hyperlocomotion in the MAM model. However, after pretreatment of MAM rats with haloperidol for 3 weeks and 1 week withdrawal, this compound was no longer effective at reversing DA dysfunction, which we propose is due to D2 supersensitivity. Pomaglumetad was also effective in normalizing DA neuron function and hippocampal hyperactivity via a direct action within the hippocampus. In another study, animals that were treated with olanzapine for 3-4 weeks were found to exhibit an induction of DA neuron depolarization block; we posit that this inactivation of DA neuron firing drove the induction of DA supersensitivity. In contrast, when we administered aripiprazole, a D2 partial agonist, either acutely or for 3-4 weeks, there was an inhibition of DA neuron firing in the MAM model; however, this was not accompanied by depolarization block, but instead appears to be due to a direct DA agonist inhibition of DA neuron activity.

Conclusions: These data support the hypothesis that prior administration of a D2 antagonist drug and a short withdrawal period interfered with the actions of novel target compounds by confounding D2 supersensitivity. While withdrawing patients from antipsychotic drugs for a sufficient period to normalize D2 receptors, which may require months, is not ethically feasible, our data suggest that transitioning patients from an effective compound that does not induce supersensitivity, such as aripiprazole, may be a more effective strategy. Alternately, while it is not ethically feasible to withdraw patients from an antipsychotic drug for extended periods, it is known that a large number of patients are not compliant with their current medication. If we can test novel compounds either on demonstrably noncompliant patients or patients early in their treatment, we may have a more effective strategy for testing the efficacy of these compounds in the treatment of schizophrenia.

37. PREVENTION AND PREDICTION IN PSYCHOSIS; FROM IMAGING TO ETHICS WITH PROTEINS, SOCIAL FACTORS AND METABOLISM ON THE JOURNEY

David Cotter, *Royal College of Surgeons in Ireland*

Overall Symposia Abstract: In psychosis, as in medicine, we aim to treat better by treating early. If tools become available to allow the prediction of psychotic disorders, then primary prevention could be facilitated, or the trajectory of illness diverted. However, prediction is imperfect and the gains from early treatments must outweigh the risks at both population and individual levels. Ethical issues come to the fore here, and perhaps these issues need to be reconsidered before we proceed too far down the road of prevention. This symposium aims to do just that.

First, Sophia Frangou will focus on the prediction of symptoms and diagnosis using normative models of brain morphometry. Using cortical and subcortical regional brain imaging data from over 37,000 healthy individuals, the model parameters were applied to the regional morphometric data of individuals at clinical high-risk for psychosis, and individuals at the early stages of psychosis from the Human Connectome Project – Early Psychosis. The study found that the distribution of the normative regional morphometric measures from Individuals in the HCP-EP and CHR-P groups overlapped nearly completely with that of the healthy individuals. These findings challenge the usefulness of macroscale morphometric measures as predictive biomarkers of psychosis. Jonah Byrne will present the performance of an a priori-specified proteomic prediction model of transition from clinical high-risk to psychotic disorder. In the largest study of its kind to date, plasma samples were collected from participants in three CHR cohorts: the North American Prodrome Longitudinal Studies 2 and 3, and the NEURAPRO randomized control trial (total n=754). This study did not confirm the findings from a previous protein-based prediction model of transition from CHR to psychosis, although certain complement proteins may be weakly associated with transition at a group level. Benjamin Perry focuses on cardiometabolic dysfunction in young people with psychotic disorders across the globe as the most important contributor to a shortened life expectancy of 15-20 years. The Psychosis Metabolic Risk Calculator (PsyMetRiC) has been externally validated in the UK and internationally. Here Benjamin Perry will detail consistent evidence that PsyMetRiC maintains its predictive performance and potential for clinical usefulness across borders. Tecelli Dominguez will present an investigation into psychosocial factors associated with the risk of developing psychosis in a Mexican general population. Overall, the findings highlight a distinction between psychosocial contributors to psychosis vulnerability in different sociocultural contexts, which will contribute to better context-targeted preventive intervention efforts. Finally, Natalie Lane as discussant will overview the presentations and bring an overarching ethical perspective to this area of prevention and prediction in psychosis.

37.1. PREDICTING SYMPTOMS AND DIAGNOSIS USING NORMATIVE MODELS OF BRAIN MORPHOMETRY

Sophia Frangou*¹

¹*Icahn School of Medicine at Mount Sinai*

Background: The lack of robust neuroanatomical predictors of psychosis has been traditionally attributed to heterogeneity. Here we tested the alternative hypothesis that the neuroanatomical measures in the majority of individuals with psychosis or at psychosis risk are not discriminative as they are nested within the normal variation.

Methods: We created CentileBrain an empirically validated framework for the normative modeling of FreeSurfer-derived cortical and subcortical regional morphometric measures from an international, pooled sample of 37,437 healthy individuals through our collaboration with the ENIGMA Lifespan Working Group. The model parameters are freely available at <https://centilebrain.org/>. The model parameters were applied to the regional morphometric data of individuals at clinical-high-risk for psychosis (CHR-P; N= 1,340) from the ENIGMA CHR-P Working Group and individuals at the early stages of psychosis from the Human Connectome Project – Early Psychosis Study (HCP-EP; N=

For each morphometric measure, the normative deviation z-scores were used to define supranormal (z GREATER THAN 1.96) and infranormal ((z LESS THAN -1.96) values.

Results: The distribution of the normative regional morphometric measures from Individuals in the HCP-EP and CHR-P groups overlapped nearly completely with that of the healthy individuals. The proportion of individuals in the HCP-EP and CHR-P groups with infranormal or supranormal values in any regional measure was low (LESS THAN 12%) and similar to that of healthy individuals. CHR-P converters versus CHR-P non-converters had a higher percentage of infranormal values in temporal regions (5–7% vs 0.9–1.4%). Neither observed nor normative morphometric measures distinguished cases (CHR-P or HCP-EP) from controls. In both groups, normative deviation scores explained a trivial amount of variance in psychotic symptoms and general cognitive ability

Conclusions: These findings challenge the usefulness of macroscale morphometric measures as predictive biomarkers of psychosis.

37.2. PROTEOMIC BIOMARKERS FOR THE PREDICTION OF TRANSITION TO PSYCHOSIS IN INDIVIDUALS AT CLINICAL HIGH RISK - A MULTI-COHORT MODEL DEVELOPMENT STUDY

Jonah Byrne^{*1}, Colm Healy², Melanie Föcking², Subash Raj Susai², David Mongan³, Kieran Wynne⁴, Eleftheria Kodosaki⁵, Meike Heurich⁵, Lieuwe de Haan⁶, Ian Hickie⁷, Stefan Smesny⁸, Andrew Thompson⁹, Connie Markulev⁹, Alison Ruth Yung¹⁰, Miriam Schaefer⁹, Anita Riecher-Rössler¹¹, Nilufar Mossaheb¹², Gregor Berger¹³, Monika Schlögelhofer¹⁴, Merete Nordentoft¹⁵, Eric YH Chen¹⁶, Swapna Verma¹⁷, Dorien H. Nieman⁶, Scott Woods¹⁸, Barbara Cornblatt¹⁹, William Stone²⁰, Daniel Mathalon²¹, Carrie Bearden²², Kristin Cadenhead²³, Jean Addington²⁴, Elaine Walker²⁵, Tyrone D. ¹Royal College of Surgeons in Ireland, ²RCSI University of Medicine and Health Sciences, ³Queen's University Belfast, ⁴Proteome Research Centre, University College Dublin, ⁵Cardiff University, ⁶Academic Medical Center, University of Amsterdam, ⁷Brain and Mind Centre, University of Sydney, ⁸University Hospital Jena, ⁹Orygen, The National Centre of Excellence in Youth Mental Health, ¹⁰University of Manchester, ¹¹University of Basel, ¹²Medical University of Vienna, ¹³University of Zurich, ¹⁴BioPsyC, ¹⁵University of Copenhagen, ¹⁶The University of Hong Kong, ¹⁷Institute of Mental Health, Singapore, ¹⁸Yale University, ¹⁹Zucker Hillside Hospital, ²⁰Harvard Medical School/Beth Israel Deaconess Medical Center, ²¹University of California, San Francisco, ²²University of California, Los Angeles, ²³University of California, San Diego, ²⁴University of Calgary, ²⁵Emory University, ²⁶University of North Carolina at Chapel Hill

Background: Psychosis risk prediction is one of the leading challenges in psychiatry. Previous investigations have suggested that plasma proteomic data may be useful in accurately predicting transition to psychosis in individuals at clinical high risk (CHR). We hypothesized that an a priori-specified proteomic prediction model would have strong predictive accuracy for psychosis risk and aimed to replicate longitudinal associations between plasma proteins and transition to psychosis.

Methods: Plasma samples were collected from participants in three CHR cohorts: the North American Prodrome Longitudinal Studies 2 and 3, and the NEURAPRO randomised control trial (total n=754). Plasma proteomic data were quantified using mass spectrometry. The

primary outcome was transition to psychosis over the study follow-up period. Logistic regression models were internally validated, and optimism-corrected performance metrics derived with a bootstrap procedure.

Results: In the overall sample of CHR participants (age: 18.5, SD: 3.9; 51.9% male), 20.4% (n=154) developed psychosis within 4.4 years. The a priori-specified model showed poor risk-prediction accuracy for the development of psychosis (C-statistic: 0.51 [95% CI: 0.50, 0.59], calibration slope: 0.45). At a group level, Complement C8B, C4B, C5 and leucine-rich α -2 glycoprotein 1 (LRG1) were associated with transition to psychosis but did not survive correction for multiple comparisons.

Conclusions: This study did not confirm the findings from a previous protein-based prediction model of transition from CHR to psychosis. Certain complement proteins may be weakly associated with transition at a group level. Previous findings, derived from small samples, should be interpreted with caution.

37.3. THE PSYCHOSIS METABOLIC RISK CALCULATOR (PSYMETRIC): VALIDATION & REFINEMENT ACROSS CONTINENTS

Benjamin Perry^{*1}, Emanuele Osimo², Graham Murray¹, Rachel Upthegrove³

¹University of Cambridge, ²Imperial College London, ³University of Cambridge, ³University of Birmingham

Background: Cardiometabolic dysfunction is common in young people with psychotic disorders across the globe, and is the most important contributor to a shortened life expectancy of 15-20 years in people with psychotic disorders. Recently, the Psychosis Metabolic Risk Calculator (PsyMetRiC) was developed and externally validated in the UK, predicting up-to six-year risk of metabolic syndrome (MetS) from routinely collected data. However, clinical risk prediction algorithms can only be confirmed to be suitable for populations they have been tested in, and international populations are likely to vary in ethnicity; culture and dietary habits; average population health, healthcare access; social norms, behaviours and attitudes, and legislation.

Methods: In order to bring PsyMetRiC closer to a globally-useful tool for clinicians and researchers, we performed detailed external validation analysis of PsyMetRiC in multiple continents including Europe (Spain, Switzerland, Finland); North America (Quebec); East Asia (Hong Kong); and Australasia (Sydney). In each sample, predictive performance was assessed using measures of discrimination (C-statistic); calibration (calibration plots), and clinical usefulness (decision curve analysis), as recommended. Furthermore, we considered site-specific recalibration of the intercept and slope terms (i.e., logistic calibration) to tune PsyMetRiC to the individual populations.

Results: Analyses are ongoing and will be finalised prior to the Congress. However, in summary, we have found consistent evidence that PsyMetRiC maintains its predictive performance and potential clinical usefulness across borders. In each international setting, as expected due to population differences we found differing degrees of miscalibration. However, this was fully corrected following site-specific recalibration.

Conclusions: PsyMetRiC has the potential to be generalisable for use across international borders. Our findings can pave the way toward a future globally-useful bedside tool to encourage personalized treatment decisions with the aim of improving the long-term physical health of young people with psychotic disorders.

37.4. PSYCHOSOCIAL FACTORS ASSOCIATED WITH THE RISK OF DEVELOPING PSYCHOSIS IN A MEXICAN GENERAL POPULATION SAMPLE

Tecelli Dominguez*¹, Tamara Sheinbaum², Ana Fresán², Lourdes Nieto², Rebeca Robles², Steven R López³, César Celada², Mauricio Rosel², Ricardo Saracco², Neus Barrantes Vidal⁴

¹*Instituto Nacional de Psiquiatría "Ramón de la Fuente Muñiz"*, ²*National Institute of Psychiatry*, ³*University of Southern California*, ⁴*Universitat Autònoma de Barcelona, Spain*

Background: Epidemiological evidence has linked an array of sociodemographic and psychosocial factors with an increased risk of developing psychosis. However, there is a lack of research on samples from low- and middle-income countries, where early psychosis programs are still scarce. This study used a Mexican sample to explore (i) sociodemographic and psychosocial differences between individuals with and without a positive screen for Clinical High-Risk for psychosis (CHR), and (ii) sociodemographic and psychosocial factors associated with screening positive for CHR.

Methods: The sample consisted of 1519 individuals from the general population who completed an online survey. Of the participants, 18.8% (n = 286) met the CHR screening criteria. Participants were assigned to the CHR-positive group if they met the established cut-offs on both the Prodromal Questionnaire (PQ-B: GREATER THAN 6 item rated as positive and distress score ≥ 29) and Social Functioning Questionnaire (SFQ: score ≥ 10).

Results: Comparisons between those who screened positive (CHR-positive group) and those who did not (non-CHR group) showed that participants in the CHR-positive group were younger ($t=2.9$; $p=0.003$), had a lower educational level ($\chi^2=36.7$, p LESS THAN 0.001), and reported more mental health problems than the non-CHR group ($\chi^2=59.9$, p LESS THAN 0.001). In the Non-CHR group, there were more participants with a partner ($\chi^2=9.6$, $p=0.05$) and of upper-middle class ($\chi^2=11.0$, $p=0.004$) than in the CHR group ($\chi^2=11.0$, $p=0.004$). Furthermore, relative to the non-CHR group, the CHR-positive group had a greater prevalence of medium/high risk associated with cannabis use, a higher prevalence of adverse experiences (i.e. bullying, intimate partner violence, and experiencing a violent or unexpected death of a relative or friend), as well as higher levels of childhood maltreatment, poorer family functioning, and more distress associated with the COVID-19 pandemic. Finally, when examined in multivariate analyses, the variables associated with screening positive for CHR were: having an unhealthy family functioning (OR=2,75; IC 95%: 1,87-4,04; p LESS THAN 0.001), a higher risk associated with cannabis use (OR=2,45; IC 95%: 1,70-3,54; p LESS THAN 0.001), a lower level of education (OR=1,90; IC 95%: 1,42-2,55; p LESS THAN 0.001), having experienced a violent or unexpected death of a relative or friend (OR=1,36, IC 95%: 1,01-1,82; p LESS THAN 0.05), higher levels of childhood emotional abuse (OR= 2,25, IC 95%: 1,52-3,34; p LESS THAN 0.001), physical neglect (OR=1,53, IC 95%: 1,11-2,08; p LESS THAN 0.01), and physical abuse (OR=1,40, IC 95%: 1,03-1,92; p LESS THAN 0.05), bullying (OR=1,40, IC 95%: 1,02-1,93; p LESS THAN 0.05), and higher COVID-related distress (OR=1,13, IC 95%: 1,07-1,20).

Conclusions: Overall, the findings highlight the importance of examining potential psychosocial contributors to psychosis vulnerability across different sociocultural contexts to delineate risk and protective processes relevant to specific populations and better target preventive intervention efforts.

38. DOPAMINERGIC IMPAIRMENT IN SCHIZOPHRENIA: FROM MECHANISMS TO NEW THERAPEUTIC TARGETS

Dragos Inta, *University of Fribourg*

Overall Symposia Abstract: Converging evidence implicate dopaminergic impairment in the pathophysiology of schizophrenia (SCZ). However, both the underlying pathogenic mechanisms and the superior therapeutic action of several atypical antipsychotics related to dopamine are not yet understood, hampering the development of more efficient therapies. We aim to discuss new aspects of molecular and cellular factors associated with dopaminergic dysfunction in SCZ, including innovative models and technologies, such as the Monocyte-Derived-Neuronal-like cells (MDNCs) or PharmacoSTORM.

Dr. Bellon will present data about neurostructural effects of dopamine in MDNCs in SCZ. Excessive pruning is considered the cause of the most consistent finding in SCZ, namely decreased brain volume. However, obtaining developing neurons from living patients is not feasible. He used a new protocol to transdifferentiate human circulating monocytes into neuronal-like cells, MDNCs that structurally resemble developing human neurons, as model to study the effect of dopamine on pruning of neuronal extension. His results indicate that MDNCs from patients grow more extensively and prune more primary neurites when exposed to dopamine than that of controls.

Dr. Inta will talk about the development and role of the Islands of Calleja (ICj), a largely understudied new site of adult neurogenesis in the ventral striatum, expressing highest levels of dopamine D3 receptors (D3R) in the brain. Recent dating studies showed robust adult neurogenesis in the human striatum. He will present data about the occurrence of this process in rodents and primates and the ICj as preferential target for antipsychotics effective also against negative symptoms of SCZ (clozapine, cariprazine, xanomeline and emraclidine).

Dr. Prokop will present data obtained by using PharmacoSTORM, a novel fluorescent-ligand based framework that unifies advanced pharmacology and super-resolution anatomical studies and allows the exact receptor binding profile of drugs at nanoscale. She demonstrated that the majority of fluorescent cariprazine molecules bind to D3R in the ICj in the mouse brain. Moreover, her three-dimensional reconstruction of high-affinity drug binding sites unveiled that the ICj represent an unexpectedly large continuous network of granule cells. She further showed that they are densely innervated by dopaminergic fibers and that D3R are localized mostly extrasynaptically, suggesting that D3R play a key role in dopaminergic volume transmission.

Dr. Papaleo will present results regarding the astrocytic regulation of basal ganglia dopamine-dependent behaviors with relevance for SCZ. Astrocytic involvement in sensory processing and its role in SCZ are unknown. He will show data on the consequences of the disruption of the SCZ-associated dysbindin Dys1A, the only isoform expressed by astrocytes on motivation and sensorimotor gating deficits, as well as astrocytic dopamine D2 receptors and dopaminergic tone within basal ganglia. His results reveal the role of astrocytes in motivational and sensory processes through Dys1A/dopamine-dependent mechanisms within the basal ganglia, suggesting them as therapeutic target in SCZ.

38.1. INCREASED PRUNING IN RESPONSE TO DOPAMINE IN NEURONAL-LIKE CELLS FROM PATIENTS WITH SCHIZOPHRENIA

Alfredo Bellon*¹

¹*Penn State Hershey Medical Center*

Background: Dopamine, a neurotransmitter consistently associated with the pathophysiology of schizophrenia (SCZ), participates in several aspects of brain development including pruning of neuronal extensions. Excessive pruning is considered a plausible etiological factor of decrease brain volume in SCZ. Therefore, we hypothesize that patients with SCZ carry an increased susceptibility to dopamine's pruning effects and that this susceptibility would be more obvious in the early stages of neuronal development when dopamine pruning effects are more prominent.

Methods: Since obtaining developing neurons from living patients is not feasible, we used Monocyte-Derived-Neuronal-like Cells (MDNCs). These cells are obtained from a standard blood sample and can be generated in only 20 days. The characterization of MDNCs involved electrophysiology, flow cytometry, immunofluorescence, qPCR, single cell mRNA sequencing as well as other techniques including comparing its structure to that of human developing neurons (HDNs) in vitro. We have tested the reproducibility of MDNCs in two separate studies. We have tested our transdifferentiation protocol in over 100 individuals including males and females.

Results: MDNCs respond similar to HDNs when exposed to colchicine, an agent that elicits pruning of neuronal extensions. We then studied MDNCs from 12 controls and 13 patients with SCZ and we found that patients' MDNCs differentiate more efficiently, extend longer secondary neurites and grow more primary neurites. Moreover, MDNCs from medicated patients expresses less dopamine 1 receptor (D1R) and prune more primary neurites when exposed to dopamine. D1R participates in pruning of primary neurites in MDNCs. Haloperidol did not influence our results but the role of other antipsychotics could not be excluded and is currently under investigation.

Conclusions: MDNCs mimic the structure of HDN in vitro. MDNCs also reproduce the pruning of neuronal extensions found in HDN when exposed to colchicine. In addition, patients with SCZ show structural differences in MDNCs when compared to cells from controls, while a subpopulation of patients evidence increased pruning in response to dopamine.

38.2. ISLANDS OF CALLEJA: THE HIDDEN NEUROANATOMICAL SUBSTRATE IN THE MECHANISM OF CARIPRAZINE

Susanne Prokop^{*1}, Péter Ábrányi-Balogh², Benjámín Barti¹, Miklós Zöldi¹, Márton Vámosi³, Barna Dudok⁴, Gabriella Urbán³, László Barna³, Attila Egyed², Hui Deng⁵, Gian Marco Leggio⁶, András D. Tóth⁷, Mario van der Stelt⁸, László Hunyady⁷, György M. Keserű², István Katona³

¹*Institute of Experimental Medicine*, ²*Research Centre for Natural Sciences*, ⁴*Stanford University*, ⁵*Leiden University and Oncode Institute*, ⁶*University of Catania*, ⁷*Semmelweis University*, ⁸*Leiden University and Oncode Institute*,

Background: A comprehensive understanding of the mechanisms of existing clinical compounds is crucial to enhance the efficacy and minimize the side effects of future neuropsychiatric treatments. While in vitro pharmacological assays can provide the exact receptor binding profile of drugs, it is increasingly acknowledged that the same drug-target interaction can differently modulate complex neuronal networks in the brain, depending on its cell-type and subcellular compartment-specific localization. On the other hand, a significant gap exists in the availability of techniques capable of visualizing cell-type specific drug-target interactions within complex tissue specimens.

Methods: We've addressed this gap with the development of PharmacoSTORM, a novel fluorescent-ligand based framework that unifies advanced pharmacology and super-resolution anatomical studies. Our innovation is supported by robust computational drug design and

refined chemical methodologies, enabling the development of fluorescent analogues of drugs for multiscale anatomical studies, including Stochastic Optical Reconstruction Microscopy (STORM) super-resolution imaging.

Results: We presented our workflow by the investigation of cariprazine, a rapidly emerging new medication (Vraylar™/Reagila™). Cariprazine displays unique efficacy against the negative symptoms of schizophrenia and is approved for acute manic/mixed, or depressive episodes associated with bipolar I disorder. However, the neuroanatomical substance that mediates its unique therapeutic effectiveness remains elusive. We demonstrated that the majority of fluorescent cariprazine molecules bind to a largely understudied subregion of the ventral striatum, the Islands of Calleja (IoC) in the mouse brain. Moreover, our three-dimensional reconstruction of high-affinity drug binding sites unveiled that the IoC represents an unexpectedly large continuous network of granule cells. Cell-type specific nanoscale PharmacostORM imaging revealed that fluorescent cariprazine molecules bind D3 dopamine receptors (D3Rs) on the axons of granule cells, which represent the principal cell-type of this enigmatic brain region. We further showed that the IoC is densely innervated by dopaminergic fibers and found that D3Rs localized mostly extrasynaptically, suggesting that these receptors play a key role in dopaminergic volume transmission. Additionally, we demonstrated that the nanoscale binding sites of fluorescent compound in the IoC represent real in vivo targets of the original, unlabeled antipsychotic, cariprazine.

Conclusions: Our results highlight the potential importance of IoC granule cells in neuropsychiatric diseases and their enormous potential as future pharmacological targets.

38.3. POSTNATAL NEUROGENESIS IN THE STRIATUM: LINKING NEURODEVELOPMENTAL TO DOPAMINERGIC DYSFUNCTION IN SCHIZOPHRENIA WITH FOCUS ON THE ISLANDS OF CALLEJA

Dragos Inta*¹

¹*University of Fribourg*

Background: For long time, the hippocampal dentate gyrus was the only brain region in which adult neurogenesis had been demonstrated in humans. This situation recently changed due to radiocarbon-14 dating that provided evidence for robust neurogenesis of specific, mostly calretinin (CR)-positive GABAergic interneurons in the adult human striatum. Similar adult-generated interneurons were described as well in the striatum of other species; however, the main focus of research continues to be on adult neurogenesis in the olfactory bulb, which is most likely absent or occurring at very low level in the human brain. The extent and the significance of this process for neuropsychiatric disorders are still unknown.

Methods: Fate-mapping studies in wildtype mice and rats and transgenic 5-HT3-EGFP and D3-EGFP mice that allow the in vivo labelling of newborn neurons migrating from the subventricular zone (SVZ) into the striatum under physiological conditions and following treatment with antipsychotics or electroconvulsive seizure (ECS)

Results: At postnatal stages many SVZ neuroblasts migrate from the SVZ into subcortical areas, nucleus accumbens and ventral striatum. Postnatally-generated neurons belong to two classes of small-size GABAergic interneurons: CR-positive interneurons and CR-negative granule cells forming the Islands of Calleja (ICj). The ICj receive dense dopaminergic projections from the ventral tegmental area and substantia nigra, expressing high levels of dopamine D3 receptors. Moreover, they are preferentially targeted by efficient antipsychotics like clozapine, cariprazine and xanomelin/emraclidine. ECS massively stimulates neurogenesis in the SVZ and striatum resulting in similar newborn CR-positive interneurons. Most ECS-

triggered newborn interneurons were found in the medial striatum, which is part of the limbic circuitry, with afferents from the medial prefrontal and cingulate cortices.

Conclusions: The striatum represents a main, yet poorly investigated area of postnatal neurogenesis in the mammalian brain, the ICj a possible link between ongoing abnormal neurogenesis and striatal dopaminergic dysfunction. Rodents appear to represent a valid model for investigating postnatal/adult striatal neurogenesis, showing similar neuronal subtypes. ECS strongly stimulates neurogenesis in the adult striatum. The implications for striatal neuroplasticity and the dopamine system, as well as for schizophrenia are discussed.

38.4. ASTROCYTIC MODULATION OF DOPAMINE AND BASAL GANGLIA DEPENDENT BEHAVIORS RELEVANT TO SCHIZOPHRENIA

Francesco Papaleo*¹, Zisis Bimpisidis²

¹*Istituto Italiano Di Tecnologia*, ²*Istituto Italiano di Tecnologia*

Background: The mechanisms underlying the dichotomic cortical/basal ganglia dopaminergic abnormalities in schizophrenia are unclear. Astrocytes are important non-neuronal modulators of brain circuits, but their role in dopaminergic system remains poorly explored.

Methods: Microarray analyses, immunohistochemistry, fiber photometry, optogenetics, two-photon laser scanning microscopy, in vivo recordings and manipulations in mice.

Results: We revealed that Dys1 hypofunction increases the reactivity of astrocytes, which express only the Dys1A isoform. Notably, behavioral and electrochemical assessments in mice selectively lacking the Dys1A isoform unraveled a more prominent impact of Dys1A in behavioral and dopaminergic/D2 alterations related to basal ganglia, but not cortical functioning. Ex vivo electron microscopy and protein expression analyses indicated that selective Dys1A disruption might alter intra-cellular trafficking in astrocytes, but not in neurons. In agreement, Dys1A disruption only in astrocytes resulted in decreased motivation and sensorimotor gating deficits, increased astrocytic dopamine D2 receptors and decreased dopaminergic tone within basal ganglia. These processes might have clinical relevance because the caudate, but not the cortex, of patients with schizophrenia shows a reduction of the Dys1A isoform.

Conclusions: we started to show a hitherto unknown role for the Dys1A isoform in astrocytic-related modulation of basal ganglia behavioral and dopaminergic phenotypes, with relevance to schizophrenia.

39. RETHINKING RELAPSE: PREVENTION AND PREDICTION

Rob McCutcheon, *University of Oxford*

Overall Symposia Abstract: Most individuals with a psychotic disorder will experience a relapse and this is linked to poorer long-term outcomes. Relapse is associated with the discontinuation of antipsychotic medication, but many individuals with psychotic disorders would like to reduce or discontinue medication. To improve clinical outcomes we need to know how to minimise risk of relapse when reducing antipsychotic medication, and how to predict which individuals are likely to relapse. The current symposium will provide an overview of current research addressing these crucial issues.

Dr Hui will present results from a one year prospective follow up study demonstrating the ability of cognitive measures to predict relapse. Dr McCutcheon will present analyses of individual patient data from 5 relapse prevention clinical trials, investigating whether absolute receptor occupancy and rate of occupancy reduction are associated with the timing of relapse.

Dr Rubio will describe how both neuroimaging and clinical data may predict both breakthrough psychosis and relapse following antipsychotic discontinuation. Dr Brand will discuss how risk of relapse changes over the menopause and how hormone replacement therapy may reduce relapse risk. Prof Murray will act as discussant to synthesise these findings and consider what the next steps for the field are.

39.1. COGNITIVE DETERIORATION IN PREDICTING RELAPSE IN PSYCHOTIC DISORDERS

Christy Hui¹, Tiffany Junchen Tao¹, Yi Nam Suen¹, Edwin Ho Ming Lee¹, Sherry Kit Wa Chan¹, Wing Chung Chang¹, Eric Yu Hai Chen¹, Eric YH Chen^{*2}

¹The University of Hong Kong, ²Nanyang Technical University LKC School of Medicine

Background: Relapse is common after the first episode of psychosis and can have potentially irreversible consequences, yet it is poorly understood and difficult to predict. Examining changes in cognitive function preceding relapse may be useful in enriching our understanding towards the underlying mechanism of psychotic relapse. It is hypothesized that relapse in fully remitted psychosis patients was preceded by working memory deterioration.

Methods: This was a prospective 1-year follow-up study of 110 psychosis patients in full clinical remission. The primary outcome of relapse (recurrence of positive symptoms of psychosis), visual (Visual Patterns Test) and verbal (Letter-Number Span Test) working memory were assessed monthly. Other clinical, functioning and psychosocial predictors were also examined at baseline.

Results: The 1-year relapse rate was 16% (18 of 110). Multiple logistic regression analyses showed that relapse was predicted by verbal working memory deterioration 2 months prior to relapse ($p = 0.029$), worse medication adherence ($p = 0.018$), and poor resilience ($p = 0.014$). The model explained about 60% of the variance in the relapse outcome (Nagelkerke $R^2 = 0.582$).

Conclusions: Our finding in cognitive deterioration as an early sign of relapse echoes the previous literature that cognitive deficits are present even during the prodromal phase of the disorders, as well as associated with the conversion to full-blown psychosis. These testable and objective markers in cognitive function provide valuable information to inform timely intervention in relapse prevention.

39.2. DOES SLOW AND STEADY WIN THE RACE? ANTIPSYCHOTIC DISCONTINUATION AND PSYCHOTIC RELAPSE

Rob McCutcheon^{*1}, David Taylor², Jose Rubio³, Joseph Nour⁴, Robin Murray⁵, Sameer Jauhar⁵

¹University of Oxford, ²Maudsley Hospital, Denmark Hill, London and Institute of Pharmaceutical Science, King's College London, ³Northwell Health, ⁴East London NHS Foundation Trust, ⁵Institute of Psychiatry, King's College

Background: Antipsychotics are recommended for prevention of relapse in schizophrenia. It is unclear whether increased risk of relapse following antipsychotic discontinuation is predominantly associated with absolute magnitude of dose reduction or rate of antipsychotic reduction. Establishing the responsible mechanism is important, as prolonged withdrawal schedules have been suggested to reduce risk of relapse.

Methods: Individual patient data from antipsychotic discontinuation studies were obtained. We estimated occupancy of receptors over time using half-lives and ED50 values obtained from pharmacokinetic and receptor occupancy studies. Hazard ratios for relapse events were calculated using cox proportional hazards models to assess the influence of formulation (oral, 1-monthly, and 3-monthly injection). The change in hazard ratio over time was estimated, and the effect of time varying covariates was calculated including rate of occupancy reduction and absolute receptor occupancy.

Results: 5 studies including 1,388 participants with schizophrenia were identified (k=2: oral, k=2: 1-monthly injection, k=1: 3-monthly injection). Withdrawal of long-acting injectable medication did not lead to a lower hazard ratio compared to withdrawal of oral medication and this included the period immediately following randomisation. Hazard ratios were not associated with the rate of decline of receptor occupancy however they were associated with reduced absolute occupancy in trials of long-acting injections (p=0.038).

Conclusions: Antipsychotic discontinuation is associated with an increased risk of psychotic relapse, related to receptor occupancy. While relapse does not appear to be related to the rate of discontinuation, gradual discontinuation strategies may allow for easier antipsychotic reinstatement in case of symptomatic worsening.

39.3. INDIVIDUAL ESTIMATION OF RELAPSE RISK IN INDIVIDUALS WITH SCHIZOPHRENIA

Jose Rubio*¹

¹*Northwell Health*

Background: Over 80% of individuals with schizophrenia will have multiple episodes of acute psychosis over their lifetime. Relapses may have irreversible consequences, such as decreasing responsiveness to antipsychotic drugs, and may be dangerous to self/others. Most often relapses occur in the context of treatment interruption, however some individuals will still relapse despite ongoing relapse-prevention treatment. Whether relapses occur after treatment interruption or despite treatment exposure has important therapeutic and neurobiological consequences, but this distinction is often uncertain since non-adherence is common but difficult to predict. To study the neurobiology of relapse without the confounding of non-adherence, we work with individuals who are treated with long-acting injectable (LAI) antipsychotics, for whom adherence at the time of relapse can be easily confirmed.

Methods: We scanned individuals with a psychotic disorder who had been treated with a LAI for at least 3 months. The fMRI scan consisted in 2 runs of 594 volumes each at TR=0.72, amounting to approximately 15 minutes of resting state. We used the resting state scan to calculate individual Striatal Connectivity Indices, a biomarker that summarizes functional connections of the striatum associated with treatment response. In validation studies, lower SCI scores have been correlated with treatment responsiveness. After the baseline scans, individuals were followed up monthly for up to 1 year (or until dropout or LAI discontinuation), assessing symptom severity measured with BPRS, and whether relapse criteria (psychosis BPRS subscore worsening GREATER THAN 25% since baseline and CGI-I GREATER THAN =6) were met. Participants who relapsed were scanned again at that time, and non-relapsing participants matched for sex, age and duration since baseline scan were scanned as well as a control condition. Individual symptom trajectories were calculated as the random slope of the psychosis BPRS subscore over time in a mixed model. For the analyses, we studied the effect of baseline SCI scores on time to meeting relapse criteria using a Cox regression, and whether changes in SCI scores correlate with symptom trajectory in LAI treated individuals.

Results: Out of 56 individuals for whom we did obtain baseline MRI scans, we had longitudinal MRI data for 28, out of whom 11 met relapse criteria despite guaranteed antipsychotic treatment. In our sample, 34 (61.8%) participants were men, mean age was 32.01 (SD=10.31) years old, and race was non-white for 44 (74.5%) individuals. Baseline scans were not predictive of time to relapse (HR=1.17, 95%CI=0.87-1.44), and similarly, they did not predict symptom trajectory ($r = -0.18$, 95%CI= -0.45 – 0.12). However, the individual symptom trajectory was significantly correlated with the longitudinal changes in SCI scores ($r = 0.41$, 95%CI=0.02-0.70).

Conclusions: A biomarker of treatment response obtained after treatment stabilization was not able to accurately predict subsequent risk of relapse despite ongoing treatment, suggesting that at least for this biomarker, relapse risk was not identifiable as a ‘trait’ at baseline. However, the SCI tracked as a ‘state’ biomarker symptom trajectory during guaranteed treatment. As individuals worsen despite treatment, their SCI score moves from lower values (typical of treatment responders) to higher values (typical of non-responders). Therefore, these data suggest that relapse despite ongoing treatment may relate to a transition out of a ‘treatment responsiveness’ neurobiological state, closer to that of treatment resistance.

39.4. REAL-WORLD EFFECTIVENESS OF HORMONE REPLACEMENT THERAPY IN PREVENTING RELAPSE IN WOMEN WITH SCHIZOPHRENIA OR SCHIZOAFFECTIVE DISORDER

Bodily Brand¹, Iris Sommer², Shiral Gangadin², Antti Tanskanen³, Jari Tiihonen³, Heidi Taipale⁴

¹University Medical Center Groningen, ²UMC Groningen, ³Karolinska Institutet,

⁴Niuvanniemi Hospital, University of Eastern Finland

Background: Antipsychotic effectiveness in preventing relapse declines around menopausal age in women with schizophrenia or schizoaffective disorder (SSD). It is not known whether menopausal systemic hormone replacement therapy (HRT) can help to prevent relapse.

Methods: We did a nationwide, register-based cohort study in Finland, in women with SSD who initiated HRT aged between 40-62 years. HRT effectiveness in preventing psychosis relapse was studied using within-individual analyses. Age- and psychotropic drug use adjusted hazard ratios (aHR) were calculated for psychosis relapse as main outcome and any psychiatric hospitalization as secondary outcome. Ethnicity data was not available.

Results: The study population comprised 3488 women using HRT between 1994 and 2017. Use of HRT was associated with a 16% lower relapse risk (aHR 0.84 [95% CI 0.78-0.90]) when compared to non-use. Stratified by age, HRT was associated with decreased relapse risks when initiated between age 40-49 (aHR 0.86 [95% CI 0.78-0.95]) and age 50-55 (aHR 0.74 [95% CI 0.66-0.83]), but not between age 56-62 (aHR 1.11 [95% CI 0.91-1.37]). Similar effectiveness was found for estrogen alone or combined with fixed or sequential progestogens (aHR 0.79-0.86), transdermal and oral formulations (aHR 0.75-0.87), and for most specific formulations (aHR 0.77-0.85), except for tibolone (aHR 1.04 [95% CI 0.75-1.44]) and estrogen combined with dydrogesterone (aHR 1.05 [95% CI 0.85-1.30]). Similar results were observed with any psychiatric hospitalization as an outcome measure.

Conclusions: Our findings underscore the potential value of HRT in preventing psychosis relapse among women with SSD of menopausal age. Age-stratified analysis suggests optimal benefits when HRT is initiated before the age of 56.

Plenary Session VII - Matcheri Keshavan: Refining the Nosology of Psychotic Disorders: Toward Cognitive Subtypes

8:30 a.m. - 9:30 a.m.

40. REFINING THE NOSOLOGY OF PSYCHOTIC DISORDERS: TOWARD COGNITIVE SUBTYPES

Iris Sommer, *UMC Groningen*

40.1. REFINING THE NOSOLOGY OF PSYCHOTIC DISORDERS: TOWARD COGNITIVE SUBTYPES

Matcheri Keshavan, *Harvard University*

Individual Abstract: Current approaches to classifying psychotic disorders are limited by substantive heterogeneity within, blurred boundaries between, as well as overlaps across the various disorders in outcome, treatment response, emerging evidence regarding pathophysiology and presumed etiology. While symptom-based classifications have improved our reliability, they may lack validity. Critical next steps include deconstruction of disease dimensions, and endophenotypes, reclustering such data across symptom-based diagnoses using modern phenotypic and biometric approaches, and validating such entities using etio-pathology, outcome and treatment-response measures.

Cognitive impairments, being pervasive, stable, heritable and linked to neurobiology, are core aspects of psychoses, and offer a unique opportunity to parse psychosis syndromes into biologically meaning entities. The Bipolar-schizophrenia Network for Intermediate Phenotypes (BSNIP) used an agnostic, K-means clustering approach in a large sample of psychosis probands; three subtypes (biotypes) were identified that differ in regard to cognitive and electrophysiological endophenotypes. The replicability, stability and external validity of these subgroups, as well as ongoing studies investigating the potential value of this classification to treatment selection and outcome prediction, will be discussed.

Concurrent Symposia

10:00 a.m. - 12:00 p.m.

41. GENE-ENVIRONMENT INTERACTION IN PSYCHOSIS: NEW INSIGHTS INTO ETIOLOGY, PREVENTION, AND MANAGEMENT

Sinan Guloksuz, *Maastricht University*

Overall Symposia Abstract: Schizophrenia spectrum disorder has considerable genetic component, now quantifiable using a polygenic risk score. However, GWAS account for only a fraction of the variance in psychosis liability. This suggests that factors beyond genetics, such as gene-environment interactions (GxE) may play a significant role. Therefore, investigating GxE in psychosis is vital but presents complex challenges: environment is dynamic in a changing world; there are multitude of exposures; biological mechanisms underlying GxE remain unexplored.

To respond these challenges, our symposium will feature novel—yet-to-be-published—studies investigating GxE in psychosis.

Dr. Ku will discuss long-term trajectories of distressing psychotic experiences and their associations with genetic risk and environmental protective factors. He will present unpublished findings from a large cohort, age-range of 9-10 years, the Adolescent Brain Cognitive Development. He found that social aspects of physical activities may buffer the impact of genetic liability on persistently distressing psychotic experiences. These findings highlight the opportunity for early identification and potential intervention strategies throughout this sensitive developmental period and encourage investigating risk and protective factors underlying trajectories toward the psychosis spectrum.

Dr. Fusar-Poli will focus on the interplay between autistic traits and subthreshold psychotic experiences in a non-clinical population. She will discuss how genetic (i.e., polygenic risk score) and environmental risk factors for schizophrenia could interact with autistic traits in predicting the psychosis expression by leveraging the TwinssCan, a longitudinal twin cohort of adolescents and young adults from the general population in Belgium. The results may be relevant to implement preventive strategies in populations at greater risk of developing psychotic disorders, such as people with autism or elevated autistic traits.

Dr. Prachason will present unpublished findings from a study that investigated the longitudinal effects of polygenic and exposomic risks for schizophrenia on subclinical psychosis expression in early adolescence. Findings show that the aggregated environmental risk exposure additively interacted with the polygenic risk in predicting subsequent distressing psychotic experiences. Environmental influence also tended to increase when the experiences were more persistent. These findings highlight the interplay between genetic and environmental risk factors for schizophrenia on the development of subclinical psychosis expression and the clinical significance of symptom persistence in the general youth population.

Dr. Di Forti will present unpublished findings from the multisite EUGEI first episode psychosis study that investigated whether polygenic risk scores predicted age at first cannabis use and pattern of use (frequency/potency) and moderated the association between pattern of cannabis use and psychosis risk. Findings suggest that genetic load for psychosis and neurodevelopmental disorders but not for major depression might influence psychosis vulnerability among cannabis users. Moreover, engaging young adults with psychosis in an intervention for cannabis use can significantly improve illness outcome.

Prof. Murray will summarize and discuss the key findings, and implications of these findings for clinical translation and future studies of GxE in psychosis.

41.1. THE ASSOCIATIONS BETWEEN POLYGENIC LIABILITY, PHYSICAL ACTIVITIES, AND DISTRESSING PSYCHOTIC-LIKE EXPERIENCES OVER FOUR YEARS

Benson Ku^{*1}, Emerald Yuan², Angelo Arias-Magnasco³, Bochao Lin³, Elaine Walker⁴, Benjamin Druss⁵, Jiyuan Ren², Jim van Os⁶, Sinan Guloksuz³

¹Emory University School of Medicine, ²Emory, ³Maastricht University, ⁴Emory University,

⁵Emory University Rollins School of Public Health, ⁶Utrecht University Medical Centre

Background: Persistently distressing psychotic-like experiences (PLE) are associated with impaired functioning, mental health service utilization, cognitive deficits, and psychopathology. Physical activities (PA), particularly those that involve social engagement,

are potential protective factors for psychopathology among adolescents. However, the protective factor of PA against genetic risk on long-term outcomes of distressing PLE has not been examined. This study aims to assess whether the trajectories of distressing PLE are associated with a polygenic risk score for schizophrenia (PRS-SCZ), PA (including social and non-social activities), and their interaction.

Methods: This observational cohort study used four waves of data from the Adolescent Brain Cognitive Development Study 5.0. Data was collected between September 2016 and January 2022. The primary outcomes include the three distressing PLE groups (none, transiently, and persistently). PA was assessed at baseline by the average number of hours per week, further categorized into social activities (SA) and non-social activities (NSA). The PRS-SCZ was generated using the most recent GWAS of schizophrenia (freeze 3) - European subsample. Generalized linear mixed models adjusted for the following fixed effects (age, sex, parental education, income-to-needs ratio, family history of psychosis, body mass index, principal components for samples) and random effects (recruitment site, and family structure). Interaction term of PRS-SCZ-by-SA was then entered into the model to assess moderating effect of SA on the relationship between PRS-SCZ and distressing PLE.

Results; The study included 4736 adolescents of European ancestry ages 9 and 10 at baseline with 2507 (52.9%) males, and 930 (19.6%) and 670 (14.1%) had transiently and persistently distressing PLE, respectively. Greater PRS-SCZ and lower levels of PA were associated with a greater risk of persistently distressing PLE (adjusted relative risk ratio [RRR]=1.13, 95% CI=1.03 to 1.23, p LESS THAN 0.05 and adjusted RRR=0.87, 95%CI=0.79 to 0.97, p LESS THAN 0.05, respectively). Lower levels of SA were associated with a greater risk of distressing PLE (adjusted RRR= 0.81, 95% CI=0.73 to 0.90, p LESS THAN 0.05). The interaction of PRS-SCZ-by-SA was significantly associated with persistently distressing PLE such that the relationship between PRS-SCZ and distressing PLE was weaker as participants had greater levels of participation in team-based sports (adjusted RRR=0.87, 95% CI=0.73 to 0.90, p LESS THAN 0.05).

Conclusions: These findings demonstrate that the interaction between genetic liability and social-physical activities is associated with trajectories of distressing PLE. Further research is needed to understand which aspects of social activities may be protective against psychosis.

41.2. THE MODERATING ROLE OF GENETIC AND ENVIRONMENTAL RISK FACTORS FOR SCHIZOPHRENIA ON THE ASSOCIATION BETWEEN AUTISTIC TRAITS AND PSYCHOSIS EXPRESSION IN A GENERAL POPULATION TWIN SAMPLE

Laura Fusar-Poli^{*1}, Melike Karaçam Doğan², Thanavadee Prachason³, Bochao Lin⁴, Claudia Menne-Lothmann⁴, Jeroen Decoster⁵, Ruud van Winkel⁴, Dina Collip⁴, Philippe Delespaul⁴, Marc De Hert⁶, Catherine Derom⁷, Evert Thiery⁷, Nele Jacobs⁴, Jim van Os⁴, Bart Rutten⁴, Sinan Guloksuz⁴

¹University of Pavia, ²Karadeniz Ereğli State Hospital, ³Mahidol University, ⁴Maastricht University, ⁵Psychiatric Care Sint-Kamillus, ⁶Katholieke Universiteit Leuven, ⁷Ghent University

Background: The existence of subclinical psychotic experiences (PE), as well as subthreshold AT, in the general population suggests a continuum. Research has shown that people with increased autistic traits (AT) are more prone to psychotic experiences (PE). Compared with the general population, environmental risk factors for psychosis such as childhood trauma, bullying, and obstetric complications are more frequent in people with autism spectrum disorder (ASD). Additionally, genetic studies have identified several direct and indirect

associations between ASD and psychosis, further supporting the link between these phenotypes. Therefore, we have hypothesized that genetic and environmental risk for psychotic disorders could moderate the relationship between AT and PE in the general population.

Methods: We conducted analyses using the TwinssCan, a longitudinal general population twin cohort. Analyses were conducted in 794 participants aged between 18 and 35 years old. AT were evaluated using the Autism Spectrum Quotient (AQ). The frequency of PE was assessed with the Community Assessment of Psychic Experience (CAPE). Multilevel regression analyses, adjusted for age and sex, were used to evaluate the moderating role of polygenic risk score for schizophrenia (PRS-SCZ), environmental risk factors for psychosis (i.e., childhood adversities, bullying, obstetric complications) on the association between the total scores of AQ and CAPE. Childhood adversities were measured using the Childhood Trauma Questionnaire-Short Form (CTQ-SF), in the domains of physical, emotional, and sexual abuse, as well as physical and emotional neglect. Bullying was evaluated using the Retrospective Bullying Questionnaire (RBQ). Measures of environmental risk were dichotomized based on previously validated methods.

Results: AQ total scores were positively and significantly associated with CAPE total scores ($B=0.12$, 95% CI 0.10 to 0.14). We did not find any significant interaction between AQ total scores and PRS-SCZ on CAPE total scores ($B=-0.01$, 95% CI -0.03 to 0.005). As for childhood adversities, we found positive significant interactions between AQ total and emotional abuse ($B=0.08$, 95% CI 0.05 to 0.11), physical abuse ($B=0.11$, 95% CI 0.05 to 0.18), sexual abuse ($B=0.09$, 95% CI 0.03 to 0.15), emotional neglect ($B=0.04$, 95% CI 0.01 to 0.07), physical neglect ($B=0.06$, 95% CI 0.03 to 0.10) on CAPE total. No significant interactions were found between AQ total and bullying ($B=0.02$, 95% CI -0.01 to 0.05) or between AQ total and obstetric complications ($B=0.003$, 95% CI -0.002 to 0.01) on CAPE total scores.

Conclusions: Findings indicate that childhood adversities and life events may moderate the association between AT and PE in the general population. Prevention of risk factors for psychosis may be particularly relevant for reducing psychopathological symptoms in people with elevated AT

41.3. EXAMINING THE INDEPENDENT AND JOINT EFFECTS OF GENOMIC AND EXPOSOMIC LIABILITY FOR SCHIZOPHRENIA ON SUBCLINICAL PSYCHOSIS EXPRESSION IN EARLY ADOLESCENCE

Thanavadee Prachason^{*1}, Matteo Di Vincenzo², Gaia Sampogna², Angelo Arias-Magnasco³, Bochao D. Lin³, Lotta-Katrin Pries³, Jim van Os⁴, YOUTH-GEMs Investigators⁵, Bart P.F. Rutten³, Sinan Guloksuz⁶

³School for Mental Health and Neuroscience, Maastricht University Medical Centre,

⁴University Medical Center Utrecht Brain Center, Utrecht, the Netherlands; Institute of Psychiatry, King's College London, ⁵YOUTH-GEMs Investigators, ⁶School for Mental Health and Neuroscience, Maastricht University Medical Centre, Yale University School of Medicine

Background: Psychotic experiences (PE) are reported by up to 10% of children and adolescents and are associated with an increased risk of developing both psychotic and non-psychotic disorders, particularly when accompanied by distress. Although research has identified shared genetic and environmental risk factors with psychotic disorders, their combined influence on subclinical PE in young populations remains unexplored. In this study, we conducted a longitudinal analysis using the Adolescent Brain and Cognitive Development

(ABCD) Study data to investigate the independent and joint effects of genomic and exposomic liability for schizophrenia on distressing PE during early adolescence.

Methods: The ABCD release 4.0 dataset was used in the primary analyses, which included 5,057 participants of European ancestry who had genetic data and underwent annual assessments until the 2-year follow-up. Subclinical PEs were assessed annually from baseline (ages 9 – 10) using the Prodromal Questionnaire-Brief Child Version. We classified participants with at least one PE accompanied by a distress score of ≥ 3 on a 5-point scale as having distressing PE. The primary outcome was past-month distressing PE reported at the 2-year follow-up (ages 11 – 12), with secondary outcomes including lifetime distressing PE and recurring distressing PEs with varying degrees of persistence across the 3 waves of assessment. Polygenic risk score for schizophrenia (PRS-SCZ) was calculated. Conforming to our previous study, exposome score for schizophrenia (ES-SCZ) was calculated using lifetime exposure to childhood adversity domains, cannabis use, winter birth, hearing impairment, and bullying reported up to the 1-year follow-up (ages 10 – 11). The main effects of PRS-SCZ and ES-SCZ on distressing PE were tested separately using multilevel logistic regression analysis. The additive interaction between PRS-SCZ and ES-SCZ was indicated by the relative excess risk due to interaction (RERI). Age and sex were covariates in all models, and sensitivity analyses included adjustments for baseline family income and parental education. As confirmatory analyses, all the analyses were repeated based on the ABCD release 5.0 dataset, using ES-SCZ calculated from lifetime exposure up to the 2-year follow-up and distressing PEs at the 3-year follow-up as the outcomes.

Results: In primary analyses, PRS-SCZ was significantly associated with past-month distressing PE at the 2-year follow-up (OR 1.13 [95% CI 1.01, 1.26], $P = .031$). Similar main effects of PRS-SCZ were observed for lifetime distressing PE (OR 1.14 [95% CI 1.06, 1.23], $P < .001$) and recurring distressing PEs (recurring ≥ 2 waves: OR 1.16 [95% CI 1.04, 1.29], $P = .007$; recurring in all 3 waves: OR 1.22 [95% CI 1.02, 1.47], $P = .034$). ES-SCZ was similarly associated with distressing PEs of all definitions, and its influence tended to increase with more persistence of experiences (past-month distressing PE: OR 1.60 [95% CI 1.43, 1.78]; lifetime distressing PE: OR 1.60 [95% CI 1.48, 1.74]; recurring ≥ 2 waves: OR 1.72 [95% CI 1.54, 1.93]; recurring in all 3 waves: OR 2.03 [95% CI 1.68, 2.45], all $P < .001$). Significant additive interactions between PRS-SCZ and ES-SCZ were observed for past-month distressing PE (RERI 0.22 [95% CI 0.02, 0.41], $P = .028$) and lifetime distressing PE (RERI 0.20 [95% CI 0.05, 0.35], $p = .010$), but not for recurring distressing PEs at the 2-year follow-up. Sensitivity and confirmatory analyses generally aligned with results derived from the primary analyses.

Conclusions: Genomic and exposomic liability for schizophrenia were independently and jointly associated with distressing PE in early adolescence. Notably, the association of ES-SCZ with PE tended to be stronger with increasing PE persistence. These findings underscore the interplay between genomic and exposomic risk for schizophrenia in subclinical psychosis expression in the general youth population.

41.4. FROM PREDICTING ONSET OF CANNABIS-ASSOCIATED PSYCHOSIS TO IMPROVING THE OUTCOME OF THE DISORDER

⁷*Institute of Psychiatry, Psychology and Neuroscience, King's College London*, ⁸*SGDP, Institute of Psychiatry, Psychology and Neuroscience, King's College London*, ⁹*MRC Social, Genetic and Developmental Psychiatry Centre, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London*, ¹⁰*Institute of Psychiatry, King's College, London*

Background: Heavy cannabis use is the most modifiable risk factor for the onset of psychotic disorder and for its clinical and functional outcome. Some but not all studies have suggested that genetic load for schizophrenia determines cannabis use behaviour and or interacts with cannabis use to increase the risk of developing a psychotic disorder. Nevertheless, it is unclear if and how the genetic load for other psychiatric phenotypes might influence a) cannabis use and b) later risk of psychotic disorder. The first half of this presentation will clarify these issues. A further problem is that young people with a cannabis-associated psychotic disorder often fall between Addiction Services and those for psychosis, with consequent bad outcome. The second half of this presentation will describe a new specialist clinic which offers young adults who develop a psychotic disorder an intervention to support them with reducing/stopping their cannabis use.

Methods: 1) Using genetic and cannabis use data from the multisite EUGEI first episode psychosis case-control study we calculated Polygenic Risk scores (PRS) for Major Depression and Psychosis to test a) if they predicted pattern of cannabis use and b) if they explained a greater proportion of the variance for case-control status than exposure to cannabis use alone. All analyses were controlled for the main sociodemographic, tobacco smoking and Principal Components. 2) We analysed changes between baseline and end of treatment, of the outcome measures (Cannabis Dependence, Pattern of use, psychopathology, level of functioning) from the first young adults with psychotic disorders, who completed their cannabis use reduction/cessation intervention with the Cannabis Clinic for Psychosis (CCP).

Results: In the First episode Psychosis Cases N=684, Controls=970 from the EUGEI study, neither the PRS for Major depression nor a General Psychosis-PRS predicted cannabis use. However, adding a General Psychosis-PRS to measures of cannabis use increased the variance explained for the onset of psychosis.

Data from the CCP show that 80% of the 40 young adults, who completed their cannabis use reduction/cessation intervention, stopped their cannabis use and 20% reduced their use from daily to once a week or less. Stopping cannabis use was associated with a) a significant reduction in delusions and in distress associated with hallucinations b) improvement in functioning c) sleep and d) attention scores.

Conclusions: Data from the EUGEI study suggest that genetic load for Psychosis, but not for major depression, influence individual vulnerability to psychosis among cannabis users. Moreover, data from the CCP indicate that engaging young adults with psychosis in an intervention to reduce/stop their cannabis can significantly improve their illness outcome.

42. NEW DEVELOPMENTS IN PSYCHOLOGICAL TREATMENTS FOR PATIENTS WITH NEGATIVE SYMPTOMS OF SCHIZOPHRENIA. CONSUMER ORIENTED ADAPTATIONS, TRANSLATIONAL APPROACHES AND ROUTINE CARE IMPLEMENTATION

Matthias Pillny, *Universität Hamburg*

Overall Symposia Abstract: The negative symptoms of schizophrenia comprise diminished motivation and blunted emotional expression. Particularly, diminished motivation has been

found to relate to profound impairment in long-term functioning and quality of life. However, while psychopharmacology and psychological interventions can effectively alleviate the positive symptoms of schizophrenia (i.e., delusions and hallucinations), diminished motivation and functional impairments are still often considered a feature of schizophrenia that generally is resistant to intervention. This symposium will challenge this assumption by showcasing the latest findings of recent clinical trials testing novel and translational psychological interventions as well as innovative combinations of already established and efficacious approaches and their adaptations across diverse settings.

Matthias Pillny (Universität Hamburg, Germany) will present findings from a randomized controlled effectiveness trial with ecological momentary assessment of outcomes testing whether Cognitive Behavioral Social Skills Training can improve the effectiveness of routine care on daily life functioning.

Felice Reddy (University of North Carolina, USA) will present findings from two randomized controlled trials examining the efficacy of Motivational Interviewing combined with Cognitive Behavior Therapy on diminished motivation and functional outcomes. She will discuss specific adaptations for special settings such as chronically homeless consumers and virtual delivery of their intervention.

Inez Myin-Germeys (KU Leuven, Belgium) will focus on a blended care approach including Acceptance and Commitment Therapy delivered in an ecological momentary intervention. She will discuss findings of her randomized controlled trial testing the benefits of this approach for daily life functioning and negative symptoms.

Clementine Edwards (King's College London, UK) adapts a translational perspective on diminished motivation and will present preliminary evidence suggesting that a mental imagery focused autobiographical memory training can improve diminished motivation and cognitive functioning in patients with schizophrenia.

Edo Jaya (Universitas Indonesia, Indonesia) will encourage a critical reflection of the evidence presented in this symposium and facilitate a discussion about the clinical implications to improve the routine care for people with negative symptoms of schizophrenia.

42.1. IMPROVING DAILY-LIFE FUNCTIONING IN PATIENTS WITH SCHIZOPHRENIA WITH COGNITIVE BEHAVIORAL SOCIAL SKILL TRAINING: A RANDOMIZED-CONTROLLED EFFECTIVENESS TRIAL WITH ECOLOGICAL MOMENTARY ASSESSMENT OF OUTCOMES

Matthias Pillny*¹, Jason Holden², Kim Mueser³, Greg Aarons², David Sommerfeld², Dimitri Perivoliotis², Eric Granholm²

¹Universität Hamburg, ²University of California, San Diego, ³Center for Psychiatric Rehab, Boston University, USA

Background: Negative Symptoms of schizophrenia cause profound impairments in everyday functioning. Medications can effectively alleviate positive symptoms and prevent relapses, but they do not meaningfully improve long-term daily life functioning. By contrast, psychological interventions, such as Cognitive Behavioral Social Skills Training (CBSST), showed moderate effects on functional outcomes in efficacy trials. However, it remains unclear to what extent improvements that have been observed using retrospective in-lab assessments of functional outcomes in previous trials translate to the patients' daily life experiences. Furthermore, it has

not yet been tested whether CBSST can be effectively delivered in routine practice settings such as Assertive Community Treatment (ACT) in the United States. This study therefore aims to test whether the combination of ACT+CBSST leads to greater improvements in daily life functioning of patients with schizophrenia than ACT alone.

Methods: We conducted a parallel-group randomized-controlled effectiveness trial in seven ACT teams from the community mental health system in San Diego, California. Participants were eligible if they met diagnostic criteria for schizophrenia or schizoaffective disorder, were GREATER THAN 18 years of age and received ACT services for at least three months. Eligible participants were randomized to either ACT+CBSST or ACT alone, stratified by ACT team and gender. Participants in both conditions continued to receive weekly ACT visits. For participants in the ACT+CBSST condition the study goal was to deliver at least 36 sessions of CBSST within 18 months in the context of their weekly ACT visits. Assessments were obtained at baseline, 9 months and 18 months. At each study visit, participants were prompted 10 times per day over the course of one week with ecological momentary assessment surveys asking them to indicate their current activity from a list of ‘productive’ (e.g., self-care, home-care, work/school, socializing, etc.) and ‘non-productive’ (e.g., watching television, resting, etc.) activities. Daily life functioning was defined as the number of ‘productive activities’ and the ratio of ‘productive-’ to ‘non-productive activities’. Hierarchical linear mixed models were used to test group differences in the change of daily life functioning across study visits.

Results: The intent-to-treat population included N=155 participants (nACT = 80, nCBSST = 75). The median number of CBSST sessions delivered was 13 sessions, indicating low therapy exposure. We found significant group x time interactions in the models predicting the number of productive activities and the ratio of productive and non-productive activities. These interactions were driven by significant large improvements in the ACT+CBSST group, whilst the change in productive activities in ACT alone was not significant.

Conclusions: Our findings suggest that integrating CBSST into ACT leads to greater improvements in daily life functioning than ACT alone. Notably, this effect was evident despite relatively low therapy exposure with CBSST. This indicates that CBSST appears to be a highly potent psychological intervention that, even with low implementation, leads to significant improvements in daily life functioning.

42.2. A NOVEL PSYCHOSOCIAL INTERVENTION FOR MOTIVATIONAL NEGATIVE SYMPTOMS IN SCHIZOPHRENIA: COMBINED MOTIVATIONAL INTERVIEWING AND CBT

Felice Reddy^{*1}, Michael Green², Shirley Glynn³

¹University of North Carolina at Chapel Hill, ²VISN 22 MIRECC, VA Greater Los Angeles Healthcare System, UCLA Semel Institute for Neuroscience and Human Behavior, ³UCLA/VA Greater Los Angeles Healthcare System

Background: Negative symptoms significantly interfere with daily functioning among individuals with schizophrenia and are considered an unmet treatment need. Among the types of negative symptoms, experiential negative symptoms (amotivation and anhedonia) are the primary determinants of impaired functioning. We developed a novel recovery-oriented psychosocial intervention aimed at reducing motivational negative symptoms and improving community functioning in individuals with moderate to severe negative symptoms. The intervention combines two evidence-based practices, Motivational Interviewing and Cognitive Behavior Therapy (MI-CBT) and is delivered in 12 sessions that focus on personally meaningful goals for each participant. In recent years we have expanded the protocol to be applied in diverse settings including group and one-on-one sessions with different kinds of

providers, and for varying clinical diagnoses that are characterized by motivation deficits. This talk will present results from two randomized controlled trials that used MI-CBT to address motivational deficits. The first study applied MI-CBT to people with schizophrenia who had at least moderate levels of negative symptoms. The second study, still being completed, applied MI-CBT to improve motivational deficits in homeless-experienced Veterans.

Methods: The original study included seventy-nine participants with schizophrenia and moderate to severe negative symptoms in a randomized controlled trial comparing the 12-session MI-CBT treatment with a mindfulness control condition. Participants were assessed at three time points through the study period and a 3-month follow-up. The primary outcome measures were motivational negative symptoms and community functioning. In subsequent iterations, we have implemented the treatment with a virtual option, delivered in individual therapy sessions with monthly booster sessions following the 12-week intervention. Participants in this second RCT had deficits in motivation and functioning, a history of houselessness, and a variety of psychiatric diagnoses. We are completing data collection by Dec 2023 and will include the results in our presentation. Finally, we will present our adapted version, which incorporates social networking technology and Peer Support Specialists and is tailored specifically for people recovering from first episode psychosis with residual negative symptoms.

Results: We will present findings from two large RCTs. In the first, compared with the control group, participants in the MI-CBT group showed significantly greater improvements in motivational negative symptoms over the acute treatment period. Their gains relative to baseline were maintained at follow-up. There were nonsignificant effects toward improvements in community functioning and defeatist performance beliefs. In our subsequent study of persons who have experienced long-term houselessness and have deficits in motivation and functioning, preliminary analyses indicate significant improvements in motivational negative symptoms and defeatist beliefs, as well as gains in work and social functioning. Analyses from this study will look at the additive benefit of the booster sessions for treatment efficacy and durability and will also examine potential mediators including defeatist beliefs and motivational stages of change.

Conclusions: The results show that combining MI with CBT yields improvements in negative symptoms, a feature of schizophrenia generally thought of as resistant to intervention. In the first large study, motivational negative symptoms not only responded to the novel treatment, but the gains were maintained over the follow-up period. Our second study's interim results suggest the intervention can be adapted and disseminated. Implications for future studies and for improving the generalization of the negative symptom gains to daily functioning domains will be discussed.

42.3. REMEMBERING THE PAST TO LIVE BETTER IN THE FUTURE: A FEASIBILITY RANDOMISED CONTROLLED TRIAL OF MEMORY SPECIFICITY TRAINING FOR MOTIVATION IN PSYCHOSIS

Clementine Edwards^{*1}, Philippa Garety¹, Amy Hardy¹

¹*Institute of Psychiatry, Psychology and Neuroscience, Kings College London,*

Background: People with a diagnosis of psychosis often experience low motivation, loss of pleasure and reduced activity levels, these are described as experiential negative symptoms. These problems often persist beyond hallucinations and delusions and have a significant impact on quality of life (Starzer et al, 2023). They are also often identified as a priority for recovery by patients (Mortiz et al, 2016). Despite this, we currently have no effective targeted psychological or pharmacological interventions for these difficulties. Autobiographical

memory deficits have been identified in people with psychosis and this may limit the role of memory retrieval in supporting motivation. This pilot study adapted a recently developed protocol, Memflex, which aims to enhance autobiographical memory and has shown promise in depression (Hitchcock et al, 2018). Our single session intervention targets experiential negative symptoms of psychosis using supported autobiographical memory retrieval.

Methods: A sample of 31 participants with psychosis were recruited from inpatient and community settings and randomised in a 2:1 ratio to either an enhanced recall intervention or a basic recall control group. Participants completed a series of measures assessing experiential negative symptoms and related constructs i.e., working memory, self-efficacy beliefs, depression. Participants were then asked to generate positive autobiographical memories linked to activities they wish to repeat in the future. The enhanced recall condition described these memories to the researcher and received additional prompts from the Memflex protocol, these prompts included details of the event, experience of the five senses during the event, identity, positive themes, generalisation of positive themes to other experiences and future planning. The basic recall condition recalled and described the memories but received no additional prompts.

Results: The measures completed showed that depressive and experiential negative symptoms were linked to ratings of the memory during the intervention, as well as to measures of cognition, but not self-efficacy beliefs. The intervention delivered was acceptable (rated GREATER THAN 80%) and feasible (94% adherence) to those who took part. Participants were able to generate positive autobiographical memories linked to their goals and experienced appropriate emotions linked to these. The controlled preliminary effect sizes (0.2-0.34) showed encouraging signals for self-efficacy, motivation, positive mood, and a reduction in negative mood.

Conclusions: The measure of depression symptoms (BDI) and experiential negative symptoms (CAINS) show potential utility as outcome measures for further studies targeting low motivation in psychosis as they demonstrated relationships with key constructs. The findings suggest that guided autobiographical memory retrieval, even delivered in a brief form, is feasible and acceptable and may be an effective tool for targeting motivation in people with psychosis.

42.4. THE INTERACT STUDY: FEASIBILITY AND EFFICACY OF ACCEPTANCE AND COMMITMENT THERAPY IN DAILY LIFE IN EARLY PSYCHOSIS

Inez Myin-Germeys^{*1}, Evelynne van Aubel¹, Thomas Vaessen¹, Henrietta Steinhart¹, Annelie Klippel¹, Tim Batink², Ruud van Winkel³, Mark Van der Gaag⁴, Machteld Marcelis⁵, Therese Van Amelsvoort⁶, Frederike Schirmbeck⁷, Lieuwe de Haan⁸, Ulrich Reininghaus⁹

¹KU Leuven, Center for Contextual Psychiatry, ²Open University, The Netherlands,

³University Psychiatric Center, KU Leuven, ⁴VU University Amsterdam Clinical Psychology,

⁵Maastricht University Medical Center, ⁶Maastricht University, ⁷AMC, University of

Amsterdam, ⁸AMC, Arkin, ⁹Central Institute of Mental Health, University of Heidelberg

Background: This study aimed to investigate the usability, acceptability and efficacy of a blended care intervention - Acceptance and Commitment Therapy in Daily Life (ACT-DL) in people in the early phases of psychosis. ACT-DL combines face-to-face therapy with an Ecological Momentary Intervention (EMI), in addition to treatment as usual (TAU). The INTERACT study is a multi-center RCT comparing ACT-DL+TAU with TAU only.

Methods: Individuals aged 15-65 years with clinically established Ultra-high risk (UHR) or First Episode of Psychosis (FEP) were randomly assigned to TAU or ACT-DL+TAU. ACT-DL+TAU consisted of 8 ACT-sessions augmented with an EMI-app, delivering ACT skills and

techniques in daily life. The primary outcome was psychotic distress assessed with the Comprehensive Assessment Scale of At Risk Mental State (CAARMS) at post-intervention, 6- and 12-month follow-up. Secondary outcomes were functioning, symptom severity, and momentary psychotic distress. We performed multivariate mixed models according to intent-to-treat principles. We also collected data on treatment adherence and acceptability of ACT-DL.

Results: Between June 1, 2015 and December 31, 2018, 668 participants were referred, of whom 148 were randomized to ACT-DL+TAU (n=71) or TAU (n=77). ACT-DL+TAU participants (n=71) completed a mean of 6 (SD=3) face-to-face sessions, with 59% (n=42) of participants completing all sessions. App adherence data (n=58) shows that, on a weekly basis, participants used the app 13 times and were compliant with 6 out of 24 (25%) notifications. Distribution plots of debriefing scores (n=46) showed that 85%-96% of participants reported usefulness on all acceptability items to at least some extent, and that 91% reported perceived burden by number and length of notifications. In total, 115 (78%) participants provided primary outcome data at least at one follow-up assessment. There was no evidence of greater reduction in the primary outcome measure CAARMS distress in ACT-DL+TAU compared to TAU ($\chi^2(3)=2.36$; $p=0.50$). However, out of the tested secondary outcomes, global functioning ($\chi^2(3)=9.05$; $p=0.033$), and negative symptoms ($\chi^2(3)=19.91$; $p \text{ LESS THAN } .001$) improved in ACT-DL+TAU compared to TAU, as did momentary psychotic distress ($\chi^2(3)=21.56$; $p \text{ LESS THAN } 0.001$).

Conclusions: Our results corroborate good treatment adherence to and acceptability of ACT-DL in early psychosis. INTERACT did not support a significant effect of ACT-DL over TAU on the primary outcome measure of psychotic distress as assessed with the CAARMS. However, we found significant effects on negative symptoms and global functioning, two of the hardest-to-treat symptoms in psychosis. Although we need further replication studies to confirm the strength and specificity of these effects, the findings indicate that ACT-DL may provide an exciting new avenue for the early treatment of negative symptoms.

43. NOVEL PERSONALIZED NEUROMODULATION APPROACHES TO TREAT CORE DEFICITS AND COMORBIDITIES IN SCHIZOPHRENIA

Aristotle Voineskos, *Centre for Addiction and Mental Health*

Overall Symposia Abstract: Non-invasive neuromodulation techniques represent novel and innovative treatment approaches that can be used to target neural circuits and have been amply applied and tremendously successful in the treatment of depression. Much less neuromodulation work has been done in schizophrenia, despite the demonstration of circuit deficits associated with particular core symptoms and dysconnectivity models. More recently, research in this area is increasing, and advances in individualized targeting approaches and predictive models are starting to be applied to address variable response rates to neuromodulation. In the current symposium, we present findings on the use of novel targeted and personalized neuromodulation approaches to treat core deficits and comorbidities in individuals with schizophrenia, including negative symptoms, neurocognition, social cognition, and nicotine dependence.

Dr. Voineskos (Centre for Addiction and Mental Health (CAMH)/University of Toronto) will introduce the topic of our symposium, providing a historical context, insights from his ongoing neurostimulation research, and incorporating his clinical perspective on the utility of novel neuromodulation approaches in the treatment of individuals with schizophrenia. Dr. Hasan (University of Augsburg) will present findings regarding improving response prediction to

repetitive transcranial magnetic stimulation (rTMS) in schizophrenia with a focus on negative symptoms, moving from large-scale clinical data to multimodal predictive models. Dr. Valiengo (University of Sao Paulo) will share results from a clinical trial examining the effects of a novel form of neuromodulation called photobiomodulation on magnetic resonance spectroscopy and negative symptoms in schizophrenia. Dr. Oliver (CAMH/Toronto) will discuss results from a multi-centre study of personalized rTMS to the dorsomedial prefrontal cortex in individuals with schizophrenia, demonstrating changes in social cognitive network functional connectivity. Dr. Ward (Vanderbilt University Medical Center) will present data that identifies a schizophrenia-specific circuit of nicotine dependence, validates this network with a pharmacologic intervention, and then uses an individualized, network-targeted rTMS intervention to modulate nicotine craving in schizophrenia. The panel will conclude with a discussion and question period led by Dr. Brady (Harvard Medical School), incorporating his ongoing research on the use of accelerated neuronavigated intermittent theta burst stimulation (iTBS) in schizophrenia. Taken together, the presented studies provide evidence for the promise and efficacy of neuromodulation approaches in targeting core symptoms and comorbidities in individuals with schizophrenia. Our results also highlight the need for approaches such as individual-level prediction of treatment response or stratification and/or personalized brain mapping to identify individualized brain stimulation targets for specific symptoms to ideally allocate critical resources to maximize treatment response and improve functional outcomes for patients.

43.1. EFFECTS OF INDIVIDUALIZED TRANSCRANIAL MAGNETIC STIMULATION ON SOCIAL COGNITIVE NETWORK FUNCTIONAL CONNECTIVITY IN SCHIZOPHRENIA SPECTRUM DISORDERS

Lindsay Oliver^{*1}, Daniel M. Blumberger², Colin Hawco², Erin Dickie², Jerrold Jeyachandra¹, Zhi-De Deng³, James Gold⁴, George Foussias², Miklos Argyelan⁵, Zafiris J Daskalakis⁶, Robert Buchanan⁴, Anil Malhotra⁵, Aristotle Voineskos²

¹*Centre for Addiction and Mental Health*, ²*Centre for Addiction and Mental Health, University of Toronto*, ³*National Institute of Mental Health, Duke University School of Medicine*, ⁴*Maryland Psychiatric Research Center*, ⁵*Zucker Hillside Hospital, Feinstein Institute for Medical Research*, ⁶*University of California San Diego*

Background: Individuals with schizophrenia spectrum disorders (SSDs) often experience social cognitive impairments, which are associated with poor functional outcome. There are currently no approved treatment options for these debilitating deficits in SSDs or other brain disorders. Social processes affected in SSDs are thought to rely on a frontoparietal ‘simulation network’ and a cortical midline/lateral temporal ‘mentalizing network’, which may be amenable to modulation using neurostimulation. The present feasibility study applied a personalized targeting method to examine, for the first time, the effect of individually-targeted repetitive transcranial magnetic stimulation (rTMS) to the dorsomedial prefrontal cortex (DMPFC) on social cognitive network functional connectivity in individuals with SSDs. We examined the comparative efficacy on functional connectivity within and between social cognitive networks of conventional 10 Hz rTMS and intermittent theta burst stimulation (iTBS) to sham stimulation and examined the comparative tolerability of the different treatments.

Methods: We conducted a two-week, double-blind, sham-controlled, randomized clinical trial comparing 10 Hz rTMS and iTBS, a more time-efficient rTMS paradigm, applied to the DMPFC in clinically stable adults with SSDs across three sites. Our primary outcome measure was change in within mentalizing network connectivity. Our secondary outcome measure was tolerability. We also explored connectivity changes between the mentalizing and simulation networks. Participants completed pre- and post-treatment magnetic resonance imaging (MRI) scans, including the social processing Empathic Accuracy task which engages the simulation and mentalizing networks. Neurostimulation (10 Hz rTMS, iTBS, or sham) was individually targeted by combining electric field mapping, which accounts for anatomical brain surface variability, and functional connectivity mapping to localize each individual's point of maximal DMPFC-mentalizing network functional connectivity. Following MRI preprocessing, within-mentalizing and between mentalizing-simulation network functional connectivity metrics during the Empathic Accuracy task were calculated both pre- and post-rTMS. Given that this was a feasibility study designed to determine effect sizes and tolerability, Cohen's d effect sizes were calculated between each active treatment condition and sham to identify potential differences in the magnitude of changes.

Results: Of the 51 randomized participants, 46 completed treatment and 43 (10 Hz rTMS N = 15, iTBS N = 15, sham N = 13) were included in the imaging analyses following quality control. There was a greater increase in mentalizing network connectivity following iTBS compared to sham ($d = 0.53$). Negligible differences were observed in changes in mentalizing network connectivity following 10 Hz rTMS when compared to sham ($d = 0.07$). Little change was seen in mentalizing-simulation between-network connectivity, with negligible effect sizes when comparing iTBS to sham and 10 Hz rTMS to sham. Pain scores were low in all groups (mean LESS THAN 5 across arms) and there was no difference in drop-out rate among the three groups, suggesting good tolerability.

Conclusions: This study marks the first investigation of rTMS effects on social cognitive circuitry in SSDs, incorporating individualized targeting approaches and inclusion of both a 10 Hz rTMS and a more time-efficient iTBS arm. Our results suggest that iTBS can change mentalizing network connectivity with medium effect size. We are now embarking on a larger clinical trial using iTBS versus sham stimulation to assess changes in social cognitive performance.

43.2. NON-INVASIVE BRAIN STIMULATION TO TREAT NEGATIVE SYMPTOMS – FROM LARGE-SCALE CLINICAL DATA TO PREDICTIVE MODELS

Alkomiet Hasan^{*1}, Nikolaos Koutsouleris²

¹Universtiy of Augsburg, ²Ludwig-Maximilian-University

Background: The treatment of cognitive and negative symptoms of schizophrenia is still challenging. Non-invasive brain stimulation has been investigated as potential treatment option for this difficult-to-treat symptom domains with variable results. The response variability may be explained by several individual and methodological factors. In 2015, we were the first to publish the results of a randomized multi-centre trial applying 10 Hz rTMS to the left DLPFC in 157 patients with schizophrenia and predominant negative symptoms. The primary outcome was negative. This trial changed guideline recommendations and the results are contrary to the findings from small single-centre trials that inform current meta-analyses.

Methods: We applied a multi-modal approach to improve response rates of non-invasive brain stimulation for the treatment of cognitive and negative symptoms and schizophrenia. We hypothesized that it appears to be more likely that the response variability to brain stimulation will be targeted using more individualized predictors and predictive models or models to define

response-subtypes rather than refining stimulation paradigms and methods. We combined clinical data, imaging and genetic data to develop predictors for the response to rTMS. Moreover, we used IPD meta-analyses to evaluate whether rTMS is an effective option for ultra-treatment resistance.

Results: We will present results from classical and individual patient data meta-analysis, from subgroup analyses (e.g. treatment-resistant patients), from imaging-based predictive analyses and from multimodal predictive analyses combining imaging data, with genetic data and clinical parameters.

Conclusions: Our research track allows to conclude that the future of non-invasive brain stimulation for the management of schizophrenia symptoms is more likely to be influenced by selecting the right patient for a given intervention rather than trying to improve stimulation methods following the classic “one stimulation fits all” paradigm that has failed in the past.

43.3. A DISEASE-INFORMED, NETWORK-TARGETED NEUROMODULATION INTERVENTION AFFECTS CRAVING IN INDIVIDUALS WITH SCHIZOPHRENIA AND NICOTINE DEPENDENCE

Heather Ward*¹, Gulcan Yildiz², Jing Xie², Adam Beermann², Amy Janes³, Lauren Moran⁴, Mark Halko⁵, Roscoe Brady⁶

¹Vanderbilt University Medical Center, ²Beth Israel Deaconess Medical Center, ³National Institute on Drug Abuse, ⁴Harvard Medical School/ McLean Hospital, ⁵Harvard Medical School/McLean Hospital, ⁶Beth Israel Deaconess Medical Center, Harvard Medical School

Background: The prevalence of tobacco use in schizophrenia (SZ) is 3-times that of the general population. Yet, treatments for nicotine dependence are significantly less effective for SZ and do not target SZ-specific pathophysiology. We sought to identify and test a neuromodulation intervention on a SZ-specific circuit of nicotine dependence.

Methods: This study consisted of 3 phases: Network Discovery, Network Validation, and Network-Targeted Intervention. In Network Discovery, we used a data-driven, multi-variate pattern analysis of whole-connectome data from 35 smokers (18 SZ, 17 controls) to identify the strongest links between daily cigarette use and functional connectivity. In Network Validation, 24 participants (12 SZ, 12 control) participated in a placebo-controlled crossover study of nicotine patch with fMRI. Based on Network Discovery results, we correlated default mode network (DMN) connectivity change with nicotine patch dose. In Network-Targeted Intervention, 10 people with SZ and nicotine dependence participated in a crossover study of individualized, DMN-targeted repetitive transcranial magnetic stimulation (rTMS) with fMRI and craving assessment immediately before and after each rTMS session. rTMS was targeted to the left parietal node of an individual-specific DMN map for 3 sessions: intermittent theta burst stimulation (iTBS), continuous theta burst stimulation (cTBS), sham. We compared craving change between each rTMS type using a mixed ANOVA.

Results: In Network Discovery, the strongest ($p < .001$) correlate between functional connectivity and daily cigarette use was driven by individual variation in DMN topography specific to SZ. With higher cigarette use in SZ, the DMN spatial extent was pathologically expanded. In Network Validation, nicotine administration reversed DMN hyperconnectivity in SZ in a dose-dependent relationship ($R = -0.50$, 95% CI -0.75 to -0.12 , $p < .05$). In Network-Targeted Intervention, we observed a treatment $\times$ time effect ($p = .017$) where craving was increased by iTBS but not by cTBS or sham.

Conclusions: We identified a SZ-specific network of nicotine dependence (i.e., DMN), validated the effect of acute nicotine on that network, then applied an individualized, neuromodulation intervention to that network that affected craving in SZ. This is the first

evidence for a circuit-based intervention for substance use in SZ that was empirically derived, unique to SZ, and affected clinical outcomes.

43.4. CEREBRAL PHOTOBIMODULATION FOR THE TREATMENT OF NEGATIVE SYMPTOMS OF SCHIZOPHRENIA: DOUBLE-BLIND, SHAM-CONTROLLED, RANDOMIZED CLINICAL TRIAL WITH MAGNETIC RESONANCE SPECTROSCOPY

Leandro Valiengo^{*1}, Bianca Pinto², Andre Brunoni¹

¹University of Sao Paulo, ²Instituto de Psiquiatria, University of São Paulo Medical School – São Paulo, Brazil

Background: Negative symptoms of schizophrenia are associated with poor clinical outcomes. They tend to increase over time in severity and prognostic weight and usually persist with antipsychotic medication treatment. Studies have suggested that the dorsolateral prefrontal cortex (DLPFC) is involved in the pathophysiology of negative symptoms in schizophrenic patients, with reduced levels of metabolism in the prefrontal cortex and an inverse correlation between the severity of negative symptoms and cerebral blood flow in the prefrontal cortex. Recent clinical trials demonstrated a possible role of non-invasive neuromodulation (targeting the DLPFC) as TMS and tDCS for the treatment of these symptoms. A new form of neuromodulation is emerging, called photobiomodulation (PBM), that uses infrared light to activate mitochondria, which in turn stimulates second messenger systems, DNA transcription, and growth factors. Studies have demonstrated that PBM can change magnetic resonance spectroscopy. This treatment has not been used in schizophrenia until now.

Methods: 30 adults (18-55 years) with schizophrenia (minimum of 20 points in PANSS – positive and negative symptom score) and stable antipsychotic medications (at least six weeks with the same dosage) were recruited at the Clinical Hospital of the Medical School of University of São Paulo. We excluded drugs that can interfere with negative symptoms, neuropsychiatric conditions, contra-indications to PBM (as metallic plaques in the skull), or severe clinical conditions. Participants were randomly allocated to active or sham stimulation and received 10 sessions of PBM in 10 consecutive days, and after that, they inverted groups (who was sham went to active group and vice versa). They were evaluated at weeks 0, 1, 2, 3, 4, 6 and 12 for clinical outcomes. The operator of the PBM, the evaluators, the participants and the staff were blinded. For sham, the device has a similar electrode that does not generate the light field. A blinding scale was applied to evaluators, applicators, and volunteers to see if blinding had been effective. trained psychiatrists evaluated the participants. The PANSS scale was applied at weeks 0 (baseline), 1, 2, 3, 4 (endpoint), 6 and 12. The SANS (scale for the assessment of negative symptoms) and BPSS (brief negative symptom scale) were used as secondary outcomes. Adverse effects were assessed using a standardized questionnaire. The primary analysis was a repeated-measures analysis of variance with PBM (2 levels: active and sham) as the between independent variable and time (4 levels: week 0, 1, 2 and 4) as the within independent variable negative subscale of PANSS scores is the dependent variable. We used the command anova for crossover of Stata. Treatments was administered daily over a period of 2 weeks with a Light-Aid (Bright Photomedicine, SP, Brazil), continuous wave, 300 LED wavelength (850 nm) over the bilateral prefrontal cortex or with a placebo probe of the same appearance and display. The irradiation parameters created were based on the disease, pain intensity, and skin phototype. The Proton Magnetic Resonance Imaging and Spectroscopy was performed using the spectrum of four signals: choline, creatine, N-acetyl-aspartate and the lactate double peak in anterior cingulate gyros at baseline, week 2 and at the end of the PBM sessions (week 4).

Results: We did not have any dropouts from the study. Both groups were similar regarding clinical and demographical measures. The group that started with active stimulation had differences (more decrease in the scales of negative symptoms) with the other group after 2 weeks and maintained the effects. All the scales of negative symptoms had differences between groups and time, and without carry-on effects, the p values of intrasubjects effects on period, treatment and carryover are the following: negative PANSS (LESS THAN 0.00, .04 and 0.66), SANSS (LESS THAN 0.00, .04 and 0.68) and BNSS (0.03, 0.18 and 0.63), benefiting the active group. The positive or total PANSS and Calgary scale (depression) did not show differences between groups.

Conclusions: The group that started with the active group had a decrease of negative symptoms with statistical significance after 2 weeks. It seems that the effect of PBM started only after the 10 sessions of stimulation. We did not find differences between the levels of lactate in spectroscopy MRI in the ACC. These positive results should be better explored in further trials.

44. PROTECTIVE MECHANISMS AGAINST PSYCHOTIC EXPERIENCES

Larisa Morosan, *UMCG*

Overall Symposia Abstract: Psychotic disorders develop through subsequent stages of illness severity, from subclinical to clinical psychotic experiences. Research focused on the risk factors for psychotic experiences, but factors that may reduce symptom progression or even prevent onset of psychosis remain poorly understood. Understanding these protective mechanisms may improve early stage-specific interventions promoting resilience and preventing the disorder progression. The presentations in this symposium examine different protective mechanisms that buffer against psychotic experiences, focusing on different time-scales (i.e. daily, months, years) and on different populations (i.e., different age groups and nationalities) across the psychosis continuum (i.e. both general and clinical populations).

Sara van der Tuin, PhD candidate will present work on the daily associations between positive affect and psychotic experiences. For this purpose, she used daily diary data from the Mapping Individual Routes of Risk and Resilience (MIRORR) study. The results showed that positive affect and psychotic experiences were associated bidirectionally and that individuals at ultra-high risk (UHR) for psychosis presented a stronger negative association between daily positive affect and psychotic experiences. This highlights the protective role of positive affect against psychotic experiences, which might be stronger for UHR individuals.

Larisa Morosan, PhD will present work on the effect of daily social support on the association between daily hassles and daily suspiciousness. She also used the MIRORR daily diary. The results suggest that when people felt more supported, the association between the daily negative events and suspiciousness was weaker compared to days when they felt less supported, but only for participants with moderate psychotic symptoms without being UHR. This suggests the buffering effect of daily social support on daily suspiciousness differs depending on the clinical stage.

Neus Vidal Barrantes, PhD will present work investigating the Differential Susceptibility model, which suggests that genetic variants that increase the negative effects of adverse experience, also enhance the beneficial effects of positive experiences. The model was tested in nonclinical young adults and adults sampled for schizotypy. The presence of high genetic sensitivity moderated the effect of childhood adversity and the effect of daily negative and positive contexts on psychotic experiences, positive schizotypy, and depression. The results

highlight the role of genetic sensitivity in the psychotic and affective reactivity in daily life and the transdiagnostic protective role of positive experiences.

Daniel Nuñez, PhD will present results from a randomized controlled trial study aiming to test the effectiveness of a blended cognitive-behavioral intervention (CBT) to reduce mental health problems and to improve emotion regulation in adolescents. Participants allocated to the intervention group were presented with 12 sessions CBT sessions and the control group received treatment as usual. The program reduced psychotic experiences, depression symptoms, suicide ideation and improved cognitive and emotional skills. This shows that CBT based interventions delivered in school settings could be suitable to reinforce protective mechanisms against psychotic experiences and psychopathology during adolescence.

44.1. THE DAILY ASSOCIATION BETWEEN POSITIVE AFFECT AND PSYCHOTIC EXPERIENCES IN INDIVIDUALS ALONG THE EARLY STAGES OF PSYCHOSIS CONTINUUM

Sara van der Tuin^{*1}, Lorna Staines², Larisa Morosan¹, Esdras Raposo de Almeida¹, David van den Berg³, Sanne Booij¹, Albertine Oldehinkel¹, Johanna Wigman⁴

¹UMCG, ²Royal College of Surgeons in Ireland, ³Parnassia Psychiatric Institute, The Hague | ⁴VU University, Amsterdam, ⁴University Medical Center Groningen

Background: Psychosis often develops gradually along a continuum of severity. Little is known about the role of protective factors as positive affect (PA) in the development of psychotic experiences

(PEs). This study investigated (i) the temporal (between-day) and contemporaneous (within-day) daily associations between PA and PEs in individuals at different early clinical stages for psychosis and (ii) whether these associations differed per clinical stage.

Methods: Daily diary data of 90 days came from 96 individuals at risk for psychosis, distributed over four subgroups defined according to the clinical staging model (stages 0-1b). Multilevel models were constructed with PA as predictor of PEs and vice versa. We investigated within- and between-person temporal and contemporaneous associations, and tested whether these associations differed among early stages with multilevel moderation analyses.

Results: We found no within-person temporal effects between PA and PEs in either direction. Contemporaneously, current day PA predicted current day PEs ($B = -0.14$, p and $lt;0.001$) and vice versa ($B = -0.61$, p and $lt;0.001$). Between persons, more 90-day PA predicted less PEs in the temporal model ($B = -0.14$, $p = 0.03$). In addition, more 90-day PEs predicted PA in the temporal ($B = -0.26$, p and $lt;0.001$) and contemporaneous ($B = -0.36$, p and $lt;0.001$) model. The contemporaneous association between PA and PEs was stronger in individuals at ultra-high risk (UHR) for psychosis than in earlier stages.

Conclusions: Our study supported a significant within-day, bi-directional relationship between PA and PEs. This suggests that a focus on PA and methods to improve PA might be an important addition to early intervention practices, particularly in those at UHR for psychosis.

44.2. THE IMPACT OF DAILY SOCIAL SUPPORT ON THE ASSOCIATIONS BETWEEN DAILY NEGATIVE EVENTS AND DAILY SUSPICIOUSNESS ACROSS DIFFERENT CLINICAL STAGES OF PSYCHOSIS

Larisa Morosan^{*1}, Esdras Raposo de Almeida¹, Sara van der Tuin¹, David van den Berg², Sanne Booij³, Johanna Wigman⁴

¹UMCG, ²Parnassia Psychiatric Institute, The Hague | VU University, Amsterdam,

³Groningen University, ⁴University Medical Center Groningen

Background: Psychosis mostly develops gradually, from mild to more severe manifestations. Research focused mostly on risk factors predicting illness progression, but little attention is paid to the daily factors decreasing this risk. The current study aimed to investigate: i) the impact of daily negative events on daily suspiciousness and ii) the potential buffering effect of daily social support on the association between daily negative events and daily suspiciousness and whether this effect differs across clinical stages for psychosis.

Methods: Diary data from the Mapping Individual Routes of Risk and Resilience study were used. Participants (N=96, 76% females, aged 18-35 years old) were assigned into four subgroups representing clinical stages, from the general population to Ultra High Risk (UHR) for psychosis. For 90 days, participants reported on the unpleasantness of negative events, social support and suspiciousness. Multilevel models were fitted to test the contemporaneous (i.e. same day) and lagged (i.e. from one day to another) relations hypothesized in both research questions.

Results: On days when participants reported more unpleasant negative events, they also reported more suspiciousness. On days with more social support, the association between the unpleasantness of negative events and suspiciousness was weaker than during the days when social support was lower, but only for participants presenting moderate psychotic symptoms, without being UHR. The lagged effects were not statistically significant.

Conclusions: These results may improve the theoretical understanding of psychosis and guide the development of stage-specific interventions and prevention strategies enhancing and targeting social support in specific at-risk populations.

44.3. GENETIC SENSITIVITY TO THE ENVIRONMENT MODERATES BOTH THE RISK- AND RESILIENCE-INDUCING EFFECTS OF CHILDHOOD EXPERIENCES ON PSYCHOTIC, DEPRESSIVE AND ANXIETY DIMENSIONS

Neus Barrantes-Vidal^{*1}

¹Universitat Autònoma De Barcelona

Background: Gene-by-environment (GxE) studies in psychosis have exclusively focused on negative exposures. However, emerging evidence supports the resilience-enhancing effect of positive factors on psychosis outcome. The Differential Susceptibility (DS) model proposes that common genetic variants may confer not only disproportionate responsiveness to negative environments, but also greater sensitivity to positive, resilience-enhancing conditions. This study is the first to apply the DS model to the expression of subclinical psychosis, employing polygenic risk scores of environmental sensitivity (PRS-ES). PRS-ES were hypothesized to moderate, in a DS manner, associations between childhood adversity and psychosis, affective, and anxiety dimensions in young adults. An exploratory goal examined whether PRS for psychotic-like experiences (PRS-PLE) also showed DS patterns.

Methods: PRS, schizotypy, PLE, depression, anxiety, and childhood adversity ratings were obtained for 197 nonclinical young adults. LEGIT software for testing competitive-confirmatory GxE models was employed.

Results: Results largely supported DS: Individuals high on PRS-ES showed increased subclinical psychosis, depression and anxiety if they had experienced elevated childhood adversity, and lower symptoms if exposed to low levels of adversity as compared to those with low PRS-ES. Similarly, PRS-PLE moderated the effect of adversity on PLE, positive schizotypy, and depression following the DS model, but only PRS-ES moderation on PLE survived statistical correction.

Conclusions: Our results suggest that genetic DS to the environment is relevant to psychosis, depression, and anxiety. Current debates on reconceptualization of genetic ‘risk’ and resilience may benefit from this insight that support optimistic views on preventative efforts for early detection and intervention.

44.4. THE EFFECT OF A PILOT CBT BLENDED INTERVENTION ON PSYCHOTIC EXPERIENCES, DEPRESSIVE SYMPTOMS, SUICIDAL IDEATION AND COGNITIVE-EMOTIONAL REGULATION SKILLS IN ADOLESCENTS FROM CHILE

Daniel Nunez¹, Jorge Gaete², Daniela Meza³, Javiera Andaur³, Jo Robinson⁴, Lorna Staines*⁵

¹Universidad de Talca, Chile, ²Universidad de los Andes, Chile, ³Universidad de Talca,

⁴University of Melbourne, Australia, ⁵Royal College of Surgeons in Ireland

Background: Under the common mental disorder perspective, psychotic experiences, depressive and anxiety symptoms are prevalent in adolescents and could be manifestations of a latent continuum of common mental distress, which in turn is associated with suicidal ideation in this population. Prior evidence suggests that cognitive-behavioral skills and emotional regulatory process could be protective factors against these phenomena during the adolescence. We conducted a pilot randomized controlled trial (RCT) study to test the effectiveness of a blended cognitive-behavioral intervention (BCBT) to reduce mental health symptoms and suicide ideation, and to improve cognitive-behavioral skills and emotion regulation strategies in adolescents from high schools in Chile.

Methods: We assessed psychotic experiences (CAPE-P15), depressive symptoms (PHQ-9), anxiety symptoms (GAD-7), suicidal ideation (SIQ-JR), social -problem skills (SPSI-RS), cognitive-behavioral skills (CBTQ) and emotion regulation (ERQ-CA). After a cluster randomization (3 intervention schools and 3 control schools), participants allocated to the intervention group were presented with 12 sessions (8 online, 4 face-to-face sessions) delivered in school settings. Participants allocated to the control group received the treatment as usual in primary care centers. We used linear mixed-effects model analysis to compare the intervention and control groups regarding the change in outcome measures from baseline to post-intervention. Schools were included as a random factor for each outcome measure to account for possible school effects.

Results: At post-intervention, in the intervention group (N=30, Mean age=15.40 (SD=0.97)), we found significant reductions in depressive symptoms ($\beta=-3.5$; -5.0 to -2.0, $p < 0.001$), suicide ideation ($\beta=-15.3$; 95% CI-19.1 to -11.4, $p < 0.001$) and psychotic experiences ($\beta=-6.7$; -10.5 to -2.8, $p < 0.001$). Moreover, we found improvements in social-problem skills ($\beta=1.2$; 0.1 to 2.4, $p < 0.001$), behavioral activation ($\beta=2.4$; .4 to 3.4, $p < 0.001$) and cognitive reappraisal ($\beta= 3.9$; 0.9 to 6.7, $p < 0.001$).

Conclusions: The program was effective to reduce symptoms, including psychotic experiences and suicidal ideation, and to improve cognitive and emotional skills. This supports that CBT based interventions delivered in school settings could be suitable to reinforce resilience

mechanisms against common mental symptoms during adolescence. We expect to confirm these preliminary results through the RCT study being conducted during 2023.

45. CARDIOMETABOLIC CO-MORBIDITY IN SCHIZOPHRENIA SPECTRUM DISORDERS - UNRAVELING THE MIND-BODY INTERACTION

Wiepke Cahn, *University Medical Center Utrecht*

Overall Symposia Abstract: Patients with schizophrenia spectrum disorders (SSDs) demonstrate evidence of metabolic abnormalities at the earliest stages of illness. These precede treatment with antipsychotic (AP) medications, which through well-documented metabolic adverse effects exacerbate the problem. Individuals with SSDs subsequently lose 15-25 years of life to premature cardiovascular disease. Beyond the medical sequelae of these comorbidities, AP- metabolic adverse effects contribute to medication non-adherence, low self-esteem, decreased quality of life, and worse cognitive functioning. Obesity and other cardiometabolic abnormalities are also associated with brain alterations and add to the burden of brain changes in SSD. Together, this suggests that targeting metabolic comorbidity can have a meaningful effect on cardiometabolic, mental health, and brain outcomes.

This symposium, chaired by Dr. Wiepke Cahn (UMC, Utrecht, NL), takes a translational approach to dissect an emerging and complex topic: the underlying causes of metabolic comorbidity in SSDs and the potential impact of effectively managing metabolic comorbidity in relation to physical and mental health. Building on previous findings demonstrating that APs inhibit central insulin action, Dr. Margaret Hahn (University of Toronto, ON, Canada) will present novel preclinical data demonstrating that APs – across low and high metabolic liability medications, interfere with brain nutrient sensing including glucose (the key fuel source of the brain) and fatty acids, resulting in whole body insulin resistance, contributing to risk of diabetes. Dr. Tomas Hajek (National Institute of Mental Health, Klecany, Czech Republic) will present findings from a large cohort of individuals hospitalized for their first episode of psychosis in networks of hospitals in Czech Republic, which examined risk factors for weight gain/metabolic alterations including prospectively collected trajectories of daily medication use. Dr. Mahavir Agarwal (Centre for Addiction and Mental health, Toronto, Canada) will present data from a combined analysis of 3 weight loss intervention randomized controlled trials (Denmark and Canada), demonstrating that reductions in BMI are associated with reductions in brain age. Finally, Dr. Toby Pillinger (Institute of Psychiatry, Psychology and Neuroscience, King's College London, UK) will discuss new clinical data investigating metabolic dysregulation and cardiac abnormalities in children and young people with first-episode psychosis. Additionally, Dr. Pillinger will discuss the development of initiatives to facilitate metabolically-minded prescription practices including app development to reduce incidence of metabolic comorbidity. Dr. Belinda Lennox (Oxford University, UK) will act as discussant, to review the complexities of cardiometabolic disorders and their treatment in SSDs, as well as perspectives to move the field forward.

Collectively, this symposium provides new insights into central and peripheral mechanisms of metabolic dysfunction produced by APs, including risk factors in the earliest phases of illness. Moreover, we provide evidence that effective management of metabolic comorbidities can have a significant impact on brain health, and we discuss development of novel technologies to prevent and manage metabolic comorbidities across the lifespan of individuals with SSDs.

45.1. ANTIPSYCHOTICS DISRUPT BRAIN FATTY ACID SENSING RESULTING IN WHOLE BODY GLUCOSE DYSREGULATION

Emily Au¹, Sandra Pereira², Sally Wu³, Raghunath Singh⁴, Kristoffer Panganiban⁵, Sri Mahavir Agarwal², Margaret Hahn*¹

¹*Center for Addiction and Mental Health*, ²*Centre for Addiction and Mental Health*, ³*Institute of Medical Science, University of Toronto*, ⁴*Centre for Addiction and Mental Health (CAMH), Toronto*, ⁵*Centre for Addiction and Mental Health, University of Toronto*

Background: Antipsychotics (APs) are the cornerstone treatment for schizophrenia and are widely prescribed for other conditions. However, APs are associated with adverse metabolic effects, increasing the risk for type 2 diabetes in a population suffering from early cardiovascular mortality. APs can directly perturb whole body glucose metabolism independently from changes in body weight, and this occurs in part through actions on the central nervous system (CNS). We have previously shown that olanzapine impairs CNS insulin and glucose sensing, resulting in whole body insulin resistance. In addition to key metabolic regulatory functions of insulin and glucose in the brain, post meal increases in circulating free fatty acids (FFAs) signalling “nutrient abundance”, can also strongly regulate food intake and whole body glucose homeostasis. In the current study, we set out to examine the effects of the APs olanzapine and haloperidol on central sensing of the fatty acid oleic acid and subsequent regulation of peripheral glucose metabolism.

Methods: Gold standard pancreatic euglycemic clamps were used to assess changes in glucose kinetics in response to a primed, continuous intracerebroventricular (ICV) infusion of oleic acid or vehicle solution (1.71 mM, 5 μ L/hour, into the third ventricle). Male rats were co-treated with a subcutaneous injection of olanzapine (Ola) (3 mg/kg), haloperidol (Hal) (0.25 mg/kg), or vehicle. Groups included (central–peripheral) Veh–Veh (n=11), Ole–Veh (n=9), Ole–Ola (n=5), Veh–Ola (n=5), Ole–Hal (n=6), and Veh–Hal (n=8). A radioactive tracer (3-³H-glucose) infusion throughout the clamp procedure was used to assess glucose kinetics, including hepatic glucose production and peripheral glucose uptake.

Results: Intracerebroventricular (ICV) oleic acid infusion caused an increase in peripheral glucose infusion rate (mg/kg/min) compared to ICV vehicle (Ole-Veh 7.82 $\pm$ 0.47 vs Veh-Veh 2.44 $\pm$ 0.52, p LESS THAN 0.001). This effect was inhibited by co-treatment with olanzapine (Ole-Ola 1.99 $\pm$ 0.46 vs Veh-Veh, p GREATER THAN 0.05) or haloperidol (Ole-Hal 2.25 $\pm$ 0.58 vs Veh-Veh, p GREATER THAN 0.05). ICV oleic acid also suppressed hepatic glucose production (clamp relative to basal: Ole-Veh 79% $\pm$ 11.93 vs Veh-Veh 25.23% $\pm$ 6.19, p LESS THAN 0.001) and this effect was prevented by co-treatment with olanzapine (Ole-Ola 28.86% $\pm$ 6.64 vs Veh-Veh, p GREATER THAN 0.05) or haloperidol (Ole-Hal 22.18% $\pm$ 7.75 vs Veh-Veh, p GREATER THAN 0.05). ICV oleic acid increased glucose utilization which was not observed in the antipsychotic co-treatment groups.

Conclusions: Olanzapine and haloperidol disrupt the ability of central oleic acid to regulate peripheral glucose kinetics, resulting in impaired whole-body glucose metabolism. Impairments in brain nutrient sensing can have detrimental metabolic effects and have been observed in type 2 diabetes. Our findings suggest that impairments in central lipid sensing represent a mechanism by which APs mediate metabolic adverse effects. We also confirm that weight gain independent effects on glucose homeostasis can occur across AP classes, including “lower” metabolic risk agents like haloperidol.

45.2. TRAJECTORIES OF DAILY ANTIPSYCHOTIC USE AND WEIGHT GAIN/METABOLIC CHANGES IN PEOPLE HOSPITALIZED FOR FIRST EPISODE OF PSYCHOSIS

Tomas Hajek*¹, Kristyna Vochoskova², Marian Kolenic³, Sean McWhinney⁴, Filip Spaniel⁵

¹National Institute of Mental Health, Klecany, ²National Institute of Mental Health, Czech Republic, ³National Institute of Mental Health, Topolova 748, 250 67 Klecany, Czech Republic., ⁴Dalhousie University, Halifax, NS, Canada, ⁵National Institute of Mental Health, Topolova 748, 250 67 Klecany, Czech Republic

Background: Most people with schizophrenia die from cardiovascular disorders closely related to metabolic syndrome/obesity. While there are other causes, antipsychotic medications are a key contributor to weight gain/metabolic dysregulation in schizophrenia. It is also the one factor, which is mostly under the control of the psychiatrist. Yet, we know very little about how medication switches and combinations of medications impact weight.

Methods: We recruited participants with first episode psychosis (FEP, N=173) during their first psychiatric hospitalization in a network of collaborating hospitals in Czech Republic. We prospectively collected weight, body mass index, metabolic markers and daily medication exposure at admission and during hospitalization.

Results: One third of people with FEP remained on monotherapy. Almost half of individuals (43%) experienced an escalation of medications, mostly a switch to a medication with a worse metabolic profile than their initial treatment. Only 23.7% of individuals moved from a metabolically more to a metabolically less problematic medication. Individuals with FEP gained on average 0.97+/-2.26 BMI points or 3.46+/-7.81 kg of weight after an average of 44.6 days of their first inpatient treatment. Greater antipsychotic exposure was associated with greater BMI increase, but only in people with normal/low baseline BMI, who were treated with clozapine, olanzapine, sertindole, or quetiapine. Patterns of medication changes were not related to weight gain and would not be even with thousands of individuals. Antipsychotic treatment was not directly linked to metabolic markers, but higher BMI was associated with higher TGC, TSH, and lower HDL.

Conclusions: Clinicians should be especially cautious in prescribing metabolically more problematic antipsychotics to people with a normal to low baseline BMI. Weight was the best predictor of metabolic alterations, thus emphasizing regular weight monitoring during antipsychotic treatment.

45.3. THE EFFECT OF WEIGHT LOSS ON BRAIN AGE IN SCHIZOPHRENIA

Mahavir Agarwal*¹, Vittal Korann², Nicolette Stogios³, Bjorn Ebdrup⁴, Filip K Knop⁵, Margaret Hahn⁶

¹University of Toronto, ²Centre for Addiction and Mental Health, University of Toronto, ³Institute of Medical Science, University of Toronto, Centre for Addiction and Mental Health, ⁴University of Copenhagen, ⁵Gentofte Hospital, University of Copenhagen, , ⁶University of Toronto, Centre for Addiction and Mental Health (CAMH)

Background: Individuals with schizophrenia often have metabolic comorbidities, such as type 2 diabetes, and experience a reduced life expectancy due to cardiovascular diseases. Obesity, a common comorbidity in schizophrenia, can negatively affect brain health. However, there is limited understanding of how metabolic disorders impact brain structure in individuals with schizophrenia, and the effects of weight changes following pharmacological interventions have not been explored. In this study, we will investigate changes in brain morphology, specifically

brain-age, in overweight or obese individuals with or without diabetes who have been diagnosed with schizophrenia. We will assess these changes before and after a 12-week period of pharmacological treatment targeting metabolic dysfunction. We hypothesized that 1) a change in BMI will be positively associated with the change in brain age between baseline and endpoint; 2) there will be no significant difference in the strength of the correlation between the medication and placebo groups. As exploratory analyses, we also looked at the association between brain age and cognition and metabolic parameters.

Methods: This analysis includes 48 participants, aged 18 to 65, from three double-blind studies investigating interventions for antipsychotic-induced metabolic dysfunction: TAO study (NCT01794429, 9 on medication and 8 on placebo), Metformin for prediabetes/diabetes study (NCT02167620, 11 on medication and 8 on placebo), and Topiramate in clozapine study (NCT02808533, 12 on medication). In brief, inclusion criteria include patients with a diagnosis of schizophrenia, schizoaffective disorder, or bipolar disorder, metabolic comorbidity of prediabetes or type 2 diabetes, and BMI of above 25 kg/m². We collected brain structural MRI, metabolic measures, cognition data, and body mass index at baseline and week 12. We utilized a convolution neural network-based classifier that was trained and tested to estimate the brain age of each participant using high-quality brain anatomical T1 image. The study aims to examine the changes in BMI and estimated brain age scores using baseline and endpoint data.

Results: BMI change was found to be statistically significant in the whole sample ($p < 0.001$), as well as in the medication group ($p = 0.005$) and placebo group ($p = 0.008$). Likewise, significant changes were found only in total and HDL (high-density lipoprotein) cholesterol levels across all three groups in terms of metabolic parameters. However, none of the groups exhibited any substantial changes in psychopathological scores or cognitive data between the baseline and endpoint assessments. Multiple regression analysis revealed a positive correlation between BMI change and alterations in brain age for the whole sample ($\beta = 0.263$; $t = 1.85$; $p = 0.05$) and the medicated group ($\beta = 0.372$; $t = 2.12$; $p = 0.04$), but not in the placebo group ($\beta = -0.106$; $t = -0.40$; $p = 0.69$). However, no significant difference in the correlation strength was observed between the medication and placebo groups ($p = 0.12$). Furthermore, there was no significant association between changes in brain age and metabolic indicators such as total and HDL cholesterol. Lastly, no significant correlation was found between brain age and cognition.

Conclusions: our study showed a link between brain health (as assessed by delta brain age) and significant weight loss by anti-diabetic medication in patients with SCZ and comorbid obesity. These findings imply that large and extended weight loss, together with general improvements in cardiometabolic alterations, can prevent obesity-related abnormalities in brain health.

45.4. PHYSIOLOGICAL EFFECTS OF ANTIPSYCHOTICS ACROSS THE AGE SPECTRUM: CURRENT UNDERSTANDING AND IMPLICATIONS FOR PRECISION MEDICINE

Toby Pillinger^{*1}, Maria Rogdaki², Christoph Correll³, Stefan Leucht⁴, Oliver Howes⁵, Orestis Efthimiou⁶, Robert McCutcheon⁷

¹*Institute of Psychiatry, King's College London*, ²*King's College London, Institute of Psychiatry*, ³*The Zucker Hillside Hospital*, ⁴*Klinikum Rechts der Isar, Technical University of Munich*, ⁵*King's College/ Clinical Sciences Centre*, ⁶*Institute of Social and Preventive Medicine, University of Bern, Switzerland*, ⁷*Institute of Psychiatry, Psychology and Neuroscience*

Background: Antipsychotics are associated with physiological disturbance, with clear differences observed between drugs in adults. However, the degree to which these alterations occur in children and adolescents is unclear. Furthermore, although clinical guidelines recommend discussing side-effects with patients when making treatment decisions, considering all side-effects of all treatments is a complex, multidimensional process. Therefore, we aimed to compare and rank antipsychotics based on their physiological effects in children and young people using network meta-analysis. We aimed to use these side-effect data within a digital tool that facilitates evidence-based and personalized prescribing.

Methods: First, we first conducted a systematic review, searching MEDLINE, EMBASE and PsychINFO from inception until 31 September 2023. We included clinical trials that compared acute treatment with 13 antipsychotics and placebo in individuals aged LESS THAN 18 years. We performed frequentist random-effects network meta-analyses to investigate treatment-induced changes in body weight, BMI, total cholesterol, LDL cholesterol, HDL cholesterol, triglycerides, glucose, prolactin, heart rate, blood pressure, and QTc interval. Second, these data were then incorporated into a digital tool, termed the Psymatik Treatment Optimizer. This combines the side-effect data with side-effect concerns of an individual user, to enable users to select side-effects of concern and the relative degree of concern for each side-effect. Concern weightings and the side-effect databases are synthesised via a multicriteria decision analysis method (technique for order of preference by similarity to ideal situation, or TOPSIS).

Results: Of 6697 citations, we included 40 RCTs (median duration=6 weeks (IQR 6-12), comprising 6007 patients (mean age=15.13±0.94 years). 13 antipsychotics were included in the study. Estimated mean differences for change in weight compared with placebo ranged from -2.01kg (95% confidence interval: -3.61 to -0.41) for molindone to 4.68kg (0.63 to 8.66) for clozapine; and for BMI from -0.70kg/m² (-1.21 to -0.19) for molindone to 2.03kg/m² (0.51 to 3.55) for quetiapine. The majority of antipsychotics were associated with increased triglycerides, with an increase of up to 0.52mmol/L (-0.02 to 1.06) observed with clozapine. Risperidone/paliperidone was associated with the largest increase in prolactin levels, with an increase of 26.40ng/mL (21.13 to 31.67). Quetiapine was associated with the largest increase in heart rate of +12.42bpm (3.83 to 21.01) and systolic blood pressure of +10.04 (5.56 to 14.51). The Psymatik Treatment Optimizer synthesises these side-effect data with individual user-defined concern weights. Psymatik ranks antipsychotics in order of preference for the individual user, with the output presented in a heatmap.

Conclusions: We found strong evidence of clinically significant differences between antipsychotics in physiological side-effects when used in children and adolescents. For cardiometabolic changes, olanzapine, quetiapine, risperidone, paliperidone, and clozapine exhibited the worst profiles, and aripiprazole, blonanserin, ziprasidone, lurasidone, and molindone the more benign profiles. For alterations in prolactin, risperidone/paliperidone performed the worst and aripiprazole the best. Incorporation of these data into the Psymatik Digital Optimizer facilitates collaborative, personalised, and evidence-based prescribing decisions.

46. DISTURBED MYELIN PLASTICITY IN SCHIZOPHRENIA: FROM RISK FACTORS TO TREATMENT

Andrea Schmitt, *LMU*

Overall Symposia Abstract: Despite the critical role of cognitive deficits in schizophrenia, we neither understand their pathophysiology nor have a psychopharmacological treatment for them. Evidence from diffusion-weighted magnetic resonance imaging studies show impaired structural connectivity, reduced fractional anisotropy and white matter microstructure (WM)

across the lifespan in schizophrenia. These findings are interpreted as indicators of decreased myelination. In post-mortem brain regions such as the hippocampus, prefrontal cortex and cingulum, decreased numbers of oligodendrocytes, which are responsible for myelination, have been reported in schizophrenia. J Seitz-Holland combined multi-site cognitive, imaging, and clinical data to characterize cognitive deficits across the schizophrenia lifespan and assessed the association between cognitive deficits, clinical symptoms, and WM. WM mediated the association between schizophrenia and language/processing speed/working memory/non-verbal memory. In addition, processing speed mediated the influence of diagnosis and WM on the other cognitive domains. Oligodendrocyte-related risk variants are not among the top associations in genome-wide association studies (GWASs). However, in an enrichment analysis study of cell type-specific gene expression, oligodendrocytes and oligodendrocyte precursor cells (OPCs) showed enrichment in genes associated with schizophrenia. S Papiol evaluated the modulatory role of cell type-specific schizophrenia polygenic risk scores (PRS) on volume changes after three months aerobic exercise in hippocampal subfields. The analyses shows that the PRS associated with OPCs significantly influenced the volume changes in the CA4/DG subfield in schizophrenia patients. A higher OPC-associated genetic risk burden was associated with a less pronounced volume increase during the exercise intervention. Results are discussed in the light of recent animal studies showing that exercise promotes OPC differentiation. M Wegner analyzed the role of Tcf4 in oligodendroglial cells and studied Tcf4-deficient as well as the double heterozygous Tcf4/Olig2 null mutant mice. In this work, the GWAS-based schizophrenia risk gene Transcription Factor 4 (Tcf4) was shown to be the preferred heterodimerization partner for the Oligodendrocyte Transcription Factor 2 (Olig2) in oligodendrocytes and is required for differentiation of OPCs. These mice have oligodendroglial deficits and display reduced numbers of oligodendrocytes. The mouse models are suitable to investigate effects of oligodendrocyte-related pathophysiology on schizophrenia-related behavior with the aim to develop new treatment strategies. J Liu administered clemastine, an antimuscarinic compound that has been shown to enhance oligodendrocyte differentiation and myelination in vitro, and in adult mice following social isolation as a mouse model with schizophrenia-related behavioural deficits. Clemastine successfully reversed social avoidance behavior in mice undergoing prolonged social isolation. Impaired myelination was rescued by oral clemastine treatment, and was associated with enhanced OPC differentiation and epigenetic changes. This symposium highlights the need for new treatment strategies targeting deficits in myelination-related pathological processes. Because OPCs are capable of remyelination, triggering their differentiation could rescue deficits of white matter structures, thereby promoting connectivity and improving cognitive symptoms in schizophrenia.

46.1. THE ASSOCIATION BETWEEN WHITE MATTER MICROSTRUCTURE AND COGNITION IN PSYCHOSIS

Johanna Seitz-Holland^{*1}, Cornelius Berberich¹, Joanne D. Wojcik², Suheyla Cetin Karayumak¹, Alan Breier³, Martha Shenton¹, Marek Kubicki¹

¹Brigham and Women's Hospital, Harvard Medical School, ²Beth Israel Deaconess Medical Centre, Harvard Medical School, ³Indiana University School of Medicine

Background: Several neuroimaging studies highlighted the role of white matter microstructure in the psychopathology of psychosis. Specifically, diffusion magnetic resonance imaging studies utilized the fractional anisotropy (FA) measure and frequently interpreted reduced FA findings in psychosis as indicators of compromised white matter (e.g., myelination). Smaller studies reported a link between FA and cognitive deficits in individuals with psychosis.

However, other studies fail to find these associations, suggesting time, domain, or diagnosis-specific effects. Here, we present our recent findings from studies utilizing state-of-the-art imaging methods to explore the association between white matter microstructure and cognition across the psychosis spectrum.

Methods: We will present the results of two studies. While the first study focuses on the overall association, the second introduces a transdiagnostic multi-dimensional approach to examine white matter microstructure and cognitive functioning in the early phases of psychosis.

In the first study, we examined data from a multisite study of 900 individuals diagnosed with schizophrenia. We harmonized imaging and cognitive data and examined eight cognitive domains (language, processing speed, vigilance, working memory, verbal memory, non-verbal memory, motor function, and executive function). We compared cognitive function between individuals with schizophrenia and healthy individuals using t-tests and Cohen's d-effect sizes. Next, we applied regression and mediation analyses to examine the association between a diagnosis of schizophrenia, whole-brain FA, and cognition.

In the second study, we examined data from 203 individuals diagnosed with psychosis collected as part of the Human Connectome Project for Early Psychosis (HCP-EP). We used harmonization and novel processing methods and clustered individuals based on their cognitive performance. We compared general functioning, Perceived Stress, Life Satisfaction, Meaning and Purpose, Self-Efficacy, and voxel-wise cellular and extracellular white matter structure between the cognitive clusters.

Results: The first study demonstrated cognitive deficits in all domains ($p < 0.006$) and an association between white matter microstructure and language, processing speed, working memory, and non-verbal memory in individuals with schizophrenia. Processing speed mediated the influence of diagnosis and WM microstructure on the other cognitive domains. In the second study, we found two clusters with good stability and prediction strength based on cognitive measures: cluster 1 with lower ($n = 82$) and cluster 2 with higher performance ($n = 100$). There were more individuals with affective psychosis in cognitive cluster 2 ($\chi^2(1) = 5.70$, $V = 0.19$, $p = 0.017$), and cluster 2 was associated with lower Meaning and Purpose ($T(176) = 3.38$, $d = 0.51$, $p < 0.01$), better Social Functioning ($T(179) = -2.06$, $d = 0.31$, $p = 0.041$) and Self Efficacy ($T(180) = -2.23$, $d = 0.33$, $p = 0.027$), but not white matter microstructure.

Conclusions: Together, the studies highlight the critical role of cognitive deficits across the psychosis spectrum. Importantly, cognition seems to be related to measures of Efficacy, Meaning, and Purpose, all relevant to the quality of life but traditionally neglected in psychosis research. In addition, they emphasize that white matter microstructure is crucial in explaining the association between psychosis and cognition, specifically in later, more severe stages of the disorder. The findings also suggest the potential of early neuroprotective treatment for individuals with impaired cognition.

46.2. RISK GENES ASSOCIATED TO MYELIN PATHOLOGY IN SCHIZOPHRENIA

Sergi Papiol^{*1}, Isabel Maurus², Man-Hsin Chang², Thomas Schneider-Axmann³, Daniel Keeser³, Florian J. Raabe³, Andrea Schmitt³, Moritz J. Rossner³, Peter Falkai³

¹IPPG / LMU, ²University Hospital, LMU, ³Ludwig-Maximilians University 4⁴⁵

Background: Despite the compelling evidence of an oligodendroglial/myelin dysfunction in at least a subset of schizophrenia (SCZ) patients, genome-wide association studies (GWAS) in SCZ have not been able to identify a remarkable role of oligodendrocyte lineage-related genes

on the risk of this disorder. Compared to neuronal cell types, only discrete enrichment of SCZ risk loci has been reported in gene sets associated with oligodendroglial cells so far. However, these negative results may be the consequence of poorly-defined oligodendrocyte/myelin-related gene sets due to several technical and methodological reasons. In this presentation we will present gene set enrichment analyses based on novel data derived from human induced pluripotent stem cells (hiPSCs) to re-evaluate the oligodendroglial-specific impact on SCZ genetic burden.

Several studies have shown that physical exercise represents an effective intervention for patients with severe mental disorders such as schizophrenia. Recent findings have shown the specific effects of physical exercise on cognitive functions and brain structure in schizophrenia patients. However, little is known regarding the biological underpinnings of such an effect. In this presentation we provide novel evidence of the impact of schizophrenia polygenic risk related to oligodendrocyte lineage on the modulation of the effects of aerobic training on hippocampal brain structure in SCZ patients.

Methods: After an initial clustering analysis of hiPSC-differentiated neuronal cells including oligodendrocyte precursor cells (OPCs) and oligodendrocytes (OLs) with human postmortem brain cells based on single-cell RNA sequencing (scRNAseq), we performed a MAGMA gene set enrichment analysis leveraging the hiPSC-derived cell type-specific gene sets. Regarding the polygenic analyses, three different PRS were generated exclusively on the basis of the genetic variants in the genes (± 10 kb) that constitute the radial glia (PRS-Rad), OPCs (PRS-OPC), and mature oligodendrocyte (PRS-Oli) gene sets. Univariate linear regression was used to ascertain the role of such polygenic scores on hippocampus subfields volumes upon physical activity intervention, while correcting for the appropriate covariates.

Results: Genetic features of hiPSC-OLs were highly enriched in SCZ GWAS. Specifically, the enrichment was observed in the OL2 lineage, corresponding to a mature stage of oligodendrocyte development. In addition, polygenic analyses showed that the PRS-Rad and PRS-OPC were significantly associated with the volume changes in the CA4/DG hippocampus subfields in SCZ patients. A higher OPC/Radial glia-associated genetic risk burden was associated with a less pronounced volume increase (an potentially a lesser degree of beneficial effects) after the exercise intervention.

Conclusions: Our enrichment analyses results suggest that oligodendrocyte genes, especially in the stage of more mature differentiation (OL2), could actually have an outstanding contribution to the polygenic architecture of SCZ. Likewise, we provide further evidence of the interest of oligodendrocyte-related genes to understand the heterogeneity in the response to a physical activity intervention. Taken together, our results suggest intriguing links between genetic risk for SCZ associated to the oligodendrocyte lineage and plastic processes in the brain in these patients with therapeutic potential.

46.3. THE SCHIZOPHRENIA RISK GENE TCF4 DOES NOT ONLY AFFECT NEURONAL DEVELOPMENT, BUT HAS ADDITIONAL FUNCTIONS IN OLIGODENDROCYTES AND MYELINATION

Michael Wegner*¹

¹*FAU Erlangen-Nürnberg*

Background: Several genes that are linked to schizophrenia by GWAS or similar studies are not only expressed in neurons, but at similar levels in the macroglial cells of the central nervous system, including the myelin-forming oligodendrocytes. Their mutation, inactivation or malfunction may therefore not only contribute to schizophrenia because of their role in neurons

but also because of their function in oligodendrocytes. TCF4 is such a gene and it codes for a class I basic helix-loop-helix (bHLH) type transcription factor. Haploinsufficiency of TCF4 also causes the neurodevelopmental disorder Pitt–Hopkins syndrome.

Methods: To study the role of TCF4 in oligodendrocytes, we analyzed oligodendroglial development in knockout mice and complemented our study by TCF4 gain- and loss-of-function approaches in cultured mouse and human oligodendrocytes.

Results: Our results consistently showed that TCF4 is required cell-autonomously for proper terminal differentiation and myelination. In the absence of TCF4, oligodendrocytes differentiate in lower numbers and fewer myelin sheaths are formed. These phenotypes may also contribute to the severe impairment of commissure development observed in TCF4 knockout mice. Considering that class I bHLH proteins usually function as heterodimerization partners and functional modulators of class II bHLH proteins and that OLIG2 is a highly expressed and functionally important class II bHLH protein in oligodendrocytes, we also investigated the possibility of a functional link between TCF4 and OLIG2. Indeed we established that TCF4 is the preferential heterodimerization partner of OLIG2 and that both proteins together influence myelin gene expression. In line with biochemical results mice with combined heterozygous loss of TCF4 and OLIG2 show clear deficits in oligodendrocyte differentiation and myelination that are not observed in the single heterozygous mice.

Conclusions: In summary, our findings establish a role of TCF4 in oligodendrocytes and point to the possibility that part of the consequences of TCF4 malfunction in neuropsychiatric disorders such as schizophrenia is due to altered oligodendroglial rather than neuronal function.

46.4. TREATING DISTURBED MYELINATION IN SCHIZOPHRENIA: REPURPOSING A WAY AHEAD?

Jia Liu*¹

¹*City University of New York, Advanced Science Research Center*

Background: Emerging evidence shows that oligodendrogenesis and myelination are highly responsive to behavioral experience, including physical activity and social experience. Transcriptional, translational and ultrastructural changes in the oligodendrocyte and subsequent myelin have been identified and represent powerful mechanisms to regulate neuronal circuit function. Our laboratory has demonstrated that various traumatic social experience has a significant impact on myelination and oligodendrocyte, the myelin-forming cells. Impaired myelination preceded depressive-like behavior in socially isolated mice and was associated with aberrant epigenetic modifications in the oligodendrocytes.

Methods: Through oral administration of clemastine, an antimuscarinic compound that has been shown to enhance oligodendrocyte differentiation and myelination in vitro, we showed here it successfully reversed social avoidance behavior in mice undergoing prolonged social isolation and was associated with enhanced oligodendrocyte progenitor differentiation and epigenetic changes.

Results: Clemastine induced higher levels of repressive histone methylation (H3K9me3), a marker for heterochromatin, in oligodendrocytes, but not neurons, of the PFC. This was consistent with the capability of clemastine in elevating H3K9 histone methyltransferases activity in cultured primary mouse oligodendrocytes, an effect that could be antagonized by co-treatment with muscarine.

Conclusions: Our data suggest promoting adult myelination as a potential strategy to reverse depressive-like social behavior.

Oral Session: Biological Mechanisms

1. THE MEDIATING ROLE OF INFLAMMATION ON ASSOCIATIONS BETWEEN MARKERS OF METABOLIC DYSFUNCTION AND DEFICITS IN MOTIVATION AND PLEASURE IN PATIENTS WITH SCHIZOPHRENIA

David Goldsmith*¹, Courtney S. Ning¹, Robin E. Gross¹, Benson Ku¹, Evanthia Wommack¹, Elaine Walker², Michael T. Treadway², Jennifer Felger¹, Andrew Miller¹

¹Emory University School of Medicine, ²Emory University

Background: Bidirectional relationships between inflammation and metabolic dysfunction may contribute to the pathophysiology of psychiatric illness, including patients with schizophrenia. Obesity and other metabolic disturbances drive systemic inflammation via activation of macrophages in adipocytes, and in turn, increased inflammation contributes to further metabolic dysfunction, such as insulin resistance. In patients with schizophrenia, inflammatory markers such as C-reactive protein (CRP) have been shown to be associated with deficits in motivation and pleasure, but it is unknown whether markers of metabolic dysfunction may also contribute to these debilitating symptoms that are difficult to treat. Herein, we hypothesize that markers of metabolic dysfunction would also be associated with deficits in motivation and pleasure, but not negative symptoms related to deficits in expressivity. Moreover, we hypothesize that the association between metabolic dysfunction and deficits in motivation and pleasure would be mediated by increased inflammation, as measured by CRP.

Methods: 57 medically healthy patients with schizophrenia were recruited from Grady Memorial Hospital in Atlanta, Georgia (USA). Negative symptoms were assessed using the Brief Negative Symptom Scale (BNSS), from which individual items can be examined and domain scores can be calculated for the two domains of Deficits in Motivation and Pleasure (MAP) and Deficits in Expressivity (EXP). Fasting blood was collected between 8AM -10AM and stored at -80C for later batched analysis. Plasma markers related to glucose metabolism, including glucose, insulin, resistin, adiponectin, and leptin were measured and a composite was calculated from the sum of Z-scores of all markers to examine the shared contribution of all circulating metabolic markers to negative symptoms. High sensitivity CRP was measured using an immunoturbidimetric assay. Associations between symptoms and metabolic markers were assessed using correlation (Spearman) and in linear regression models including age and sex. Finally, mediation models were used to examine the mediating role of CRP on observed relationships between metabolic markers and negative symptoms. Bootstrapping was used to examine the indirect effects. All analyses were conducted using SPSS version 27, including the PROCESS version 4.2 macro for the mediation analyses. We assessed significance at a p LESS THAN 0.05, uncorrected.

Results: There was a significant correlation between the metabolic composite score and the MAP Domain ($r=0.277$) as well as the anhedonia subscale ($r=0.273$, both p LESS THAN 0.05). Only resistin showed a significant relationship with avolition ($r=0.3$, $p=0.02$). Trend level associations (all p LESS THAN 0.1) were found between resistin and MAP and total BNSS score, leptin and total BNSS and anhedonia, as well as the composite score and avolition. No relationships were found with the EXP domain score or individual items. In regression models, there was a significant association between the composite score and MAP ($\beta=0.292$, $p=0.041$), as well as resistin and avolition ($\beta=0.277$, $p=0.039$). In the mediation analyses, the indirect effect of the metabolic composite score on MAP through CRP was $\beta=0.2937$, bootstrapped SE=0.1945, and bootstrapped 95% CI (0.0024, 0.7499). The direct effect of the

metabolic composite score on MAP was $\beta=0.6987$, $SE=0.4232$, $p=0.1045$ (95% CI, -0.1497, 1.5471). The direct effect of CRP on MAP was $\beta=1.8288$, $SE=0.8516$, $p=0.0363$ (95% CI, 0.1213, 3.5362).

Discussion: These results provide preliminary evidence that metabolic dysfunction contributes to negative symptoms related to deficits in motivation and pleasure, and not deficits in expressivity, similar to what has previously been shown with CRP. The results of the mediation analyses suggest that the impact of metabolic dysfunction on these negative symptoms are mediated by the influence of inflammation. Of the metabolic markers that contributed to the composite score, resistin and leptin were most strongly associated with these negative symptoms. Resistin has been shown to induce production of inflammatory cytokines and could serve as a link between disturbances in metabolism and inflammatory processes that may impact the brain and subsequent behavior. Leptin is a protein made by adipose cells and controls appetite and satiety in order to regulate energy balance. Relevant to negative symptoms, it may function as a way to limit motivated behaviors in order to conserve energy stores. Future studies will need to elucidate the relative contributions of metabolic dysfunction and inflammation, which may provide insights into novel treatment approaches to address deficits in motivation and pleasure. Furthermore, this work has the potential to support precision medicine approaches to identify those patients who may benefit from targeting these metabolic and inflammatory pathways.

2. GROUP III METABOTROPIC GLUTAMATE RECEPTOR ALTERATIONS IN THE NUCLEUS ACCUMBENS IN SCHIZOPHRENIA

Samara Walpole*¹, Jeremy S. Lum¹, Rose Chesworth Vieyra², Tim Karl², Cynthia Shannon Weickert³, Kelly A. Newell¹

¹University of Wollongong, ²Western Sydney University, ³Neuroscience Research Australia; Upstate Medical University

Background: Group III metabotropic glutamate receptors (mGluRs) (consisting of mGluR4, 7 and 8) are of increasing interest in the pathophysiology and treatment of schizophrenia. These receptors largely sit on presynaptic terminals where they regulate neurotransmitter release. The nucleus accumbens (NAc) is a brain area critical for reward learning and motivated behaviour known to be altered in schizophrenia and involved in current antipsychotic treatment. Group III mGluRs can regulate the activity of medium spiny neurons within the NAc, through tight control of cortical glutamate and local dopamine release. Therefore, due to their intricate involvement with both the glutamatergic and dopaminergic systems, group III mGluRs are a promising target for novel antipsychotics. However, little is known about their expression levels in the NAc in schizophrenia.

Methods: To investigate group III mGluR mRNA and protein levels in the nucleus accumbens (NAc), frozen postmortem NAc tissue from 30 individuals who had schizophrenia and 30 matched controls was obtained from the NSW Brain Tissue Resource Centre, Sydney. Gene expression of the individual group III mGluRs, GRM4, GRM7 and GRM8 was measured via qRT-PCR. Protein expression of mGluR4 and mGluR7 was assessed via western blot. We used t-tests or ANCOVAs to uncover differences between schizophrenia and control cases. Exploratory subgroup analyses were performed to examine the impact of sex and suicide on glutamate receptor levels.

Results: Gene and protein expression of the group III mGluRs in the NAc was not changed between schizophrenia and control subjects (all p GREATER THAN 0.05). However, subgroup analyses, revealed that females with schizophrenia had increased mGluR7 protein

levels (+33%, $p=0.014$) and a trend towards increased mGluR4 protein levels (+36%, $p=0.067$) compared to female controls. In contrast, males with schizophrenia showed decreased mGluR7 protein levels in comparison to male controls (-20%, $p=0.040$). mGluR7 protein expression was significantly elevated in schizophrenia subjects that died by suicide compared to schizophrenia subjects that died from other causes (groups that were matched for sex) (+46%, $p=0.017$). There were no changes in GRM4, GRM7, or GRM8 gene expression according to sex or suicide (all p GREATER THAN 0.05).

Discussion: Overall, we detected sex-specific alterations of mGluR7 in the NAc in schizophrenia, suggesting that alterations in mGluR7 protein levels are consequently altered or potentially underlie the disrupted glutamate regulation within the ventral striatum. Since the glutamate receptor pathology is not found at the mRNA level in the NAc, this also supports that the mGluR protein changes may be localized on glutamate or dopamine axon terminals. A strategy used to normalize mGluR7 within the NAc may differ in males and females with schizophrenia, implicating that sex-specific drugs/treatment may need to be developed. Our results support that group III mGluRs are involved in the pathophysiology of schizophrenia, and that further investigation of mGluR7 changes in terms of cellular localization and regulation of ventral striatal signalling is warranted.

3. HEPATITIS C VIRUS INFECTION OF THE CHOROID PLEXUS IS ASSOCIATED WITH SCHIZOPHRENIA AND BIPOLAR DISORDER

Maree J. Webster¹, Ou Chen², Sarven Sabunciya*²

¹Stanley Medical Research Institute, ²Johns Hopkins University School of Medicine

Background: Many epidemiological studies have shown an association between infectious agents, particularly viruses, and psychiatric disorders including schizophrenia. However, evidence of a viral infection has not been found in the brain of people with schizophrenia. To further investigate the possible association between viral infections and psychiatric disorders, we performed next generation sequencing in the choroid plexus, combined with sequence enrichment technology targeting 3153 different viruses.

Methods: We enriched for viral sequences and performed RNA sequencing in postmortem choroid plexus isolated from 84 schizophrenia (SCZ), 73 bipolar disorder (BPD), 23 major depression (MDD) cases and 76 unaffected controls (CNT) from the Stanley Medical Research Institute brain collection. We reanalyzed previously generated RNA sequencing data in the hippocampus to determine if hepatitis C infection of the choroid plexus could alter the brain transcriptome and we used the TriNetX electronic health record database to determine the rate of chronic hepatitis C in a population of 285 million patients, including SCZ, BPD, MDD and controls.

Results: We found multiple viruses in the choroid plexus, including the Hepatitis C Virus (HCV) that was present in 6 SCZ and 4 BPD at relatively high levels but absent in control and MDD samples. We validated this finding with quantitative PCR and verified that not everyone with a history of HCV infection has the virus in their choroid plexus. Analysis of hippocampus RNA sequencing data generated on the same subjects revealed that although the virus was absent in this tissue, HCV infection of the choroid plexus was associated with consistent transcriptional changes in the hippocampus that were related to the innate immune response. Analysis of the electronic medical records revealed that the rate of chronic HCV was 3.6 and 3.9 percent respectively in the SCZ and BPD populations which was almost double that observed for MDD (1.8%) and approximately 7-fold higher than the control population (0.5%).

Discussion: Our data suggest that viral infection of the choroid plexus, instead of the brain itself, may be associated with psychiatric disorders. We discovered an association between

HCV infection of the choroid plexus and SCZ and BPD. Our results are consistent with the observation that nearly 50% of HCV patients suffer cognitive or psychiatric symptoms and that the prevalence of HCV infection is increased in SCZ and BPD populations. Our finding that the prevalence of HCV in MDD is half the rate of SCZ and BPD suggests that the HCV infection may be associated with disease pathology rather than behaviors such as intravenous drug injection, since these behaviors are present in all three disorders. Finally, we were able to demonstrate that the infection of the choroid plexus alone may be able to alter transcription in the hippocampus. Additional studies with larger sample sizes are required to replicate our results. Potentially, HCV screening of all SCZ and BPD patients followed by subsequent treatment of the infection may prove to be an effective therapy for this subset of the psychiatric population. Given that the estimates for SCZ is 1% and BPD is 3% of the population worldwide, these findings are worth exploring further as they could impact the lives of millions of patients.

4. HETEROGENEOUS MICROCIRCUIT PHENOTYPES DRIVE A COLLECTIVE DEFICIT IN THE 22Q11.2 DELETION IN CA1

Stephanie Herrlinger^{*1}, Bovey Rao¹, Anna Tuttman², Haroon Arain¹, Bert Vancura¹, Tristan Geiller¹, Joseph Gogos¹, Attila Losonczy¹

¹Columbia University, ²Mt. Sinai

Background: Individuals with the 22q11.2 deletion syndrome (22q11.2DS), one of the largest known genetic risk factors for schizophrenia, demonstrate cognitive impairments, including episodic memory (EM) dysfunction. Our group previously showed that EM and place cell stability in the hippocampus is impaired in a mouse model for the 22q11.2DS (Df(16)A+/-). Place cells are under strong inhibitory control by heterogeneous subtypes of GABAergic interneurons, several which are implicated in the pathophysiology of schizophrenia. In this study, we examined the unique contributions of hippocampal interneuron subtypes to local microcircuit dysfunction in CA1.

Methods: Wild-type and Df(16)A+/- mice performed a goal-oriented learning task on a cued belt while undergoing large-scale, unbiased 3D GCaMP-Ca2+ imaging of in vivo CA1 interneuron dynamics. Molecular identification of interneuron subtypes was performed post-hoc with immunohistochemistry. Interneuron subtype-specific activity was assessed through Pearson cross-correlations with velocity, peristimulus time histograms around behavioral indicators, spatial bin occupancy, and a linear classifier support vector machine to decode position.

Results: Fewer interneurons exhibit place preference in Df(16)A+/- mice (n=5ea, p=0.014), and interneuron activity decodes space more poorly than controls (n=5ea, p=0.0001). Interneuron-selective interneurons (ISI2/3-types) exhibit altered velocity-correlated (n=4ea, p=0.03/0.001) and less predictable activity (n=4ea, p=0.01). Somatostatin expressing interneurons exhibit a failure to extinguish old reward location enrichment activity when a reward zone is translocated (n=5ea, p=0.0001), while parvalbumin basket cells exhibit an aberrant reward modulation not observed in controls (n=5ea, p=0.006).

Discussion: We identify heterogeneous subtype-specific alterations in interneuron dynamics in the hippocampus during reward extinction, suggesting a dysfunctional microcircuit causing impaired learning in Df(16)A+/- mice.

5. INTESTINAL PERMEABILITY BIOMARKERS IN PATIENTS WITH SCHIZOPHRENIA: ARE THEY ASSOCIATED WITH PSYCHOPATHOLOGY AND COGNITIVE FUNCTION?

Leticia González-Blanco^{*1}, Francesco Dal Santo², M. Paz García-Portilla³, Miquel Alfonso⁴, Carla Hernández⁴, Mónica Sánchez-Autet⁴, Gerard Anmella⁵, Silvia Amoretti⁶, Gemma Safont⁷, Stefanie Malan-Müller⁸, David Martín-Hernández⁸, Miquel Bernardo⁹, Belen Arranz⁴

¹*Servicio de Salud del Principado de Asturias, University of Oviedo - CIBERSAM*, ²*Servicio de Salud del Principado de Asturias, University of Oviedo*, ³*University of Oviedo - CIBERSAM - INEUROPA - ISPA - Servicio de Salud del Principado de Asturias, Oviedo, Spain*, ⁴*Hospital Parc Sanitari Sant Joan de Déu*, ⁵*Barcelona Clinic Schizophrenia Unit, Institute of Neurosciences, University of Barcelona, IDIBAPS, CIBERSAM. Barcelona*, ⁶*Barcelona Clinic Schizophrenia Unit (BCSU). Bipolar and Depressive Disorders Unit. Hospital Clinic of Barcelona. University of Barcelona. IDIBAPS, CIBERSAM*, ⁷*Hospital Universitari Mutua Terrassa*, ⁸*Complutense de Madrid*, ⁹*Barcelona Clinic Schizophrenia Unit (BCSU), Hospital Clinic Barcelona. Universitat Barcelona. IDIBAPS. CIBERSAM*

Background: There is emerging evidence that increased intestinal permeability, along with the dysbiosis of gut microbiome, could be implicated in the pathophysiology of schizophrenia (SZ) (Caso et al., 2016). It involves the translocation of lipopolysaccharides (LPS), endotoxins found on the membrane of gram-negative bacteria, from the gut into the peripheral circulation, triggering a pro-inflammatory cascade (Ghosh et al., 2020).

The study aims to: (1) describe intestinal permeability in a cohort of SZ patients through plasma parameters of bacterial translocation: LPS, LPS binding protein (LBP), and intestinal fatty acid binding protein (I-FABP); (2) to investigate its association with the clinical severity of schizophrenia across the main symptomatic domains including positive, negative symptoms, and cognitive impairment.

Methods: The sample consisted of 242 adult patients with confirmed diagnosis of SZ (DSM-5) from an observational, cross-sectional and multicentric study including 4 centers in Spain (Anmella et al., 2023): mean age = 44.09 ± 12.63 , range = 18-76; males = 63.3%.

Assessment:

- a) Sociodemographic variables, years of illness, toxic habits, psychopharmacological treatment, body mass index (BMI), Mediterranean Diet Adherence Scale (MEDAS) and the Short Scale of Physical Activity (IPAQ).
- b) The PANSS to evaluate clinical severity and the Screen for Cognitive Impairment in Psychiatry (SCIP) to assess cognitive performance (immediate and delayed verbal learning, working memory, verbal fluency, processing speed).
- c) Plasma C-reactive protein (CRP), LBP, LPS and I-FABP levels.

Statistical analyses: U-Mann Whitney test, Spearman correlation and partial correlation analyses.

Results: Mean $\pm$ SD plasma concentrations of LBP, LPS and I-FABP were 17.93 ± 7.53 $\mu\text{g/mL}$, 0.76 ± 2.43 EU/mL and 0.23 ± 0.44 ng/mL respectively, and 62% of patients presented increased intestinal permeability (LBP GREATER THAN 15).

Correlations were found between LBP and age ($r=0.162$, $p=0.012$), BMI ($r=0.182$, $p=0.004$), CRP ($r=0.387$, p LESS THAN 0.001), between LPS and BMI ($r=0.194$, $p=0.003$), CRP ($r=0.298$, p LESS THAN 0.001), and between I-FABP and CRP ($r=0.227$, $p=0.001$). No

differences by sex were detected. Regarding lifestyle habits, only I-FABP showed significant correlation with MEDAS score ($r=-0.149$, $p=0.030$), and cigarettes per day with LPS ($r=0.285$, $p < 0.001$) and I-FABP ($r=0.178$, $p=0.007$).

Clinical severity: I-FABP showed a weak correlation with PANSS-Total ($r=0.185$, $p=0.004$), and both LPS ($r=0.145$, $p=0.026$) and I-FABP ($r=0.179$, $p=0.006$) with PANSS-Negative subscore.

Cognitive function: Only LBP showed inverse relationship with delayed verbal learning ($r=-0.198$, $p=0.011$).

However, when adjusted for age and BMI (partial correlation analyses), correlations of intestinal permeability parameters with clinical scores were no longer statistically significant.

Discussion: Plasma levels of intestinal permeability biomarkers were positively related to systemic inflammation, obesity and lower adherence to the Mediterranean diet in our sample of patients with SZ. However, like previous studies (Gokulakrishnan et al., 2022; Scheurink et al., 2023), we do not identify any association with clinical severity or cognitive impairment once confounding factors were controlled.

6. MICROGLIAL CANNABINOID RECEPTOR TYPE 1 MEDIATES SOCIAL MEMORY DEFICITS IN MICE PRODUCED BY ADOLESCENT THC EXPOSURE AND 16P11.2 DUPLICATION

Yuto Hasegawa^{*1}, Juhyun Kim², Gianluca Ursini³, Yan Jouroukhin⁴, Xiaolei Zhu¹, Yu Miyahara¹, Feiyi Xiong¹, Samskruthi Madireddy¹, Mizuho Obayashi¹, Beat Lutz⁵, Akira Sawa¹, Solange Brown⁶, Mikhail Pletnikov⁴, Atsushi Kamiya¹

¹Johns Hopkins University School of Medicine, ²Korea Brain Research Institute, ³Lieber Institute for Brain Development, ⁴Jacobs School of Medicine and Biomedical Sciences SUNY, University at Buffalo, ⁵Institute of Physiological Chemistry, University Medical Center of the Johannes Gutenberg University, ⁶Solomon H. Snyder

Background: Given recent marijuana legalization in the US, heightened attention has been the deleterious effect of cannabis use during adolescence, a critical period for prefrontal cortex (PFC) maturation, as a risk factor for psychiatric disorders such as schizophrenia. Notably, most cannabis users do not develop psychiatric symptoms, implying that cannabis exposure might act as an environmental risk factor for individuals with a genetic predisposition to psychiatric disorders. The cannabinoid receptor type 1 (Cnr1) is not only expressed in neurons and astrocytes, but also in microglia, which play a role in shaping neural connections during adolescence. However, the specific involvement of microglia in mediating the adverse effect of cannabis remains unexplored. In this study, we investigate the impact of adolescent delta-9-tetrahydrocannabinol (THC) exposure on microglia of which disturbance may be exacerbated by a genetic risk factor for psychiatric disorders, leading to aberrant PFC maturation and producing adult pathophysiology. Of particular interest is the interplay between THC exposure and 16p11.2 duplication (16p11dup), a major Copy number variation (CNV) risk associated with schizophrenia.

Methods: 16p11dup and control mice (both male and female) were chronically exposed to THC (8mg/kg) during adolescence by single daily subcutaneous injections. Subsequently, we conducted a series of molecular, histochemical, biochemical, electrophysiological, and behavioral assays to reveal the convergent effect of THC and 16p11dup on microglial function, resulting in disturbance of medial PFC (mPFC) neuronal function and cognition in adulthood.

Results: Adolescent THC treatment induced mPFC-specific microglial molecular and morphological changes via *Cnr1*-mediated mechanisms ($p=0.0001$, $t=10.97$, $df=10$). We also found that these microglia changes were exacerbated by 16p11dup, leading to neuronal subtype-specific deficits in intrinsic excitability of mPFC pyramidal neurons and resultant social memory deficits (THC x 16p11dup interaction [$F_{1,30}=5.665$, $p=0.0239$]). By performing microglia-specific RNA-seq experiments, we identified specific genes which may mediate these phenotypes induced by the convergent action of adolescent THC treatment and 16p11dup.

Discussion: Our findings highlight the unexplored impact of adolescent THC exposure on microglial function. In particular, we identified the role of *Cnr1* expressed in microglia for mediating its gene-environment effect on adolescent mPFC maturation and adult social memory in 16p11dup mice. We are currently investigating molecular mechanisms of how adolescent THC treatment impair microglia-mediated mPFC maturation in a neuronal subtype-specific manner.

7. PHARMACOLOGICAL INHIBITION OF HISTONE DEMETHYLASE LSD1 CORRECTS SCHIZOPHRENIA-RELATED DYSFUNCTIONS IN A MOUSE MODEL OF HUMAN ENDOGENOUS RETROVIRUS EXPRESSION

Felisa Herrero^{*1}, Michelle Meier¹, Ulrike Weber-Stadlbauer¹, Urs Meyer¹

¹*University of Zurich*

Background: Endogenous retroviruses (ERVs) are remnants of germline infections that took place several million years ago and represent approximately 8% of the human genome. Accumulating evidence implicates increased ERV expression in the spectrum of psychotic disorders, including schizophrenia and bipolar disorder. Thus far, however, the link between increased ERV expression and psychotic disorders remains largely circumstantial. To gain mechanistic insights into the neurobiological disease pathways affected by ERVs, we recently characterized a novel mouse model that mimics the expression of the human-specific ERV type-W envelope protein (HERV-Wenv). Compared to wild-type (WT) littermates, HERV-Wenv transgenic (TG) mice show schizophrenia-related behavioral and cognitive abnormalities, including deficits in prepulse inhibition (PPI) of the acoustic startle reflex and social recognition memory. In addition, HERV-Wenv TG mice display reduced expression of the schizophrenia risk gene *Setd1a*, a histone methyltransferase that produces mono-, di-, and trimethylated histone H3 at the lys4 residue (H3K4). The reduction in *Setd1a* expression was further associated with increased activity of histone demethylase LSD1, indicating widespread changes in the molecular machinery regulating histone methylation in HERV-Wenv TG mice. Therefore, the present study was designed to investigate whether pharmacological inhibition of LSD1 corrects schizophrenia-related abnormalities in HERV-Wenv TG mice.

Methods: Mice with transgenic HERV-Wenv expression were generated by inserting the multiple sclerosis-derived retrovirus (MSRV)-pvl4env sequence, featuring the HERV-W envelope open reading frame (ORF) and 3' long terminal repeat (3'LTR) under the CAG promoter, into the hypoxanthine-guanine phosphoribosyl transferase (HPRT) locus. Adult male HERV-Wenv TG mice and WT littermates were treated orally with the LSD1 inhibitor, ORY-1001 (0.01 mg/Kg per day) or were subjected to vehicle treatment only. Behavioral and cognitive testing commenced after two weeks of drug or vehicle treatment. After completion of testing, brain samples were collected for molecular analyses of histone methylation and gene expression in hippocampal tissue.

Results: ORY-1001 fully mitigated the deficits in social recognition memory and PPI in HERV-Wenv TG mice without affecting these behavioral functions in WT mice. In addition,

the pharmacological treatment increased the expression of Setd1a and other histone methyltransferase genes, including, Kmt2a, Kmt2b, Kmt2d, and Setdb1. Additional molecular analyses are currently ongoing and will also be presented.

Discussion: Our preclinical data provide causal evidence for a role of HERV-W in disrupting schizophrenia-related behavioral and cognitive functions and epigenetic changes involving histone methylation. Moreover, our findings obtained in this preclinical model suggest that the inhibition of histone demethylase LSD1 may be an effective pharmacological approach for ameliorating schizophrenia-related dysfunctions, at least under conditions of abnormal HERV-W expression.

Oral Session: Neurophysiological Markers, Functional MRI and Neuromodulation

8. FUNCTIONAL NEUROIMAGING ANALYSIS OF ALTERED BRAIN METABOLIC PATTERNS IN SCHIZOPHRENIA: A COMPARATIVE HEAD-TO-HEAD TREATMENT-RESISTANT VS. TREATMENT-RESPONSIVE SCHIZOPHRENIA PATIENTS VS. CONTROLS

Mariateresa Ciccarelli^{*1}, Felice Iasevoli¹, Annarita Barone¹, Licia Vellucci¹, Giuseppe De Simone¹, Benedetta Mazza¹, Luigi D'Ambrosio¹, Valeria Gaudieri¹, Alberto Cuocolo¹, Sabina Pappatà², Andrea de Bartolomeis¹

¹University of Naples "Federico", ²Biostructure and Bioimaging Institute, CNR, Naples

Background: Antipsychotics represent the first-line therapy for schizophrenia, however a third of patients suffer from a treatment-resistant schizophrenia (TRS) condition characterized by more frequent brain structural and functional alterations. In this context, TRS shows putative unique neuroimaging correlates compared to treatment-responsive schizophrenia (nTRS), probably related to specific functional disconnection patterns. The present functional neuroimaging study aims at identifying significant differences in brain glucose metabolism of TRS vs. nTRS patients and healthy controls (HC) to be used as metabolic biomarkers to address clinical response in schizophrenia. The object of this study is to identify a functional metabolic alteration that may predict the response to antipsychotics in schizophrenia.

Methods: The study enrolled 70 subjects: 28 nTRS patients (15 males, 13 females; mean age 37.3 ± 10.1 ; disease duration 13.7 ± 8.1 ; chlorpromazine equivalents 333.6 ± 211.4 ; education years 12.6 ± 3.9), 26 TRS patients (23 males, 3 females; mean age 38.5 ± 10.5 ; disease duration 13.7 ± 8.1 ; chlorpromazine equivalents 604 ± 392.7 ; education years 11.6 ± 2.8), and 16 HC matched in age and sex. The clinical features were evaluated using the PANSS 5-factor model, and a t-test was performed using SPSS (p LESS THAN 0.01). The images were acquired with ¹⁸(F)FDG PET and analyzed using PMOD. The PET datasets were anatomically parcellated into 71 volumes of interests (VOIs) according to the AAL-merged atlas. The averaged VOI uptake values were normalized to the global GM matter average values. TRS, nTRS, and HC groups were compared using the one-way ANOVA statistical model ($p \leq 0.01$). Post hoc analyses were conducted with Bonferroni correction for multiple comparisons ($p \leq 0.00075$) and Tukey's test in all pairwise comparisons between groups ($p \leq 0.05$).

Results: 1. TRS patients compared to nTRS and HC showed a significant gradual frontal relative hypometabolism in the Left and Right Superior Frontal Gyri, Left and Right Middle Frontal Gyri, Left and Right Inferior Frontal Gyri (p LESS THAN 0.000).

2. TRS patients compared to HC showed significant relative hypometabolism in the Left Rectus Frontal Gyrus (p LESS THAN 0.000).

3. TRS patients compared to nTRS and HC showed a significant gradual relative hypermetabolism in the Right Calcarine Sulcus and Right Lingual Gyrus ($p < 0.000$).

4. TRS patients compared to HC showed significant relative hypermetabolism in the Left Calcarine Sulcus, Left Lingual Gyrus, Right Fusiform Gyrus, Vermis, Left and Right Cerebellum ($p < 0.000$).

Discussion: The results confirm that a more severe hypometabolism in the frontal cortex is one of the neurobiological underpinnings of TRS. These data suggest that the gradually altered brain metabolism in TRS patients compared to nTRS and HC potentially indicates a progressive more severe aberrant functional brain network associated with the resistance to antipsychotics.

9. DIMINISHED PAIRED CLICK RESPONSES IN PATIENTS WITH SCHIZOPHRENIA ASSOCIATED WITH IMPAIRED EXCITATORY-INHIBITORY CONNECTIVITY: INSIGHTS FROM THE BSNIP DATABASE

Hope Oloye^{*1}, Daniel J. Hauke², Julia Rodriguez-Sanchez¹, Vishal Thakkar³, David Parker⁴, Brett Clementz⁴, Carol Tamminga³, Karl Friston¹, Rick Adams⁵

¹University College London, ²Centre for Medical Image Computing, University College London, ³University of Texas Southwestern Medical Center, ⁴University of Georgia, ⁵University College London - Institute of Cognitive Neuroscience and Division of Psychiatry

Background: The paired click paradigm provides a simple, and reliable measure of early sensory processing (Boutros et al., 2004; Lijffijt et al., 2009; Wan et al., 2009). However, when paired with electroencephalography (EEG) patients with schizophrenia show a reduced response to both stimuli (Clementz et al., 1997; Mathiak et al., 2011; Sanchez-Morla et al., 2008; Rentzsch et al., 2008; Oranje et al., 2013). Theories of schizophrenia attribute these impaired responses to (1) a loss of pyramidal cell excitability via NMDA receptor dysfunction, (2) disinhibition due to interneuron dysfunction, or (3) a global loss of pyramidal cell inputs into interneurons (Dienel and Lewis, 2018). Here, we use dynamic causal modelling (DCM) of EEG-paired click paradigm data from the BSNIP dataset, to infer excitatory and inhibitory cell function in schizophrenia.

Methods: EEG data from people with a schizophrenia diagnosis (Scz, $n = 212$) and controls ($n = 277$) were grand averaged and source-localised, yielding a network comprised of bilateral primary auditory cortex (A1), insula, and middle frontal gyrus. We then modelled EEG responses to each of two clicks in the paired click paradigm, with a microcircuit consisting of superficial and deep pyramidal cells, spiny stellate cells, and inhibitory interneurons for all modelled regions.

Results: Diminished EEG responses (N100 and P200) to the clicks in patients with schizophrenia were explained by a reduced local excitability in bilateral A1 in patients and by reduced global excitatory pyramidal to inhibitory interneuron connectivity. Conductance-based modelling further revealed that this global reduction in excitatory-inhibitory connectivity was likely AMPA receptor-mediated.

Discussion: Our findings indicate that reduced N100 and P200 elicited through the paired click paradigm in people with a schizophrenia diagnosis is potentially due to impaired A1 excitability and global changes in AMPA-mediated pyramidal inputs to interneurons. Our results support theories that postulate a loss of both pyramidal cell excitability and their inputs to interneurons in schizophrenia. This modelling approach could potentially be employed as a

computational assay to probe AMPA-mediated receptor function and identify individuals who will benefit from glutamatergic pharmacological interventions.

10. CORTICAL REACTIVITY AND PLASTICITY AS TREATMENT BIOMARKERS OF SCHIZOPHRENIA: A PERTURBATION BASED STUDY

Sohini Chakraborty*¹, Urvakhsh Mehta¹, Jagadisha Thirthalli¹, Vanteemar Sreeraj¹, Rakshathi Basavaraju¹

¹*National Institute of Mental Health and Neurosciences*

Background: One of the most complex severe mental illnesses with a chronic course is schizophrenia. The age of onset in, most cases, is adolescence to early adulthood; ambushing individuals at a period when they are trying to be independent. However, around 20-30% do not respond to medication. Till the current year, we are searching for methods to reliably predict who will respond better to treatment with antipsychotic agents.

In this scenario, biomarkers like diminished cortical plasticity rose to prominence. This is especially significant since schizophrenia has evolved as a conceptual archetype of excitation/inhibition imbalance in the brain as a result of gene-environment interaction. Non-invasive biomarkers have gained much attention like TMS or transcranial magnetic stimulation. TMS is a neuro-psychiatric tool for measuring cortical activity using Faraday's law of electromagnetic conduction. This study aims to build on the previously conducted research to ascertain the degree to which treatment response with antipsychotics can be associated with cortical reactivity and plasticity, along with the speed of response, and the hypothesis proposed was higher cortical plasticity would be associated with better and faster treatment response.

Methods: A longitudinal study design was implemented where a total of 70, either medication-free or minimally treated, consenting adults of any gender, who were diagnosed with schizophrenia, psychosis NOS, or schizoaffective disorder based on ICD 10 were to be recruited. Participants with co-morbid substance use (except nicotine use), seizure disorder, intellectual disability, neurological disorder, head injury, gravid or post-partum females, or with metallic brain implants were excluded from the study.

Baseline psychopathology was determined using relevant scales: SAPS, SANS, BPRS, and CGI-SCH. The cortical reactivity parameters of 1-mV motor evoked potential (MT1), 120% of resting motor threshold (120% RMT), Short-interval intracortical inhibition (SICI), Long-interval intracortical inhibition (LICI), and Intracortical facilitation (ICF) along with cortical plasticity measures of MT1 and 120 RMT at 5 and 10 minutes post-intermittent Theta Burst protocol were recorded using TMS procedure.

The follow-up period for each patient was 4-8 weeks after starting antipsychotic treatment. This is an interim analysis of 40 patients recruited so far who have been successfully followed up weekly using CGI-SCH via either in-person or teleconsultation, with SAPS, SANS, and BPRS applied in the last follow-up.

Results: Equal male and female participants were recruited. Age of onset (39.4 years) and duration of illness (54 months) were highest for widowed females, while it appeared urban and rural residents had similar ages of onset of illness, 28.7 and 28.6 years respectively. The duration of education in years received by the individuals was negatively correlated with the age of onset of illness. Most of them belonged to Upper Lower socio-economic status and did not have an earlier age of onset of psychosis when compared with other socioeconomic groups. The duration of untreated illness appeared to be around one year, significantly lower than other

studies done in the Indian population. Only 10% of participants had a comorbid psychiatric illness and 60% had an additional medical illness, the most common being over-weight.

The interquartile range of baseline MT1 was higher for females than males while mean baseline MT1 and 120% RMT were lower for treatment-naïve individuals and those who had a history of prodrome. Participants with a family history of psychosis and who had poor pre-morbid functioning show facilitation instead of short-interval cortical inhibition. Average cortical plasticity at MT1 showed a wider variation in males (IQR=1.44) as compared to females (IQR=0.419), with overall cortical plasticity higher in those with a prodrome of psychosis.

In the follow-up, it was noted that treatment response was correlated with only the baseline LICl i.e., the higher the cortical inhibition better the treatment response in terms of positive symptoms rating scale SAPS and BPRS, a novel finding. Other factors like ICF, SICl, and cortical plasticity did not show a significant link with treatment response, which shall be re-examined further once recruitment is completed.

Discussion: The study aimed to determine if cortical reactivity or plasticity is associated with treatment response, which would in turn allow its use as a predictive biomarker. In this regard, the only stand out of the study is LICl. This is as per previous TMS and post-mortem-based findings where there are GABAergic inhibitory deficits in patients of schizophrenia. LICl, which is a paired-pulse TMS parameter utilizing a suprathreshold conditioning pulse 50–200 msec before the test pulse helps us understand GABA-B interneuron activity. This can be theorized as the stronger the activity of the inhibitory system in the brain, positive symptoms mediated by dopamine are more favourably controlled by additional dopamine-blocking effects of antipsychotics. However, we acknowledge there might be changes associated with prior medication use, even though 2 months of a drug-free period is considered critical for the inclusion of participants.

11. ALPHA-BAND EEG DESYNCHRONIZATION IN A VISUAL ODDBALL TASK PREDICTS CLINICAL OUTCOMES IN THE PSYCHOSIS RISK SYNDROME

Wendy Zhang^{*1}, Sarah Chang¹, Holly Hamilton², Sullivan Salone¹, Rui Ma¹, Charles Schleifer¹, Gregory Light³, Jean Addington⁴, Kristin Cadenhead³, Tyrone Cannon⁵, Barbara Cornblatt⁶, Matcheri Keshavan⁷, Diana Perkins⁸, William Stone⁹, Ming Tsuang³, Elaine Walker¹⁰, Scott Woods⁵, Carrie Bearden¹, Daniel Mathalon¹¹

¹University of California, Los Angeles, ²University of California, San Francisco; San Francisco VA Health Care System, ³University of California, San Diego, ⁴University of Calgary, ⁵Yale University, ⁶The Zucker Hillside Hospital, ⁷Harvard University, ⁸University of North Carolina At Chapel Hill, ⁹Harvard Medical School / Beth Israel Deaconess Medical Center, ¹⁰Emory University, ¹¹University of California, San Francisco

Background: Event-related desynchronization (ERD) of posterior alpha-band (8-12 Hz) oscillations following the presentation of task-relevant visual stimuli has been proposed as a key neural mechanism underlying visual perception and attentional control in service of ongoing goals. While attenuated posterior alpha ERD has been observed in individuals with schizophrenia and linked to visual attention impairment in this population, it remains unclear whether this neural deficit is readily evident among individuals at clinical high risk for psychosis (CHR-P) and predictive of clinical outcomes.

Methods: Electroencephalography (EEG) data were collected as part of the North American Prodrome Longitudinal Study (NAPLS-2) study. Individuals with CHR-P syndrome (n=492) and healthy control participants (HC; n=207) completed at baseline a visual oddball task in

which they were instructed to press a button in response to infrequently presented target visual stimuli while withholding responses to standard and distractor stimuli. Alpha ERD was measured as the change in alpha power at posterior electrode sites following target stimulus presentation relative to the pre-stimulus interval. The magnitude of alpha ERD was compared between CHR-P participants who developed psychosis before 24-month follow-up ($n=63$), those who remained symptomatic ($n=138$) or remitted from CHR-P ($n=52$) at follow-up, and HCs.

Results: Alpha ERD was attenuated in CHR-P individuals compared to controls ($d = 0.24$). Baseline magnitude of alpha ERD was significantly reduced in those who later converted to psychosis compared to non-converters ($d = 0.31$). CHR-P participants who remitted showed similar degrees of baseline alpha ERD to that of control participants and significantly greater alpha ERD than those who remained symptomatic ($d = 0.23$) and converted to psychosis ($d = 0.48$).

Discussion: Modulation of posterior alpha oscillations in response to task-relevant visual stimuli, a neural index of visuospatial attention, was associated with clinical outcomes in individuals at clinical high risk for psychosis. Impairment in alpha ERD was only observed at baseline for at-risk individuals who later developed psychosis and, to a lesser degree, those who continued to be symptomatic at follow-up, but not for those with subsequent symptom remission. The study demonstrates a promising neural marker of psychosis risk that may contribute to ongoing efforts to improve outcome prediction in CHR-P.

12. FUNCTIONAL CONNECTIVITY GRADIENTS AND THOUGHT-PATTERNS IN SCHIZOPHRENIA - NEGATIVE SYMPTOMS

Tal Geffen^{*1}, Samyogita Hardikar², Jonathan Smallwood³, Mariia Kaliuzhna⁴, Fabien Carruzzo⁴, Teresa Katthagen⁵, Stephan Kaiser⁶, Florian Schlagenhauf⁵

¹*Campus Charité Mitte, Charité - Universitätsmedizin, Berlin*, ²*Max Planck Institute for Human Cognitive and Brain Sciences*, ³*Queen's University*, ⁴*University of Geneva, Clinical and Experimental Psychopathology Laboratory, Faculty of Medicine*, ⁵*Campus Charité Mitte, Charité - Universitätsmedizin, Berlin*, ⁶*Geneva University Hospital, Adult Psychiatry Division*

Background: In schizophrenia patients (SZP) with predominantly negative symptoms, we investigated Thought-Patterns (TP) and their links with macroscale neural connectivity patterns known as ‘gradients’. The first gradient (G1) reveals a change in connectivity pattern from the unimodal Visual network to the multimodal Default Mode Network (DMN). The second gradient (G2) reflects a change between two sensorial networks: the Somatomotor (SomMot) and Visual (Margulis et al., 2016). We compared the results to healthy controls (HC).

Methods: 77 SZP and 66 HC participants underwent a 9.8-minute resting-state fMRI scan at two study centers in Berlin and Geneva. Post-scan, they reported thoughts using the Multi-Dimensional-Experience-Sampling (MDES: Gorgolewski et al., 2014). TP were summarized using Principal Component Analysis (PCA) and (A) compared between groups, controlling for center. We generated cortical connectivity gradients using PCA in the BrainSpace toolbox (Vos de Wael et al., 2020), using Schaefer-400 parcellation and incorporating 7 Yeo networks. (B) Gradients were compared between groups at both parcel and network levels. We used 400 parcels from the first three gradients (1200 General Linear Models; GLM) and seven network scores from the first three gradients (21 GLMs in total) as independent variables, controlling for center and motion. Results were corrected for False Discovery Rate (FDR) and additional Bonferroni correction for multiple comparisons. (C) Using significant parcels and TPs from analyses A and B, we regressed, parcel connectivity values against group and TP, and

corrected all results for multiple comparisons. (D) Finally, within the SZP group, we calculated partial Spearman correlation, controlling for motion, between the TP and parcels that were significantly different between groups.

Results: SZP had lower Abstract-Spontaneous TP values [$t(140) = -2.68$, $P_{\text{bonf6}} = 0.048$] and higher Intrusive-Negative TP values than controls [$t(140) = 3.49$, $P_{\text{bonf6}} = 0.003$]. (B) Network Gradient analyses revealed that SZP exhibit greater dissociation between attentional-related networks (Control and Dorsal Attentional Network: DAN) and the DMN and more similarity of the attentional networks to sensorial networks in G1 and G2 [G1-DAN: $t(139) = 3.42$, $P_{\text{bonf21}} = 0.01$; G2-Control: $t(139) = 3.33$, $P_{\text{bonf21}} = 0.021$]. An important finding was a shorter G2 in SZP, [G2-visual: $t(139) = 3.34$, $P_{\text{bonf21}} = 0.021$], i.e., less segregation between the two dissociate networks on G2, the SomMot and the Visual. Three parcels differed significantly between the groups, replicating some of the network-level findings. (C) Furthermore, the parcel score of G2_SomMot/ Temporal-Parietal-right was predicted based on the group and the Abstract-Spontaneous TP [$t(136) = 2.63$, $P_{\text{bonf3}} = 0.02$]. (D) In addition, a positive Spearman correlation was found in SZP between Intrusive-Negative TP and parcel score of G3_DAN/Post-central-gyrus-right (POSTc_r) [$r(74) = 0.25$, $p = 0.02$].

Discussion: MDES effectively assesses TP and differentiates HC and SZP. Gradient analyses in SZP showed increased similarity between attention and sensorial networks and dissociation of the DMN from the attentional networks. SZP display a shorter G2, indicating reduced segregation between SomMot and visual networks, aligning with previous findings in SZ (Holmes et al., 2023). We could predict gradient parcel score based on TP. Additionally, in SZP, Intrusive-Negative TP correlates positively with G3_DAN/POSTc_r score, suggesting increased DMN dissociation and Control network similarity of that parcel, associated with more intrusive-negative TP. A similar finding was noted in HC with Specific-Intrusive TP (Hardikar et al., 2022).

13. NETWORK-INFORMED BRAINAGE PREDICTION IN EARLY PSYCHOSIS

Shalaila Haas^{*1}, Yuetong Yu², Hao-Qi Cui², Faye New¹, Ruiyang Ge², Sophia Frangou²

¹*Icahn School of Medicine at Mount Sinai*, ²*University of British Columbia*

Background: Extensive research has established the difference between neuroimaging-predicted and actual chronological age (brainAGE), as a robust and biologically meaningful measure of brain health. This has been convincingly demonstrated by the ENIGMA Schizophrenia Working Group which found an average acceleration of brain aging of ~4 years using brain morphometric data obtained from 2803 patients (Constantinides et al. 2023). However, brainAGE is generally computed as a global index of age-related brain changes, disregarding information about spatial variation. To address this gap, we developed brainAGE models for various brain networks in healthy individuals that were applied to patients with affective and non-affective early psychosis.

Methods: The T1w structural images were processed using Freesurfer v7.1 in 9473 healthy individuals (aged 3-92 years; N [%] female = 5126 [54.11%]) across 9 datasets. Subsequently, the Schaefer atlas was used to generate parcels (200, 400, 600, 800, 1000) of cortical thickness and cortical surface area, each assigned to one of the 7 Yeo networks. Sex-specific pooled datasets were split into a training (80%) and testing (20%) subsets. Model performance was assessed by mean-absolute-error (MAE) and the correlation between predicted and chronological age in the test set after age-related bias adjustment. The parcellation with the lowest MAE was subsequently applied to 93 non-affective psychosis (mean [SD] age = 22.19 [3.36]; 28 [41.79%] female), 28 affective psychosis (mean [SD] age = 24.46 [4.26]; 19 [28.36%] female), and 57 healthy individuals (mean [SD] age = 24.79 [4.12]; 20 [29.85%])

female) from the Human Connectome Project for Early Psychosis, and compared with respect to brainAGE.

Results: For all networks except the visual network, the mean-absolute-error reduced with increasing number of parcels (ranges across all: visual=6.00-6.70; somatomotor=5.00-5.67; dorsal-attention=6.91-7.32; salience=5.31-5.92; limbic=5.82-6.65; control=5.46-6.20; default=4.89-5.51). Correlation between predicted and chronological age was high across all networks (mean correlation across networks = 0.93) and varied by maximally 0.02 with increasing parcels. Correspondence between males and females for mean-absolute-error across networks was high (GREATER THAN 0.97). Network-brainAGE was highest across networks in patients with non-affective psychosis (mean brainAGE = 5.42), then affective psychosis (mean brainAGE = 3.57), and healthy individuals (mean brainAGE = 1.42). In patients with non-affective psychosis, brainAGE was greatest in sensory networks including the visual (mean [SD] = 6.25 [9.76]) and somatomotor networks (mean [SD] = 8.13 [8.03]). In patients with affective psychosis, brainAGE was greatest in somatomotor (mean [SD] = 6.64 [7.58]) and salience/ventral attention networks (mean [SD] = 5.31 [8.33]).

Discussion: This study introduces novel network-specific brainAGE models that offer spatially distinct insights into aging patterns in clinical samples, including patients with early psychosis. These network-informed measures might demonstrate stronger associations with cognitive deficits, psychopathology, and risk factors.

14. THE EEG MULTIVERSE OF SCHIZOPHRENIA

Dario Gordillo*¹, Janir Ramos da Cruz², Eka Chkonia³, Wei-Hsiang Lin¹, Ophélie Favrod¹, Andreas Brand¹, Patrícia Figueiredo⁴, Maya Roinishvili⁵, Michael H Herzog¹

¹EPFL, ²EPFL, *Universidade de Lisboa*, ³Tbilisi State Medical University, *Free University of Tbilisi*, ⁴Universidade de Lisboa, ⁵Free University of Tbilisi, *Beritashvili Centre of Experimental Biomedicine*

Background: Studies in patients with schizophrenia typically use a single experimental paradigm. The results often show a clear-cut difference in patients compared to healthy controls. Subsequent studies then try to understand the underlying cognitive, neural, and genetic abnormal mechanisms. This approach rests on the implicit assumption that the paradigms tap into a key abnormality of schizophrenia. If true, the different paradigms should strongly correlate with each other. Here, we explicitly tested this assumption by examining whether different features from resting-state electroencephalogram (EEG) are correlated in patients with schizophrenia.

Methods: We recorded resting-state EEG from 121 patients with schizophrenia and 75 healthy controls and extracted 194 EEG features, including EEG microstates, source and sensor connectivity, and spectral features, which have long been well-established in schizophrenia research. We identified the EEG features with significant differences between patients and healthy controls. We recorded the EEG from 38 patients with schizophrenia and 27 healthy controls after approximately 5 years to investigate the stability of our results.

Results: We found that 69 of the 194 EEG features showed significant group differences between patients and healthy controls with medium to large effect sizes (Cohen d ranged from 0.46 to 1.04), indicating that important mechanisms are targeted. Surprisingly, the correlations between these 69 EEG features were very weak in the patient population, suggesting that different EEG features target different mechanisms. As such, they may be less representative of schizophrenia than initially thought. Importantly, we show that most of these EEG features show very good long-term reliability, i.e., the results are stable.

Discussion: Our findings raise several questions about the specific nature and interpretation of significant results in schizophrenia research. We propose that analyzing the relationship between several features from a multiple of paradigms and analysis methods may help to identify the most representative paradigms and mechanisms of schizophrenia. We argue that representing schizophrenia within a high-dimensional space holds promise as an approach to address the heterogeneity of the disorder.

15. COMPUTATIONAL MODELLING OF P300 RESPONSES TO PROBE INHIBITORY AND EXCITATORY CELL FUNCTION IN PATIENTS WITH SCHIZOPHRENIA AND ACROSS TRANSDIAGNOSTIC BIOTYPES: INSIGHTS FROM THE BSNIP STUDY

Daniel J. Hauke^{*1}, Hope Oloye¹, Julia Rodriguez-Sanchez¹, Vishal Thakkar², David Parker³, Brett Clementz³, Carol Tamminga², Rick Adams¹

¹University College London, ²University of Texas Southwestern Medical Center, ³University of Georgia

Background: The P300 is a brain response that is elicited when individuals detect a behaviorally relevant change in the environment and is reduced in schizophrenia. Impaired responses have been attributed to (1) a loss of pyramidal cell excitability via NMDA receptor dysfunction, (2) disinhibition due to interneuron dysfunction or (3) a global loss of pyramidal cell inputs into interneurons (Dienel and Lewis, 2018). Recent efforts to identify transdiagnostic biotypes across schizophrenia, bipolar disorder and schizoaffective disorder further suggest that P300 responses may be differentially impaired in different biotypes (Clementz et al., 2016). Here, we modelled P300 responses in schizophrenia patients and previously derived biotypes to determine how inhibitory and excitatory circuit function is changed across these groups.

Methods: Electroencephalography (EEG) data was recorded during an auditory oddball paradigm from healthy controls (n=284), patients with schizophrenia (n=231) and three transdiagnostic biotypes that included patients with schizophrenia, bipolar and schizoaffective disorder diagnoses (biotype 1: n=167, biotype 2: n=163 and biotype 3: n=169; Clementz et al., 2016). We modelled circuit function in a network of regions comprising the dorsal attention network including bilateral inferior frontal junction (IFJ), intraparietal sulcus (IPS) and primary auditory cortex (A1) as an auditory input region. Each region was modelled as a microcircuit comprising spiny stellate cells, inhibitory interneurons and superficial and deep pyramidal cells.

Results: Our results suggest that impaired P300 responses in individuals with a schizophrenia diagnosis are associated with a loss of local excitability in IPL (group-by-condition interaction, $p < 0.05$). Interestingly, biotype 1 exhibited a more severe loss of excitability in IPL, but also net disinhibition of pyramidal cells due to loss of pyramidal inputs to interneurons and disinhibition due to loss of interneuron function (all $p < 0.05$). Biotype 2 showed a loss of local excitability in IPL (similar to biotype 1, but less severe) accompanied by globally reduced excitatory inputs to pyramidal cells (all $p < 0.05$). Lastly, biotype 3 showed no loss of excitability but was rather characterized by a net disinhibition of pyramidal cells due to loss of pyramidal inputs to interneurons (all $p < 0.05$).

Discussion: Our findings support aetiological theories that postulate that schizophrenia is characterized by disturbances in regulating the excitation/inhibition balance. They also suggest that transdiagnostic biotype 1, showing the most severe impairments, may map onto all three postulated dysfunctions: (1) loss of pyramidal cell excitability, (2) interneuron function and (3)

pyramidal cell inputs into interneurons. Conversely, biotype 2 and biotype 3 were better explained by only (1) a loss of pyramidal cell excitability or (3) a loss of pyramidal cell inputs into interneurons, respectively. This modelling approach could be used to probe different cell functions non-invasively in the future and identify new drug targets for individualized pharmacological interventions to restore excitation/inhibition balance and alleviate psychotic symptoms.

Oral Session: Clinical Trajectories

16. INTEGRITY OF AUDITORY SENSORY PROCESSING AT FIRST-EPISODE PSYCHOSIS PREDICTS SYMPTOM RECOVERY: EVIDENCE FROM MEG AND EEG USING A SINGLE-TONE PARADIGM

Francisco José López Caballero*¹, Mark Curtis¹, Brian Coffman¹, Dean Salisbury¹

¹*University of Pittsburgh School of Medicine*

Background: Predicting the course of symptoms in individuals experiencing their First Episode of Psychosis (FEP) is essential for tailoring precise treatment strategies and enhancing clinical outcomes. Recent findings highlight the role of temporal lobe function, specifically assessed through biomarkers like N100, in predicting the progression of psychotic symptoms and its association with the consequences of untreated psychosis. Our laboratory's recent report supported that Magnetoencephalographic (MEG) M100 responses to tones in an oddball paradigm predicted the longitudinal recovery of positive symptoms in FEP individuals, as evaluated by the Positive and Negative Syndrome Scale (PANSS). Additionally, the Duration of Untreated Active Psychosis (DAP), a metric of untreated psychosis based on the onset of clinician-recognized symptoms, predicted symptom change through its influence on M100. In this study, our objective was to extend these findings by 1) using a simpler single-tone paradigm, easier to incorporate in routine clinical practice; 2) incorporating both MEG and EEG methodologies; and 3) examining associations across PANSS dimensions (Positive, Negative, General).

Methods: We recorded MEG (M100) and EEG (N100) in 29 FEP individuals, assessing symptom severity at baseline and approximately seven months later. Sequential Regression analyses predicted overall symptom change (Δ PANSS Total) from DAP and baseline M100 source-localized in bilateral auditory cortex, controlling for baseline symptoms. Identical regressions were performed for each PANSS subscale. Parallel regression analyses were conducted in a subsample of participants with usable EEG ($n = 24$), measuring N100 at FCz.

Results: Results revealed that a smaller baseline M100 predicted poorer overall symptom recovery at follow-up, independently of baseline symptom severity. Longer DAP showed a similar prognostic relationship, with this association being fully mediated by M100. Regression analyses with PANSS factors indicated that M100 predictions were primarily associated with the general psychopathology factor, rather than specific positive or negative symptoms. Parallel results were observed when measuring N100 with EEG.

Discussion: Our findings underscore the significance of temporal lobe dysfunction, particularly compromised auditory sensory processing, as an indicator of a more challenging recovery trajectory in general psychopathology during the initial months post-disease onset. Prolonged untreated psychosis exacerbates temporal lobe dysfunction, further predicting a worsened disease progression. Notably, utilizing N100 measured with EEG and a single-tone task emerges as a cost-effective and easily implementable tool for informing clinicians about

the likely progression of overall psychotic symptomatology, thereby guiding resource allocation, closer monitoring, or intensified pharmacological intervention.

17. CHILDHOOD TRAUMA TYPES AND ANTIPSYCHOTIC EFFECTIVENESS IN PSYCHOSIS: A PROSPECTIVE, RANDOMIZED, CONTROLLED TRIAL

Nina Mørkved*¹, Erik Johnsen², Rune A. Kroken³, Christoffer A. Bartz-Johannessen⁴, Else-Marie Løberg⁵

¹*Mosjoen District Psychiatric Centre, Helgeland Hospital*, ²*Division of Psychiatry, Haukeland University Hospital; University of Bergen*, ³*Division of Psychiatry, Haukeland University Hospital; NORMENT Center of Excellence, University of Oslo; Department of Clinical Medicine (K1), University of Bergen*, ⁴*Division of Psychiatry, Haukeland University Hospital; NORMENT Center of Excellence, University of Oslo*, ⁵*Faculty of Psychology, University of Bergen; Division of Psychiatry, Haukeland University Hospital*

Background: Treatment with antipsychotics (APs) for schizophrenia spectrum disorders (SSDs) is generally effective, however, a significant proportion does not respond favorably to first-line APs. Factors influencing effectiveness may include exposure to childhood trauma (CT), including subtypes such as physical, sexual, and emotional abuse, and physical and emotional neglect. There is a paucity of research on CT in relation to treatment with APs in SSDs. Some studies find CT to be associated with less treatment effect, others fail to find this association. Possibly, the variation and heterogeneity in treatment response could be explained by different subtype profiles of CT.

Methods: The Bergen-Stavanger-Trondheim-Innsbruck (BeSt InTro) study is a pragmatic, single-blinded, randomized controlled drug trial. Participants (n = 98) with diagnoses within the schizophrenia spectrum (F20-29 in the International Classification of Diseases – 10th Revision) were randomized to receive one of the first-line atypical APs amisulpride, aripiprazole or olanzapine. The present study examined the relation of CT subtypes on the level of psychosis symptoms as measured by the PANSS after 52 weeks of antipsychotic treatment. The Childhood Trauma Questionnaire Short-Form (CTQ-SF) was used to assess subtypes of trauma; sexual, physical, and emotional abuse, and physical and emotional neglect. We used multiple linear regression analyses, and included relevant confounders: baseline psychosis symptoms, onset age, duration of untreated psychosis, years of education, dosage of antipsychotic medication, and previous exposure to antipsychotics.

Results: Regression analyses showed statistically significant effects for the CT subtypes on PANSS total scores, $F(13, 14) = 4.69$, $p = .004$, adjusted R^2 (R^2a) = .64, mainly driven by CT subtype sexual abuse ($p = 0.042$). CT subtypes significantly predicted PANSS general psychopathology subscale scores, $F(13, 14) = 10.18$, $p < .001$, $R^2a = .82$, which was also mainly driven by sexual abuse ($p = 0.014$). While the regression models on CT subtypes predicting PANSS positive and negative subscale scores were not statistically significant, there was a possible relation between emotional neglect and positive psychosis symptoms ($p = 0.18$), although those models overall showed poor fit.

Discussion: CT subtypes, especially childhood sexual abuse, predicted psychosis symptom levels and antipsychotic effectiveness in SSDs. The present results point to CT subtypes influencing AP effectiveness, and is consistent with the extant but scarce available body of research on the association of CT subtypes, especially sexual abuse, and clinical features in SSDs. Limitations of the present study concern the failure of comparing different groups of patients, such as first-episode compared to more chronic cases, and we were not able to examine potential clinical mediators such as dissociation and trauma symptoms. The data on

CT were retrospectively reported, which is associated with concerns related to validity of the data. We did however have prospectively gathered data on AP effectiveness from real-life clinical practice, and a relatively long follow-up period. The present results support clinical guidelines recommending assessment and treatment of trauma in SSDs.

18. TIME TO ANTIPSYCHOTIC DISCONTINUATION AND ASSOCIATION WITH CLINICIAN-RECORDED SIDE EFFECTS IN PATIENTS WITH FIRST EPISODE PSYCHOSIS

Rashmi Patel^{*1}, Aimee Brinn¹, Jessica Irving¹, Jaya Chaturvedi¹, Shanmukha Gudiseva², Christoph U. Correll³, Paolo Fusar-poli¹, Philip McGuire⁴

¹*Institute of Psychiatry, Psychology and Neuroscience, King's College London*, ²*BRC Nucleus, South London and Maudsley NHS Foundation Trust*, ³*The Zucker Hillside Hospital; The Donald and Barbara Zucker School of Medicine at Hofstra/Northwell*; *Charité-Universitätsmedizin Berlin, Corporate Member of Freie Universität Berlin, Humboldt-Universität zu Berlin, and Berlin Institute of Health*, ⁴*University of Oxford*

Background: In people with first episode psychosis (FEP), antipsychotics are effective in improving symptoms and reducing the risk of subsequent relapse. However, many patients discontinue antipsychotic medications during the first year of treatment due to a lack of efficacy or side effects. Antipsychotic medications have varying side effect profiles based on their pharmacological properties but among individuals with FEP, little is known about the associations of side effects with subsequent antipsychotic discontinuation in real-world clinical practice. We investigated the associations of side effects recorded by clinicians in electronic health records (EHRs) with antipsychotic discontinuation in a large sample of patients receiving treatment for FEP. We hypothesised that recorded side effects are associated with greater rates of antipsychotic discontinuation.

Methods: De-identified EHR data were assembled from the South London and Maudsley (SLaM) NHS Trust Biomedical Research Centre (BRC) case register using the Clinical Record Interactive Search tool (CRIS). SLaM provides mental healthcare for people with FEP through Early Intervention Services (EIS) covering a catchment area of four South London boroughs. Data were obtained from patients who received antipsychotic treatment from a SLaM EIS between 1st April 2008 and 31st March 2019. Follow-up data were obtained up to 31st March 2021 from the index date, defined as the date of acceptance to a SLaM EIS. Structured clinical and demographic data were assembled including age, gender, ethnicity, psychotic disorder diagnosis and EIS team. Data on prescribed antipsychotic, prescription setting (inpatient vs outpatient), start and end dates of antipsychotic treatment, and clinician-recorded side effects (sedation, weight gain, extrapyramidal side effects (EPSEs), sexual side effects or hyperprolactinemia) were obtained from unstructured, free text clinical records through manual review. Multivariable Cox regression analyses were performed to investigate the associations of (i) prescribed antipsychotic and (ii) clinician-recorded side effects with time to antipsychotic discontinuation.

Results: Data from 2,309 patients (64.6% male) were analysed with a mean age of 26.7 years and a total follow-up duration of 6,380.8 person years. The three most frequently prescribed antipsychotics during the first treatment episode were olanzapine (n=1,013), risperidone (n=571) and aripiprazole (n=460). A total of 1,551 patients (67.4%) discontinued the first antipsychotic prescribed during the follow-up period. At least one side effect was recorded in 1,136 (49.2%) patients and more than one side effect was recorded in 365 (15.8%) patients. Among male patients, 476 (31.9%) experienced sedation, 249 (16.7%) weight gain, 136 (9.1%)

EPSEs, 56 (3.8%) sexual side effects, and 48 (3.2%) hyperprolactinaemia. Among female patients, 265 (32.4%) experienced sedation, 181 (22.2%) weight gain, 60 (7.3%) EPSEs, 42 (5.1%) sexual side effects, and 59 (7.2%) hyperprolactinaemia. Female patients discontinued antipsychotics faster than male patients (hazard ratio (HR)=1.23, 95%CI=1.11-1.37). The median time to discontinuation was 9.4 months for olanzapine, 8.8 months for risperidone, and 12.9 months for aripiprazole. Compared to olanzapine, haloperidol (n=18, median time to discontinuation: 1.2 months; HR=2.78, 95%CI=1.69-4.60) and quetiapine (n=145, median time to discontinuation: 4.7 months; HR=1.43, 95%CI=1.16-1.80) were discontinued significantly earlier. Sexual side effects (HR=1.59, 95%CI=1.03-2.46) and EPSEs (HR=1.33, 95%CI=1.08-1.64) were associated with significantly faster discontinuation.

Discussion: Most patients discontinued the first prescribed antipsychotic following presentation with FEP. EPSEs and sexual side effects were associated with a substantially increased discontinuation rate indicating that these side effects are particularly likely to lead to discontinuation of antipsychotic treatment. Haloperidol was discontinued at a substantially higher rate than olanzapine which may reflect the high risk of EPSEs associated with its use. Only 98 (4.2%) patients had recorded sexual side effects suggesting that these are under-recognised or poorly documented in clinical records. Antipsychotic discontinuation is strongly associated with increased risk of relapse. When considering treatment options for FEP, the potential impact of side effects on treatment discontinuation should be taken into account.

19. SEASONAL MODULATION OF NEUROCOGNITION AND ELECTROPHYSIOLOGICAL BRAIN FUNCTIONING IN INDIVIDUALS WITH SCHIZOPHRENIA

David Kimhy*¹, Sloane A. Miller¹, Abraham Reichenberg¹, Luz H. Ospina¹, Chloé Ifrah¹, René Kahn¹, Keith H. Nuechterlein², COGS Investigators³

¹*Icahn School of Medicine at Mount Sinai*, ²*University of California, Los Angeles*, ³*COGS investigators*

Background: People with schizophrenia (SZ) display substantial deficits in neurocognitive functioning that are major predictors of poor functioning and disability. These deficits have traditionally been regarded as stable. However, evidence from pre-clinical and clinical studies (e.g., Alzheimer's disease) point to seasonal variability in humans' neurocognition and related neuroplasticity. Yet, this putative variability has not been investigated in SZ. To address this gap, we aimed to examine: 1) Do neurocognition and related electrophysiological brain functioning in people with SZ vary across seasons? and 2) Are there differences in seasonal variability of neurocognition and electrophysiological functioning between people with SZ and healthy controls (HC)?

Methods: We conducted a secondary analysis of cross-sectional data from a cohort of 2249 individuals (SZ: n=1239, HC: n=1010) who completed neurocognitive and electrophysiological brain functioning measures as part of the assessment of Phase 2 of the Consortium on the Genetics of Schizophrenia (COGS) project, a multi-site NIMH-sponsored investigation of the genetic basis of neurocognitive endophenotypes. Participants were recruited from five geographically diverse United States sites in New York City, Philadelphia, Seattle, Los Angeles, and San Diego. The neurocognitive and electrophysiological phenotyping dates were first transformed to weeks of the year (e.g., January 1-7: Week 1, January 8-14: Week 2, etc.) and then aggregated to meteorological seasons based on maximum/minimum seasonal daylight (e.g., yearly solstices and equinoxes).

Results: The participants with SZ displayed significantly poorer neurocognitive performance during the summer as indexed by the Degraded-Stimulus Continuous Performance Task (DS-CPT; $F=2.72$, $p=.04$), along with trends for worse performances on the Penn Face Memory Test ($F=2.04$, $p=.10$) and Mismatch Negativity (MMN; $F=2.48$, $p=.06$). Similarly, the P300 amplitude was significantly lower during the fall ($F=4.21$, $p < .01$). Examination of group differences indicated there was a significant group by season interaction for P300 ($F=3.08$, $p=.03$), with the largest differences between the SZ and HC groups observed during the fall (SZ group performed worse).

Notably, analyses of data from the three most northern sites (New York, Philadelphia, Seattle; SZ: $n=689$, HC: $n=585$), which experience greater seasonal variation in daylight, suggested greater seasonal impact. The participants with SZ displayed significantly poorer neurocognitive performance during the summer as indexed by the Continuous Performance Task-Identical Pairs (CPT-IP; $F=3.41$, $p=.02$), DS-CPT ($F=3.04$, $p=.03$), Penn Verbal memory task ($F=2.97$, $p=.03$), and MMN ($F=4.74$, $p < .01$). Significantly poorer performance was observed in the fall on the California Verbal Learning Test ($F=3.21$, $p=.02$), with a trend for P300 ($F=2.54$, $p=.06$). Group comparisons indicated a significant group by season interaction for CPT-IP ($F=3.01$, $p=.03$; largest difference in the summer), along with trends for DS-CPT and the Penn verbal memory task ($F=2.41$, $p=.06$ and $F=2.06$, $p=.10$, respectively; SZ group performed worse on all).

Discussion: This is the first report describing the links between seasons, neurocognition, and electrophysiological brain functioning in people with SZ. Our Results: identify a novel source of variabilities in these targets, highlighting the significant impact of seasons on neurocognition and electrophysiological functioning in this population. We discuss the translational and therapeutic implications of the findings, including the impact on the design and analyses of data from clinical trials targeting enhancement of neurocognition in people with SZ.

20. LONG TERM RECOVERY AND TREATMENT RESISTANCE IN FIRST-EPISODE PSYCHOSIS: A 10-YEAR FOLLOW-UP STUDY

Kristin Wold^{*1}, Isabel Kreis², Gina Åsbø¹, Carmen Simonsen³, Ingrid Melle⁴

¹NORMENT, Division of Mental Health and Addiction, Oslo University Hospital and Institute of Clinical Medicine, University of Oslo, ²NORMENT, Institute of Clinical Medicine, University of Oslo, ³NORMENT, Division of Mental Health and Addiction, Oslo University Hospital and Institute of Clinical Medicine, University of Oslo; Early Intervention in Psychosis Advisory Unit for South East Norway, Oslo University Hospital, ⁴NORMENT, Division of Mental Health and Addiction, Oslo University Hospital and Institute of Clinical Medicine, University of Oslo

Background: There are several possible illness trajectories for patients experiencing first-episode psychosis (FEP) with considerable variation in symptoms and functional levels over time and between patient groups. This underlines the importance of stratification in treatment studies and having tools to identify patients in need of different treatment approaches. Data from previous studies indicate that early course parameters are among the most significant predictors of long-term outcome, but to identify early predictors affecting long-term course, we need longitudinal data of FEP cohorts.

We aimed to use longitudinal data to investigate the prevalence of clinical recovery (CR) and treatment resistance (TR) at 10-year follow-up (10Y FU), and to investigate clinical, demographic and pre-illness predictors of long-term outcomes.

Methods: 102 participants with FEP DSM-IV Schizophrenia spectrum disorders who were recruited to the “Thematically Organized Psychosis” (TOP) research study within their first year of treatment was eligible to this naturalistic observational 10Y FU study. The SCID-I for DSM-IV was used for diagnosis, symptoms were measured with the SCI-PANSS. Treatment history was gathered through interviews and medical charts. TR was defined by the Treatment Response and Resistance in Psychosis Working Group (TRRIP) criteria and Clinical Recovery was defined by most recent used criteria. After initial analyses, we conducted binary and multinomial logistic regression analyses to identify predictors of long-term outcome.

Results: Out of 102 participants, 29 (29%) could be classified as in CR and 32 (31%) as TR at 10Y FU. We also identified a larger middle group (n=41, 40%) consisting of both participants with partial recovery, remitting/relapsing patterns, and participants not meeting the TR criteria due to lack of treatment trials but with the same clinical outcome as the TR group. Insidious onset (OR=4,16) and disorganized symptoms at baseline (OR=2,96) were independently significantly associated with increased odds of developing TR, and acute onset (OR=3.94) were independently significantly associated with increased odds of CR. At 10Y FU only 7 (7%) of all the participants had tried Clozapine.

Discussion: Using recent consensus definitions we identified three long-term outcome groups: CR (28%), TR (31%) and a middle heterogeneous group (40%). The prevalence of CR and TR corresponds with earlier findings. However, identified predictors of 10-year outcome is not completely in line with earlier findings. We identify the potential important predictive value of assessing baseline disorganized symptoms and further target disorganized symptoms in early intervention treatments, as well as to monitor more closely patients with insidious onset.

21. 30-YEAR FOLLOW-UP OF THE CANTABRIA FIRST-EPIISODE-SCHIZOPHRENIA STUDY, FROM EARLY INTERVENTION TO CHRONICITY

Javier Vázquez-Bourgon*¹, María Jesús Cuesta², Ismael Lastra Martínez², Adriá Palau Miguel², Sara Herrera Castanedo², Álvaro De Santiago-Sánchez², Rocío Pérez-Iglesias²

¹University Hospital Marques de Valdecilla -IDIVAL; University of Cantabria; CIBERSAM,

²University Hospital Marqués de Valdecilla - Instituto de Investigación Marqués de Valdecilla (IDIVAL)

Background: Early intervention psychosis (EIP) programs are effective in treating subjects with a first episode psychosis ensuring a better outcome during the most critical period, the first 3-5 years after the psychosis breakout. However, there is little evidence on the long-term progression of those patients after being discharged from EIP to standard community treatment. We aim to report on the long-term outcome of those individuals treated 30 years earlier, in the Cantabria First-Episode-Schizophrenia study (Vazquez-Barquero et al., 1999, 1995).

Methods: We designed a cross-sectional observational study. We collected sociodemographic, clinical and functioning data from the patients' clinical records. A total of 88 patients were included in the current analyses.

Results: At the time of the medical records review, at 30-years follow-up, 56 patients (63.6%) had a diagnosis of non-affective psychosis, mainly schizophrenia (n=46, 52.3%), while 10.2% (n=9) had a diagnosis of bipolar disorder. While 67% (n=59) had a recognized disability, 20 were currently working and 5 were retired.

Only 42 (47.7%) patients continued treatment in a community mental health team while 10 patients had been discharged or abandoned treatment. Only 63.6% of patients were on psychopharmacological treatment; most of them (n=43, 76.7%) were on just one antipsychotic,

although 8 (14.8%) were on two or more antipsychotics. Nearly 20% (N=11) were on mood stabilizers. And, 16 (28.5%) were having antidepressants.

Among those treated with antipsychotics (n=51), 19.6% received long-acting injectable: 6 paliperidone palmitate, 1 aripiprazole maintenance, 1 risperidone, and 2 zuclopenthixol decanoate. The most frequently prescribed oral antipsychotic was olanzapine (n=15, 29.4%), with a mean dose of 13.5mg. 9 patients were on clozapine (17.6%, mean dose 334.4mg), 4 aripiprazole (mean dose 13.75mg), 4 risperidone (mean dose 3.5mg), 3 paliperidone (mean dose 6mg), and 5 perphenazine (mean dose 7.2 mg). Mean chlorpromazine equivalent dose for all the patients on antipsychotics was 546.7 (median 450.0).

A total of 41 patients (46.6%) required hospital admission to psychiatric ward during the 30-years follow-up, with a mean number of 8 psychiatric hospitalizations.

According to clinical records, only 3% patients were tobacco smokers and none of them had consumed illegal substances in the previous year. However, there was an important lack of information in this regard (missing data for 60 patients, 67%).

Regarding medical co-morbidities, 29.5% were obese, 30.7 had dyslipidemia, and 25% hypertension. Thirteen (15.9%) patients had died during the course of the last 30 years, with a mean age at the time of death of 52.5 years. Of these, four (28.5%) had died from suicide: three occurred within the first 5 years after the first hospitalization. The average age of those who died by suicide was 29.7 years, and all of them were men.

Seven deaths (50%) were from natural causes, with a mean age of 56.7 years. The two most prevalent causes of natural deaths were respiratory and cardiologic.

Discussion: The results showed that, despite having been treated in an specialized EIP program during their first 3 years of their psychosis, these patients present later in life high rates of premature mortality. The number of readmissions, polypharmacy and medical co-morbidities are also high. And most of patients present indirect indicators of a poor functioning.

These results suggest that the clinical improvements achieved in EIP might be lost after discharged from EIP, leading to a standard “chronification” of the condition. Thus, a major effort must be put in place in treating more effectively those patients throughout their long-term.

22. RISK OF RELAPSE DURING CONTINUOUS DOPAMINE D2 RECEPTOR BLOCKADE IN FIRST-EPISODE SCHIZOPHRENIA

Jari Tiihonen¹, Antti Tanskanen¹, Heidi Taipale*²

¹Karolinska Institutet, ²Niuvanniemi Hospital, University of Eastern Finland

Background: Concerning the neurobiology of schizophrenia, it is not known how large proportion of patients with first-episode schizophrenia relapse despite of continuous dopamine 2 (D2) receptor blockade. It has also remained controversial whether long-term use of D2-blocking antipsychotics increases the risk of relapse due dopamine hypersensitivity, since no study has investigated this during several years of assured antipsychotic treatment. We aimed to compare the risk of relapse in continuous use of long-acting antipsychotics (LAIs) to those not using LAIs among persons with first-episode schizophrenia over 5 years of follow-up.

Methods: Persons with first-episode schizophrenia, aged ≤ 45 years, were identified from Finnish nationwide register of inpatient care during years 1996-2014. During the first 30 days after first diagnosis, patients were categorized as LAI users versus non-LAI users (using oral

antipsychotic or not using any antipsychotic). Outcome was severe relapse defined as readmission to hospital due to psychosis relapse. During the follow-up, those categorized as LAI users were censored if they discontinued LAI. The follow-up was 5 years or until the first relapse.

Results: Of the entire cohort of 5367 patients (64.2% men, mean age 29.5 years, SD 7.8), 3058 (57%) had a relapse. Among those patients who were not re-admitted to hospital within the first 30 days of follow-up (N=4788), 305 initiated LAI use and 4483 did not. Among continuous LAI users, 21.6% relapsed (95% CI 17.1-26.7%; N=66) compared with 34.2% of the other patients not on LAI (95%CI 32.8-35.8%, N=1534). The relapse rate among patients using LAI continuously was 47/305 (15.4%) during year 1, 8/139 (5.7%) during year 2, 6/98 (6.1%) during year 3, 3/73 (4.1%) during year 4, and 2/47 (4.3%) during year 5 (difference between year 1 vs. year 4, $p = 0.02$, Fisher exact test).

Discussion: Up to one quarter of patients with first-episode schizophrenia relapse despite of continuous D2-blockade which may be attributable to neurobiological heterogeneity in the pathophysiology of the illness. The relapse risk decreased as a function of assured cumulative D2-antagonist use during the first 4 years, after which it plateaued, indicating that cumulative exposure to dopamine D2 receptor blockade is associated with decreased, rather than increased risk of breakthrough psychosis. A large proportion of relapses could be prevented by continuous LAI use.

23. THE CLINICAL AND FUNCTIONAL OUTCOMES OF A LARGE NATURALISTIC COHORT OF YOUNG PEOPLE ACCESSING NATIONAL EARLY PSYCHOSIS SERVICES

Andrew Thompson^{*1}, Caroline Gao¹, Georgia Williams¹, Debra Rickwood², Nic Telford², Cerissa Papanastasiou³, Patrick D McGorry¹, Eleanor Brown¹

¹Orygen, ²Headspace

Background: Services for individuals with a first episode of psychosis or at ultra-high risk of psychosis have become a treatment model of choice in mental health care. The longitudinal changes in clinical and functional outcomes as a result of real-world treatment remain under-reported in large datasets.

Methods: We analysed routine outcome data from first episode of psychosis and ultra-high risk services delivered across the whole of Australian primary youth mental health care services known as headspace between 19 June 2017 and 30 September 2019. Additional data up to September 2023 will be available making this the largest real world early psychosis longitudinal dataset. Outcome measures were completed and entered into a minimum dataset every 90 days a participant was receiving treatment and included psychiatric symptomatology (Brief Psychiatric Rating Scale and psychological distress, K10) and psychosocial functioning (Social and Occupational Functioning Assessment Scale and My Life Tracker). Linear mixed-effects models were used to evaluate changes in outcome over time.

Results: Outcome data from a total of 1252 young people were evaluated (643 first episode of psychosis, 609 ultra-high risk). Of those who entered ultra-high risk services, 11.8% transitioned to first episode of psychosis services. Overall, substantial improvement in clinical (Brief Psychiatric Rating Scale, K10) and functional (Social and Occupational Functioning Assessment Scale, My Life Tracker) outcomes were seen across groups and outcomes. Ultra-high risk patients showed a greater reduction in distress symptoms, while first episode of psychosis patients experienced a greater reduction

in positive psychosis symptoms. Although clinical outcomes showed a plateau effect after approximately 3 months of care, improvement in functional outcomes (Social and Occupational Functioning Assessment Scale, My Life Tracker) continued later in treatment. We will be able to supplement and contrast these results with an additional 3 1/2 years of data (September 2019- July 2023) and an anticipated n of over 4000 young people with first episode psychosis or ultra high risk.

Discussion: These findings support the use of real-time, real-world and low-cost administrative data to rigorously

evaluate symptomatic and functional outcomes in early psychosis treatment settings. Findings that functional outcomes improve past the remittance of clinical outcomes also support the functional recovery focus of early psychosis services and remaining high levels of distress suggest the need for ultra-high risk services to extend beyond 6 months of care. Information on important sub-groups will also be available with the substantially larger dataset (over 4000 individuals).

Oral Session: Development

24. THE IMPACT OF ESTRADIOL LEVELS AND PUBERTY TIMING ON PSYCHOTIC EXPERIENCES IN THE CONTEXT OF EXPOSOMIC VULNERABILITY FOR SCHIZOPHRENIA: AN ABCD STUDY

Lotta-Katrin Pries*¹, Thanavadee Prachason², Angelo Arias-Magnasco³, Bochao D. Lin³, Bart P. F. Rutten³, Sinan Guloksuz⁴

¹*School for Mental Health and Neuroscience, Maastricht University Medical Centre*, ²*Faculty of Medicine Ramathibodi Hospital, Mahidol University*, ³*School for Mental Health and Neuroscience, Maastricht University Medical Centre*, ⁴*School for Mental Health and Neuroscience, Maastricht University Medical Centre; University School of Medicine*

Background: Sex (biological) and gender (social/cultural) effects contribute to the diversity in the onset, progression, prognosis, and etiology of psychotic spectrum disorders (PSD). Especially during critical developmental phases, such as puberty, sex- and gender-specific processes play a pivotal role in shaping distinct symptom profiles. Although puberty timing is associated with internalizing and externalizing symptoms, research on puberty markers and PSD is limited and conflicting. Furthermore, the etiology of PSD is marked by different environmental factors. This study aims to explore whether puberty status and hormone (estradiol) levels during puberty can potentially moderate the impact of exposomic (environmental) vulnerabilities for schizophrenia on psychosis experiences (PEs) in young female individuals.

Methods: This study utilized data from 5682 female children and adolescents in the Adolescent Brain Cognitive Development (ABCD) Study, assessing them at baseline and with 3-year follow-ups. Binary significantly distressing PEs were assessed using the Prodromal Psychosis Scale. Puberty status (prepubertal, early pubertal, midpubertal, late pubertal, postpubertal) was assessed with the Pubertal Development Scale, covering changes in height, body hair, skin, breast development, and menarche (first period). Salivary samples were taken to measure estradiol levels. Exposomic vulnerability for schizophrenia (ES-SCZ) was assessed through an aggregated weighted sum score, including factors like cannabis use, hearing impairment, winter birth, and childhood adversities. ES-SCZ was dichotomized at the 75th percentile.

Multilevel mixed regression analyses, taking into account the nested structure of study site and family membership were applied to test the interaction of puberty status and estradiol levels with ES-SCZ, in association with psychosis expression in female participants at the first follow-up assessment. Furthermore, analyses were conducted to test the interaction between age of menarche and ES-SCZ on PEs at the third follow-up assessment. Analyses were adjusted for BMI, parental education, family income, ethnicity, and age. Hormonal analyses were controlled for variables that could bias salivary hormone levels.

Results: Elevated standardized estradiol levels were associated with an increased probability of reporting PEs at trend level (OR = 1.09, 95% CI = 0.99 to 1.19), while a later age of menarche was associated with a reduced likelihood of reporting PEs (OR = 0.83, 95% CI = 0.74 to 0.94). Analysis with puberty status showed significant differences between the prepubertal (reference) group and those in midpubertal (OR=1.72, 95% CI = 1.29 to 2.30) and late pubertal (OR = 2.13, 95% CI = 1.45 to 3.12) stages. Furthermore, ES-SCZ was associated with an elevated likelihood of experiencing PEs at the first (OR = 1.81, 95% CI = 1.49 to 2.19) and the third follow-up assessment (OR = 1.59, 95% CI = 1.28 to 1.98). We found a significant interaction between ES-SCZ and puberty status, comparing the prepubertal to the late pubertal stage (OR = 0.42, 95% CI = 0.19 to 0.90). No other significant interaction was detected.

Discussion: This study examines the interplay between exposomic vulnerability for schizophrenia and physical as well as hormonal puberty markers in young female participants. The study underscores the critical role of puberty, revealing it as a period of significant biological and socio-cultural changes directly tied to psychosis expression. Puberty may trigger processes impacting neurodevelopment, influencing psychosis expression. The absence of interaction effects may be attributed to the age range of the cohort. Further research during follow-ups, when clinically relevant phenotypes emerge, is essential.

25. AN ANALYSIS OF CHILDHOOD TRAUMA AND ITS RELATION TO LIMBIC STRUCTURES IN A LARGE TRANSDIAGNOSTIC SAMPLE

Varun Thvar*¹, Elisabetta C. del Re², Brett Clementz³, Elliot Gershon⁴, Sarah Keedy⁴, Godfrey Pearlson⁵, Carol A. Tamminga⁶, Matcheri S. Keshavan²

¹*Beth Israel Deaconess Medical Center, Harvard Medical School*, ²*Beth Israel Deaconess Medical Center, Harvard Medical School*, ³*University of Georgia*, ⁴*University of Chicago*, ⁵*Yale University School of Medicine*, ⁶*University of Texas Southwestern Medical Center*

Background: Childhood trauma is significantly associated with risk for regulation disorders, psychotic disorders, cognitive impairment, and suicidal behavior. Previous research has focused on investigating childhood trauma's relationship to single brain structures in clinical and non-clinical populations. To expand the understanding of how childhood trauma affects multiple brain regions, we examined the association between childhood trauma and the volume, area, cortical thickness, and local gyrification index (LGI) of limbic and associated brain structures. We also explored the relationship between childhood trauma and cognition and suicidal thoughts. We hypothesized that a) total childhood trauma score would be negatively correlated with limbic regional volume, area, LGI, and cortical thickness and b) effects of childhood trauma on cognition and suicide would be mediated at least partially through the limbic structure.

Methods: The study included 1079 participants, consisting of 672 probands and 407 controls. Childhood trauma and limbic measure associations were examined using a large, deeply phenotyped, trans-diagnostic adult sample from the BSNIP-2 database. Participants received a 3 T-MPRAGE MRI scan based on the Alzheimer's Disease Neuroimaging Initiative (ADNI)

protocol, and limbic region atlases were used to parcellate and extract data. We investigated relationships between the total score of the Childhood Trauma Questionnaire (CTQ) and several clinical measures and brain morphology of the following limbic and associated structures, individually and as a whole: the Parahippocampus, Insula, Amygdala, Hippocampus, Thalamus, Hypothalamus, and Cingulate. Demographic information for HC and PRO was analyzed using univariate analyses (ANCOVA) and χ^2/F tests. Analyses were performed with Student's t-tests, MANOVA, regressions, and Spearman correlations.

Results: Thirty-three out of 36 limbic measures showed statistically significant differences (p LESS THAN 0.001) between childhood trauma-exposed ($n = 453$) and non-exposed participants ($n = 626$). Regressions between CTQ and total limbic volume yielded significant correlation ($t = -7.28$), significantly stronger in probands. Childhood trauma-exposed probands had lower hippocampus and amygdala volumes compared to non-trauma-exposed controls, such as in the Right Anterior Hippocampus (Cohen's $d = -0.34$). FDR-corrected Spearman correlations indicated statistically significant positive relationships between childhood trauma and clinical measures, such as Depression (p LESS THAN 0.001), Anxiety (p LESS THAN 0.001), and Suicidal Thoughts ($p = 0.00345$), as well as negative relationships with Social Functioning (p LESS THAN 0.001) and Cognition ($p = 0.00562$).

Discussion: Our data indicate that childhood trauma affects the structure of several limbic and associated system regions. These observations have strong implications for early detection of risk for trauma-related psychopathology and for biopsychosocial interventions.

26. EARLY LIFE ADVERSITIES AND ADOLESCENT PSYCHOTIC EXPERIENCES: THE MEDIATING EFFECT OF PLANT-BASED DIETARY PATTERNS

Xuemei Ma^{*1}, Rebecca Pollard¹, Pei-Jung Chen¹, Svenja Kretzer², Nare Amasi-Hartoonian¹, Maryam Matter¹, Andrew J. Lawrence¹, Corentin Vallée¹, Olivia Johnson-Trewick¹, Craig Morgan¹, Seeromanie Harding³, Gunter Schumann¹, Carmine Pariante¹, Mitul Mehta¹, Giovanni Montana⁴, Ana Rodriguez-Mateos⁵, Chiara Nosarti¹, Paola Dazzan¹

¹*Institute of Psychiatry, Psychology and Neuroscience, King's College London*, ²*King's College London; Agency for Science, Technology and Research (A*STAR), Singapore*, ³*Division of Diabetes and Nutritional Sciences, King's College London*, ⁴*University of Warwick*, ⁵*Faculty of Life Sciences and Medicine, King's College London*

Background: Due to the importance of adolescence as period of risk for the emergence of psychopathology, the role of early life adversities (ELAs) in adolescence in relation to psychopathology has received more attention recently. ELAs have also been associated with a less healthy dietary pattern, which in turn is associated with more mental health disorders. However, to date no study has investigated whether different healthy dietary patterns are also associated with psychotic experiences in adolescents, and whether a healthy dietary pattern could buffer the relationship between ELAs and psychotic experiences. This study evaluated the relationship between different plant-rich dietary patterns and psychotic experiences in an adolescent cohort, testing the mediating effect of dietary patterns in between.

Methods: A total of $n=199$ school young adolescents (mean age: 12.94 ± 0.93 years) were included in this study. Individual-level ELAs were assessed by interview, and included maltreatment, household fragmentation, bullying, discrimination, and adverse life events. Area-level ELA was indicated by living in 1st to 3rd deciles of the UK Indices of Multiple Deprivation (IMD). Psychotic experiences were assessed with the adolescent psychotic-like symptom screen (APSS). Dietary patterns were estimated using food consumption data

obtained from the Food Frequency Questionnaires (FFQ) and included the Plant-based Diet Index (PDI), Dietary Approaches to Stop Hypertension Diet (DASH), Mediterranean-DASH Diet Intervention for Neurodegenerative Delay (MIND), Original Mediterranean Diet (oMED), Alternate Mediterranean Diet (aMED) and (poly)phenol-rich diet score (PPS). Multivariate linear regression models were used to test the direct effect of ELAs and dietary patterns on psychotic experiences. Hayes PROCESS macro was used to test the role of dietary pattern in the relationship between ELAs and psychotic experiences.

Results: The multivariate model showed a positive association between number of individual-level ELAs and psychotic experiences ($B=0.195$, $p < 0.001$) and a negative association between the DASH diet score and psychotic experiences ($B=-0.061$, $p=0.039$). Since the DASH score was also negatively correlated with the number of individual-level ELAs ($r=-0.215$, $p=0.002$), we explored the role of DASH as a mediator in the relationship between ELAs and psychotic experiences. When adjusted for age, energy intake and area-level ELA, the DASH score was a significant mediator in the association between number of individual-level ELAs and psychotic experiences (standardised indirect effects being 0.030 (95%CI: 0.004, 0.059)), accounting for 8.1% of the total effect. Considering each dietary component of the DASH score, we found that higher intake of nuts and legumes was particularly significant in explaining the potential positive role of DASH on psychotic experiences ($B=-0.005$, $p=0.035$).

Discussion: We confirmed that exposure to ELAs is associated with more psychotic experiences in adolescence and found that diet might contribute to understand this link. Compared to other diets, the DASH diet uniquely limits intake of saturated fats, added sugars and sodium, which are all linked to immune activation, suggesting that the anti-inflammatory potential of DASH might be the mechanism that explains its potential beneficial contribution to mental health. However, future studies will need to confirm the precise biological mechanisms underlying dietary contributions.

27. PERSISTENT CHILDHOOD INFLAMMATION AND RISK OF DEVELOPING PSYCHOSIS AND OTHER MENTAL AND PHYSICAL HEALTH PROBLEMS IN ADULTHOOD: A LONGITUDINAL BIRTH COHORT STUDY

Edward Palmer^{*1}, Isabel Morales-Muñoz², Benjamin Perry³, Jack Rogers¹, Ella Warwick¹, Steven Marwaha⁴, Rachel Upthegrove¹

Background: There is a growing body of evidence showing that inflammation or changes in the immune system play a key role in certain mental health disorders. The evidence is particularly strong for psychosis and depression. However, a potential causal link between inflammation and psychosis is yet to be proven, and less is known about the trajectories, nature and degree of inflammation that might have an impact on mental health. The aim of this study was to characterize the inflammatory trajectories within a large general population across childhood and adolescence, and how these trajectories would associate with a range of mental and cardiometabolic health conditions in young adulthood. This would help identify which mental health disorders and other cardiometabolic health outcomes in young adulthood are linked with early life inflammation. We hypothesized that there would be sub-group of young people who have different and raised levels of inflammation, and that this group would be at highest risk of developing certain mental health conditions, namely psychosis and depression,

as well as related cardio-metabolic psychological health conditions such as diabetes and associated insulin resistance.

Methods: We used data from the Avon Longitudinal Study of Parents and Children (ALSPAC) study, which has data from over 14,000 individuals at birth. Groups of inflammatory trajectories across childhood and adolescence were identified using latent class growth analysis (LCGA). Inflammation was assessed via blood samples of CRP measures at ages 9, 15 and 17. Scores above 10 were excluded to rule out the impact of acute infection, with all CRP-measures z-transformed and LCGA carried out on the z scores adjusted for BMI at each time point to provide classes of different inflammatory trajectories across childhood and adolescence.

We also investigated the prospective associations between inflammatory trajectories identified by LCGA, and different mental health (including psychosis, various severities of depression, hypomania, generalised anxiety disorder, social phobia, panic disorder, mild depression, alcohol abuse or cannabis misuse) and cardiometabolic health (including diabetes, and insulin resistance) outcomes at age 24. As well as predefined outcomes, we also calculated the Homeostatic Model Assessment for Insulin Resistance (HOMA score) at age 24 from recorded insulin and glucose measures. We used regression analyses across binary (e.g. diagnosis) and continuous (e.g. HOMA scores) outcome measures. Further, we controlled for gender, preterm, family diversity index score, ethnicity, and child health age 8 and 13. To deal with missingness, we applied inverse probability weighting.

Results: LCGA results

We identified 3 trajectories of inflammation across childhood and adolescence. Class 1 had persistently low levels of CRP (Low Group - 93% of cohort), which was used as the comparison group in the subsequent logistic regression analyses. Further, there were two divergent groups, both with persistently raised levels of CRP. Class 2 had a persistently raised level of CRP with a peak earlier at age 9 (Early Peak - 5% of cohort) and Class 3 had persistently raised CRP levels and a peak later at age 17 (Late Peak - 4% of cohort).

Regressions results

Logistic regressions were used to compare odds ratio (OR) of outcomes between the Early Peak and Late Peak groups and the comparison group (Low Group). The Early Peak was 4 times more likely to develop psychotic disorder at age 24 (OR = 4.39, 95% CI 1.73-11.13, $p=0.002$), twice as likely to develop psychotic-like symptoms at age 24 (OR = 2.31, 95% CI 1.34-3.99, $p=0.003$), over 4 times more likely to develop severe depression at age 24 (OR = 4.54, 95% CI 1.69-12.20, $p=0.003$) and more than twice as likely to develop moderate depression (OR = 2.13, 95% CI 1.14-3.97, $p=0.01$) than the Low Group. Neither group showed any significant results for hypomania, generalised anxiety disorder, social phobia, panic disorder, mild depression, alcohol abuse or cannabis misuse.

in regards to cardiometabolic outcomes, the Early Peak group (class 2) was significantly associated with an increased risk of insulin resistance (HOMA score GREATER THAN 2.9) at age 24 (OR 2.48, 95% CI 1.52-4.02, $p=$ LESS THAN 0.001) and using linear regressions, we found a significant association between the Early Peak group and higher levels of HOMA scores at age 24.

Discussion: Our findings from a large population cohort show that specific trajectories of low grade systemic inflammation across childhood and adolescence are related to later onset of mental health disorders, particularly psychosis and depression, with early rather than later inflammation potentially holding importance. Our results also show specificity in the development of psychosis and depression, and not all or other mental health disorders. Finally,

our results show that the same early peak group is also at higher risk of developing certain cardio-metabolic disorders such as insulin resistance. This study adds new information about the chronicity and timing of inflammation predating illness, and provides insight into the co-occurrence of related cardio-metabolic disorder that may be useful in developing targeted preventive interventions.

28. BULLYING VICTIMIZATION'S IMPACT ON GUT MICROBIOTA AND ADOLESCENT PSYCHOTIC SYMPTOMS: A LONGITUDINAL COHORT STUDY

Syudo Yamasaki^{*1}, Shuntaro Ando², Mitsuhiro Miyashita³, Eiji Miyauchi⁴, Kazuya Toriumi⁵, Satoshi Yamaguchi³, Makoto Arai⁵, Mariko Hiraiwa-Hasegawa³, Takefumi Kikusui⁶, Kiyoto Kasai⁷, Atsushi Nishida¹

¹*Research Center for Social Science and Medicine, Tokyo Metropolitan Institute of Medical Science,* ²*Graduate School of Medicine, The University of Tokyo,* ³*Research Center for Social Science and Medicine, Tokyo Metropolitan Institute of Medical Science,* ⁴*Laboratory of Mucosal Ecosystem Design, Institute for Molecular and Cellular Regulation, Gunma University,* ⁵*Tokyo Metropolitan Institute of Medical Science, Schizophrenia Research Project,* ⁶*Laboratory of Human-Animal interaction and Reciprocity, Azabu University,* ⁷*Graduate School of Medicine, The University of Tokyo; Tokyo Center for Integrative Science of Human Behaviour (CiSHuB), The University of Tokyo; The International Research Center for Neurointelligence (WPI-IRCN) at The University of Tokyo Institutes for Advanced Study (UTIAS), The University of Tokyo*

Background: Longitudinal cohort studies consistently support the adverse impact of adolescent bullying victimization on mental health, particularly through increased psychotic symptom risk. However, the biological pathways linking bullying to psychotic symptoms remain unclear. The gut microbiota, referred to as the "second genome," plays a crucial role in physical and mental health (Herd 2018 Nat Hum Behav), offering a promising intervention target for mitigating social stress and psychotic symptoms due to its susceptibility to environmental factors (Sherwin 2019 Science). Despite its potential, current studies are limited to animal models and cross-sectional human studies with small samples. This study aims to investigate the longitudinal relationship among bullying victimization, gut microbiota, and psychotic symptoms using a large cohort of randomly selected adolescents.

Methods: Data from 345 adolescents in the population-based biomarker subsample study of the Tokyo Teen Cohort Study (pb-TTC) were analyzed (mean age [SD] = 13.5 [0.6] years). The pb-TTC subsample was followed up after one year, with 282 participants (82%) completing the follow-up survey. Bullying victimization was measured by self-report and caregiver's report at age 12, a year before the pb-TTC baseline survey. Gut microbiota were evaluated from fecal samples using a terminal restriction fragment length polymorphism (T-RFLP) method to determine the structure and dynamics of the microbial gut community. Psychotic symptoms and other mental health problems were assessed at age 16 using the Adolescent Psychotic Symptoms Screener (APSS) and the Child Behavior Checklist (CBCL).

Results: Cluster analysis at age 13 identified five distinct gut microbiota groups, with one group exhibiting *Prevotella* genus occupancy 160 times higher, and 25% of children in this group reported bullying within the past year. Frequency of bullying victimization at age 12 significantly correlated with *Prevotella* occupancy at ages 13-14 ($r=0.31$, $p < .001$), and *Prevotella* occupancy increased by 20-fold in the group bullied at least once a week compared to the non-bullied group ($p < .001$). Path analysis revealed a longitudinal relationship: bullying victimization (age 12) increased *Prevotella* occupancy (age 13-14),

subsequently worsening mental health at age 16. Prevotella occupancy was associated with psychotic symptoms ($\beta=0.18$, $p=.0008$) and CBCL thought problems as a psychosis risk ($\beta=0.20$, $p=.0002$), and was strongly correlated with delinquent behavior, physical complaints, and self-injurious behavior ($\beta=0.28$, 0.27 , 0.23 , respectively, all $p < .001$), indicating a link between gut microbiota and adolescent psychotic symptoms, physical health, and impulsivity.

Discussion: Prevotella spp. are linked to inflammatory diseases, suggesting an association with inflammation, oxidative stress, and glycation stress (Tett 2021 Nat Rev Microbiol). Future investigations will explore the causal relationship through longitudinal analyses, including inflammation markers and glycation stress, to elucidate the process by which bullying-induced damage increases Prevotella spp. and therefore identify potential intervention targets.

29. LINKING EARLY LIFE ADVERSITY AND MENTAL HEALTH OUTCOMES WITH DISTINCTIVE INTERHEMISPHERIC FUNCTIONAL CONNECTIVITY PATTERNS

Corentin Vallée^{*1}, Xuemei Ma¹, Rebecca Pollard¹, Andrew Lawrence¹, Svenja Kretzer¹, Pei-Jung Cheng², Craig Morgan³, Seeromanie Harding¹, Giovanni Montana⁴, Ana Rodriguez-Mateos⁵, Gunther Schumann¹, Carmine Pariante⁶, Chiara Nosarti⁷, Mitul Mehta⁸, Paola Dazzan⁶

Background: Early life adversity (ELA) is the range of detrimental circumstances that an individual encounters during their formative years, typically encompassing childhood and adolescence. ELA can manifest in various forms, including abuse, neglect, disadvantageous socio-economic factors or exposure to violence. The consequences of ELA on mental health are manifold in particular regarding psychopathology: depression, anxiety, psychosis, or behavioral trouble. Current research indicates functional resting-state connectivity, as key feature in understanding the effect of ELA on the brain, and the subsequent development of MH outcomes. In the present study, we have explored interhemispheric functional connectivity (IHFC) in relation with history of ELA and MH problems.

Methods: A total of 230 adolescents aged from 11.2 to 14.9 were recruited from schools in Southeast London.

We evaluated Early Life Adversity with The Difficult and Harmful Life Event questionnaire, along with the England Index of Multiple Deprivation to address area-level adversity.

Participants were categorized as negative for ELA if they: 1) faced a maximum of two events from the Difficult and Harmful Life Event questionnaire (on 28 possible) along with lowest severity, lowest frequency, no distress nor injury for these maximum two events, and 2) resided in areas not classified as deprived by the Index of Multiple Deprivation.

We evaluated mental health of participants using four questionnaires: the Generalized Anxiety Disorder 7 for anxiety, the Short Mood and Feelings Questionnaire for depression, the Adolescent Psychotic-like Symptom Screener for psychosis, and the Strengths and Difficulties Questionnaire for overall well-being and behavioral traits.

Participants were categorized as positive for MH problems if they were screened positive by at least one of these questionnaires.

The participants were then divided into three groups: 1) with ELA but without MH problems (Group 1, $n=81$); 2) with both ELA and MH problems (Group 2, $n=71$); and 3) a control group without ELA and without MH problems (Control group, $n=29$). The group sizes are given after excluding participants with incomplete questionnaires and after fMRI quality control.

Resting-state BOLD fMRI data were collected using a 3T GE scanner. The imaging data were processed using fMRIPrep default pipeline and further denoised with CONN using the confounders calculated by fMRIPrep. We defined functional connectivity as linear correlation, specifically between BOLD signal of contralateral voxel signals for IHFC. Our group-level analysis utilized a general linear model with group classifications as predictors of connectivity. We conducted voxel-level hypothesis testing using multivariate parametric statistics with random-effects modeling. Our inferences were based on individual cluster evaluations, using non-parametric permutation testing (1000 iterations). Our results were determined using a dual-threshold approach, with a voxel-level threshold set at 1% (α_{voxel}) and a cluster-mass threshold adjusted for the false discovery rate at 5% (α_{cluster}).

Results: We investigated IHFC differences between the three groups. The size of cluster are given in number of voxels, which size is 2mm³ isotropic.

1) Control group vs group 1: We found one cluster (1316 voxels, $p=0.000127$, $p_{\text{FDR}}=0.025708$) where control group had higher IHFC. The cluster is located in posterior areas of the brain, mostly in the middle occipital and precuneus cortex.

2) Control group vs group 2: We found one cluster (2585 voxels, $p=0.000283$, $p_{\text{FDR}}=0.027140$) where control group had higher IHFC. This cluster covers similar area than the latter case (774 voxels in common), and is more extended toward the hippocampus and amygdala. We found a second cluster located in the cerebellum (2378 voxels, $p=0.000269$, $p_{\text{FDR}}=0.027140$) where Control group has a lower IHFC than group 2.

3) Group 1 vs Group 2: Only one cluster was found in the cerebellum (2816 voxels, $p=0.000165$, $p_{\text{FDR}}=0.032742$), where Group 1 IHFC is lower than Group 2. This cluster has a good overlap with the latter case cerebellum cluster (1438 voxels in common).

As in case 3) both groups are positive for ELA and only group 2 is positive for MH problems, results suggest the cerebellum IHFC increase is specific of the co-occurrence of ELA and MH problems, while the posterior IFHC decrease is specific of ELA alone.

Discussion: Our findings suggest that the ELA is associated with different alterations of interhemispheric functional connectivity depending on the co-occurrence of MH problems. These changes in IHFC might be the consequence of structural modifications in the corpus callosum, as diffusion MRI experiment found a decreased fractional anisotropy in the corpus callosum of individuals with ELA, hinting at potential myelin deterioration or localized

neuroinflammation. Additionally, the unique involvement of the cerebellum in cases where ELA and MH problems coexist could be a key factor in the development of symptoms or a sign of diminished resilience. This aspect deserves further investigation through a longitudinal approach.

30. MOTOR SKILLS, LINGUISTIC ABILITY, AND RELATED DISORDERS IN 7-YEAR-OLD CHILDREN AT FAMILIAL HIGH-RISK OF SCHIZOPHRENIA OR BIPOLAR DISORDER

Background: Developmental disorders affecting motor function and linguistic ability such as Specific Language Impairment (SLI) and Developmental Coordination Disorder (DCD) tend to co-occur in developing children and may indicate underlying aberrant neurodevelopmental processes. Although schizophrenia (SZ) and bipolar disorder (BP) are seldom diagnosed during childhood, they may be preceded by early language and motor deficits. In fact, children at familial high-risk of SZ present significantly impaired motor skills and linguistic ability compared with population-based controls (PBC) and children with definite motor problems are more likely to perceive psychotic-like experiences.

Based on these findings, we have investigated the co-occurrence of SLI and DCD in 7-year-old children at familial high-risk of SZ, at familial high-risk of BP, and PBC. Moreover, we assessed how the children's familial high-risk status and their SLI or DCD status impacted their motor skills and linguistic ability.

Methods: We leveraged data from the Danish High Risk and Resilience Study (the VIA 7 study), a cohort of 522 7-year-old children born to parents with SZ (FHR-SZ, N=202) or BP (FHR-BP, N=120) or neither of these disorders (PBC, N=200). Motor skills were tested using the Movement Assessment Battery for Children-2 (MABC-2), while linguistic ability (in the form of receptive language and verbal intelligence) was assessed using the Test for Reception of Grammar-2 (TROG-2) and the Reynolds Intellectual Screening Test (RIST) – Guess What. The relationship between motor skills and linguistic ability was investigated using correlation and linear regression. DCD and SLI status were defined based on the children’s MABC-2 and TROG-2 scores. To determine the impact of the children’s familial high-risk status on their motor skills and linguistic ability, we performed linear regressions of the quantitative linguistic or motor scores on respectively DCD or SLI status (i.e., having the disorder affecting the other domain) together with familial high-risk status and sex. We also calculated the prevalence of concomitant DCD and SLI among children in each group (FHR-SZ, FHR-BP, and PBC).

Results: We found significant correlations between most measures of linguistic ability and motor skills, and an association between DCD and SLI (OR=8.22, $P=2.28 \times 10^{-7}$). Familial high-risk of SZ had a significant negative effect on all linguistic and motor outcomes, apart from the “aiming and catching” subdomain of the MABC-2, while adjusting for DCD or SLI status and sex. Familial high-risk of BP had no effect on either linguistic or motor outcomes. Most DCD and SLI cases were found in the FHR-SZ group. The prevalence of concomitant DCD and SLI was 6.9% in the FHR-SZ group, 2.5% in the FHR-BP group, and 1.7% among PBC.

Discussion: Our results confirm an overlap between DCD and SLI. In fact, motor and language development have been reported to mutually influence each other, though other factors may also be at play. The higher prevalence of both DCD and SLI among children in the FHR-SZ group and their overall poorer performance in linguistic and motor tests may indicate the presence of group-specific factors affecting neurodevelopmental processes. Further research should focus on identifying modifiable, environmental factors on which to intervene to ensure optimal neurodevelopment in children of parents with SZ, and potentially increase their resilience to psychosis.

31. ASSOCIATION BETWEEN CHILDHOOD ADVERSITIES AND THE RISK OF PSYCHOSIS: A META-ANALYTIC UPDATE AND EXTENSION OF THE EVIDENCE

Lan Zhou^{*1}, Pengyuan Yang², Jim van Os³, Iris Sommer¹, Marieke Begemann¹

¹University Medical Center of Groningen, ²Ghent University, ³Utrecht University Medical Centre

Background: Research on the association between childhood adversity and psychosis has rapidly accumulated during the past decade, presumably in response to the first large-scale meta-analysis by Varese et al. in 2012, showing that patients with psychosis were 2.72 times more likely to have been exposed to childhood adversity than controls (41 studies). Current meta-analysis provides an update by adding studies published since 2012 and extends the evidence by investigating the effect of ten specific trauma subtypes, examining potential gender differences and evaluating the age of onset of psychosis between exposed and non-exposed individuals.

Methods: An electronic search was performed using PubMed, EMBASE, PsychINFO, Web of Science, Wanfang, and China National Knowledge Internet, with a search cutoff date of February 28, 2023. We included case-control studies comparing either the prevalence of adversity between psychotic patients and controls or the prevalence of psychotic symptoms

between adversity exposed and nonexposed subjects, as well as cross-sectional studies and cohort studies exploring the association between childhood adversity and psychotic symptoms/illness, using dichotomous or continuous measures.

Results: The main analysis included 183 unique study samples (N = 344,678), of which 120 with a case-control design (15,339 cases and 14,975 controls), 51 cross-sectional studies (total participants: 299,256), and 12 cohort studies (total participants: 15,108). Significant associations between childhood adversity and psychosis were observed across all study designs, yielding an overall effect size of OR = 2.79 (95% CI 2.15 - 3.61). When evaluating specific study designs, the largest effect size in magnitude was observed for the case-control studies with OR = 3.49 (95% CI = 3.06 - 3.98, p LESS THAN .001; 95% PI = 0.88 – 13.84), as compared to an OR of 2.37 for both cross-sectional studies (95% CI = 2.09 - 2.69, p LESS THAN .001; 95% PI = 0.92 – 6.11) and cohort studies (95% CI = 1.80 - 3.11, p LESS THAN .001; 95% PI = 0.69 – 8.13). Secondary analyses revealed statistically significant associations between all types of childhood adversity (i.e., physical abuse, physical neglect, emotional abuse, emotional neglect, sexual abuse, bullying victimization, parental death, parental separation, abuse, and neglect) and psychosis, with emotional abuse exhibiting the highest odds ratio (OR = 3.61 [95% CI: 3.10, 4.20]), and parental death displaying the lowest odds ratio (OR = 1.39 [95% CI: 1.06, 1.80]). In addition, we found that the association between childhood adversity and psychosis was similar between males (OR 2.45, 95% CI: 1.73 - 3.48) and females (OR 2.55, 95% CI: 1.96 - 3.33). We did observe that age of onset was a significant factor, as individuals exposed to childhood adversity exhibited an earlier age of onset of psychotic symptoms compared to unexposed individuals, with a mean difference of -0.79 (95% CI = -1.47 to -0.12, p LESS THAN 0.05).

Discussion: To our knowledge, this study represents the largest meta-analysis to date on childhood adversity and psychosis, including 183 studies with a total of 344,678 individuals. Our findings replicate the Odds ratio provided by Varese et al. in 2012 between childhood adversity and an increased risk of psychosis. Secondary analyses indicated that this association appears to be similar for males and females, while signifying that the age of onset of psychosis or psychotic symptoms may be earlier in adversity-exposed individuals versus those unexposed to early adversity.

Oral Session: Cognition and Symptom Profiles

32. COGNITIVE FUNCTION AND COGNITIVE HETEROGENEITY IN ANTI-PSYCHOTIC DRUG-NAÏVE FIRST EPISODE PSYCHOSIS PATIENTS - AN UPDATED META-ANALYSIS

Maria Lee^{*1}, Martin Cernvall², Jacqueline Borg³, Pontus Plavén-Sigra⁴, Cornelia Larsson³, Sophie Erhardt⁵, Carl M. Sellgren⁵, Helena Fatouros Bergman³, Simon Cervenka³

¹Karolinska Institute, Clinical Neuroscience, ²Uppsala University, ³Center for Psychiatry Research, Karolinska Institutet, ⁴Center for Psychiatry Research, Karolinska Institutet and Stockholm County Council; Neurobiology Research Unit, Copenhagen University Hospital, Rigshospitalet, ⁵Karolinska Institutet

Background: Cognitive dysfunction in psychotic disorders contributes significantly to clinical outcome and level of function. These impairments are present already at psychosis onset, however the extent of heterogeneity in cognitive function among patients has not been systematically investigated. Our objective was to quantify the level of cognitive impairment at

psychosis onset, before patients receive potentially confounding antipsychotic treatment, and to investigate within-group variability in cognitive function compared to healthy controls.

Methods: To perform a meta-analysis of mean differences and within-group variability, PubMed database was searched up to September 15th 2022, with a focus on original studies reporting data on cognitive function in antipsychotic drug-naïve first episode psychosis patients (FEP).

Data Extraction and Synthesis:

Data was independently extracted by two researchers. Cognitive tasks were clustered according to six domains of the Measurement and Treatment Research to Improve Cognition in Schizophrenia (MATRICS) and the domain of executive function. Random-effect model meta-analyses of mean differences and coefficient of variation ratios (CVR) were performed, as well as meta-regressions, assessment of study quality and publication bias.

Main Outcomes and Measures:

The main outcome measure was Hedges' g for mean differences in cognition, and CVR for within-group variability.

Results: Fifty studies were included with a total of 2625 individuals with FEP (mean age 25.2 [SD 3.6], 40% female) and 2917 healthy controls (mean age 26.0 [SD 4.6], 45% female). In all cognitive domains, the FEP group displayed a significant impairment compared to controls (Speed of processing $g = -1.16$ [95% CI: -1.35, -0.98]; Verbal learning $g = -1.08$ [95% CI: -1.28, -0.88]; Visual learning $g = -1.05$ [95% CI: -1.27, -0.82]; Working memory $g = -1.04$ [95% CI: -1.35, -0.73]; Attention $g = -1.03$ [95% CI: -1.24, -0.82]; Reasoning/problem solving $g = -0.90$ [95% CI: -1.12, -0.68] and Executive function $g = -0.88$ [95% CI: -1.07, -0.69]). Individuals with FEP also exhibited a larger variability across all domains (CVR ranged from 1.34 to 1.94).

Discussion: This meta-analysis confirms cognitive impairment in FEP before the initiation of antipsychotic treatment, with large effect sizes. The high variability within the FEP group indicates the need to identify those individuals with more severe cognitive problems who risk worse outcome and could benefit the most from cognitive remediation.

33. THE ARCHITECTURE OF PARANOIA IN THE GENERAL POPULATION: A SELF-REPORT AND ECOLOGICAL MOMENTARY ASSESSMENT STUDY

Maja Neidhart^{*1}, Sebastian Mohnke², Bob O. Vogel¹, Henrik Walter¹

¹Charite University Medical Center Berlin, ²Practice for Psychotherapy Praxis

Background: Delusions are fixed beliefs that are not amenable to change in light of conflicting evidence (APA, 2013; DSM-5). They represent a core symptom of psychotic disorders, which are among the most cost-intensive and burdensome illnesses worldwide (Bebbington et al., 2013; Rössler et al., 2005; Schneider et al., 2019). Paranoia is a prevalent type of delusion in adolescents and adults in the general population and follows a continuum, where at least 10-15% experience paranoid symptoms regularly (Bird et al., 2019; DeRosse and Karlsgodt, 2015; Freeman, 2007; Garety et al., 2013; Pechey and Halligan, 2011). Bebbington et al. (2013) conceptualized paranoia within the general population as a hierarchical, dimensional continuum. They suggested four categories, representing increasing levels of paranoia: interpersonal sensitivity, mistrust, ideas of reference and persecution ideas. In alignment with the cognitive model of persecutory delusions (Freeman et al., 2002), clinically relevant paranoia is on the extreme end of a dimensional spectrum that is built on typical and adaptive emotional concerns like worrying. What is currently lacking and could provide insights into

etiology is a comprehensive clinical characterization of the lower end of the paranoia spectrum, psychological domains that are associated with symptom severity, and how paranoia and its structure fluctuate over time.

Methods: This study was a cross-sectional and longitudinal survey. 802 people from the general German population completed self-report questionnaires assessing paranoia and general psychopathology. Furthermore, data was collected through Ecological Momentary Assessment (EMA) (N = 515). Our study aimed to reproduce and extend existing research on paranoia in the general population. First, we examined the hierarchy and structure of paranoia in a large German sample to reproduce findings from Bebbington et al. (2013) using questionnaires and EMA. We hypothesized that our data would cluster into the suggested four paranoia-subgroups. We also explored subgroup differences in psychological factors including psychopathology, emotions and coping styles. Finally, we explored the temporal dynamics of paranoia using a short EMA battery for real-time-self-reports and potential predictors of overall paranoia. To address our research questions, we employed (1) confirmatory factor analysis to examine the structure of the items from the Bebbington Questionnaire in N = 802 participants, (2) latent class analysis to determine group membership, and other statistical tests including ANOVA to investigate group differences, and (3) mixed modelling analyses in N = 515 to examine the temporal dynamics of paranoia and time associations with interpersonal sensitivity and persecutory ideation.

Results: Paranoia was common in the general population. Prevalence of the overall paranoia score in the general German population ranged from 0-15, mean score was 2.79 (SD = 2.95). It followed an exponential distribution, with many people with a low and few people with a high paranoia score. For examination of the dimensionality and hierarchical structure of paranoia, results from CFA showed that 4-factor second order model showed the best fit with high factor loadings (0.22-0.66). LCA results also showed, that subjects clustered into four paranoia severity subgroups: interpersonal sensitivity, mistrust, ideas of reference, and persecutory ideas. Significant associations existed between severity groups and various psychological domains, including increased psychiatric symptoms and maladaptive coping. ANOVA results indicate highly significant differences ($p < .001$) among paranoia severity and psychological domains. Results from mixed modelling showed that paranoia fluctuate over time in all four severity subgroups but the hierarchical subgrouping was stable. Both persecutory ideations and interpersonal sensitivity were significant predictors of paranoia ($p < .001$).

Discussion: Our study investigated the prevalence and structure of paranoia in the German general population. Results suggest that paranoia is a relatively common phenomenon in the general population which occurs along a continuum of increasing severity. We were able to identify paranoia severity subgroups, therefore subjects clustered into four groups: interpersonal sensitivity, mistrust, ideas of reference, and persecutory ideas. Here, we provide evidence that severity subgroups differ on a variety of psychological domains, which was previously unknown. Individuals with higher levels of paranoia were generally more anxious, more depressed and had higher levels of maladaptive coping strategies. Additionally, we employed EMA to assess paranoia over time and its predictors. Paranoia fluctuates, depending on time of day and severity subgroup. Both interpersonal sensitivity and persecutory ideas were significant predictors of overall paranoia, with persecutory ideation having the strongest effect. This provides further evidence for the proposed structure of paranoia in the general population.

34. REVEALING PSYCHOTIC SYMPTOM PATTERNS IN SCHIZOPHRENIA AND BIPOLAR I DISORDER: INSIGHTS FROM SYMPTOM PATTERN INVESTIGATION

Younghoon Kim^{*1}, Jinhyeok Jang¹, Nuree Kang¹, Jae Hoon Jeong¹, Jayoun Kim¹, Yong Min Ahn², Yong Sik Kim³, Se Hyun Kim⁴

¹*Seoul National University Hospital*, ²*Seoul National University*, ³*Nowon Eulji University Hospital*, ⁴*Seoul National University College of Medicine*

Background: The field of psychiatry has encountered ongoing challenges in understanding the intricate nature of psychotic symptoms, particularly when they manifest in individuals diagnosed with either bipolar disorder or schizophrenia. The overlapping characteristics and underlying neurobiology of schizophrenia and bipolar spectrum disorders, particularly bipolar I disorder, have presented difficulties in differentiation. Through an exploration of symptom patterns and their clinical significance, we aim to gain a more profound insight into these intricate disorders. Our goal is to enhance our comprehension and approach to managing these demanding psychiatric conditions by prioritizing symptom patterns over rigid diagnostic classifications.

Methods: We investigate our hypothesis regarding potential differences in the occurrence patterns of symptoms between schizophrenia and bipolar I disorder through the use of manifold and network analyses in this study. The present analysis relies on a dataset including 555 participants, consisting of 282 individuals diagnosed with schizophrenia-related disorders and 273 individuals diagnosed with bipolar I disorder. The U-MAP is employed as an initial approach for manifold analysis in order to visually represent and examine the distribution of eighteen symptoms associated with psychosis and anxiety. In addition, support vector machine analysis is utilized to examine the distinctive patterns identified by U-MAP. In the context of network analysis, the eLasso method is used to investigate the interconnections and dynamics among symptoms within the network framework. In order to evaluate the clinical implications of symptom dimensions, we used the chi-square test to compare the clinical outcomes between groups with and without specific symptom dimensions.

Results: In the context of schizophrenia, negative symptoms, particularly avolition, play a significant role in shaping the range of symptoms observed in affected individuals. The U-MAP manifold space effectively captures the significance of negative symptoms in schizophrenia by demonstrating how the manifold distributes individuals based on the overall number of negative symptoms. Furthermore, this distribution is found to be correlated with the total number of psychotic symptoms. The results obtained from the analysis of networks offer additional evidence to support the concept that avolition displays a significant level of centrality. Avolition is a phenomenon of clinical significance that has been observed to exhibit associations with the administration of clozapine, patterns of deterioration, tendencies towards remission, and the severity of the illness. On the other hand, bipolar I disorder demonstrates identifiable patterns in which positive symptoms play a significant role in network analysis. The utilization of manifold analysis unveils an unforeseen segregation of patients into two distinct clusters. In summary, it can be concluded that schizophrenia and bipolar I disorder, despite having common psychotic symptoms, demonstrate discernible patterns of co-occurrence. Schizophrenia places emphasis on negative symptoms, while bipolar I disorder places emphasis on positive symptoms. The strength of associations between these symptoms varies, with bipolar I disorder exhibiting stronger connections to psychotic symptoms.

Discussion: Negative symptoms have long been recognized as a central aspect of schizophrenia, a notion reinforced by our manifold analysis. A consistent upward trend was observed in the cumulative count of psychotic symptoms in individuals diagnosed with schizophrenia, exhibiting a positive correlation with the number of negative symptoms. This observation implies that the existence of negative symptoms in individuals with schizophrenia may be indicative of a more pronounced symptomatology. Within network analysis, negative symptoms grouped together, with aversion being the most central in a number of measures

(Katz, betweenness, and closeness). On the other hand, bipolar I disorder exhibited a greater prominence of positive symptoms. The strong intra-connectivity between symptoms and their frequent co-occurrence with positive symptoms suggest a "all-or-nothing" pattern in bipolar I disorder symptomatology. The observed clustering pattern is consistent with the DSM-5 specifier that differentiates between bipolar I disorder with and without psychotic features. In summary, our research highlights the significant impact of negative symptoms on the manifestation of symptoms in individuals with schizophrenia, emphasizing their fundamental influence. On the other hand, bipolar I disorder demonstrates a greater prevalence of positive symptoms and strong connections among psychotic symptoms. Although our study has limitations by the limited sample size, conducting future research with larger datasets could potentially yield additional insights. The present study makes a substantial contribution to the field by emphasizing the intricacy of these disorders and the significance of symptom patterns in enhancing comprehension and treatment, thereby challenging the limitations of rigid diagnostic classifications.

35. COMPREHENSIVE TRANSDIAGNOSTIC ANALYSIS OF VERBAL FLUENCY IN SCHIZOPHRENIA AND AUTISM SPECTRUM DISORDER, COMPARING WITH NEUROTYPICAL CONTROLS

Kinga Farkas*¹, Eszter Zarka¹, Orsolya Pesthy²

¹*Semmelweis University*, ²*ELTE, Eötvös Loránd University*

Background: Verbal fluency, a cognitive function that reflects executive functions and the rapid retrieval of pertinent information from memory, has yielded inconsistent findings in previous research on autism spectrum disorder (ASD), however in schizophrenia (SCH) semantic fluency exhibits a more pronounced impairment compared to letter fluency. In this study we aim to comprehensively investigate verbal fluency in ASD, SCH, and neurotypical healthy control individuals (NTP). The primary objective is to investigate disparities in novel response generation, specifically between the ASD, SCH and NTP groups, using phonemic and semantic fluency tasks. Three central inquiries guide our research: (1) whether differences between groups (ASD, SCH, and NTP) can be identified in word productivity, clustering, errors, and perseverations; (2) whether participants with ASD and SCH exhibit different word production with elevated imageability and concreteness values; and (3) if individuals with ASD and schizophrenia demonstrate reduced productivity during the earlier phases of fluency tasks.

Methods: Forty participants with ASD (12 female, 24 male, 4 other, mean age: 30.5), 39 with SCH (10 female, 28 male, 1 other, mean age: 34.7) and 41 NTP (13 female, 28 male, mean age: 31.0) were recruited from the outpatient units of the Department of Psychiatry and Psychotherapy, Semmelweis University. Participants were requested to list as many words as they could on two phonemic and two semantic category conditions. Audio recordings were later transcribed. To assess concreteness and imageability, we employed a seven-point scale and recruited independent external raters to evaluate a total of 1481 words.

Results: Preliminary results indicate that the three study groups did not differ significantly in phonemic fluency ($F(2, 119) = 0.983, p=0.377$), during either time period. However, a significant difference was observed in semantic fluency ($F(2, 119) = 6.531, p=0.002$). Post-hoc tests (Tukey corrected) revealed that this difference stemmed from impaired performance in the SCH group. Participants with schizophrenia (SCH) exhibited reduced semantic word productivity compared to both neurotypical (NTP) individuals and participants with ASD. However, there were no significant differences between participants with ASD and NTP individuals. In terms of concreteness and imageability, schizophrenic patients listed less concrete (tendency, $p=0.064$) and lower imageable ($p=0.037$) words during the phonemic

fluency task. However, contrary to our expectations, participants with autism, did not show significant differences. At the same time, individuals with autism produced significantly more neologisms (non-existent words) and rare words, than the other two groups.

Discussion: Our study investigated the characteristics of verbal fluency in a transdiagnostic approach. While phonemic fluency did not reveal significant differences among the three groups, our analysis of semantic fluency unveiled a distinction. Specifically, individuals with schizophrenia exhibited impaired semantic word productivity. Furthermore, schizophrenic group used more abstract words, and words with lower imageability during phonemic fluency task. Our study highlights the complex nature of verbal fluency impairments in different conditions and the importance of considering more nuanced methods when assessing cognitive functions.

36. OUT OF CONTEXT: A “HYPER-RECENCY” BIAS IN MEMORY CHARACTERIZES BOTH PSYCHOTICISM AND DÉJÀ VU EXPERIENCES

William Koller*¹, Joan Danielle K. Ongchoco², Michael V. Bronstein³, Brian Scholl¹, Tyrone D. Cannon¹

¹*Yale University*, ²*University of British Columbia*, ³*University of Minnesota*

Background: Psychosis is characterized by salient conflicts between reality and one’s experience of it, but the cognitive processes involved are not fully understood. A relatively more common experience – déjà vu – seems to imply similar conflicts, in that the feeling that one has lived through the present situation before is highly salient despite not being able to pinpoint why or knowing that this cannot be true. Here, we hypothesized that both psychosis-like symptoms and déjà vu experiences might be related to a breakdown in memory for when events occurred in time.

Methods: Across two preregistered studies, 500 subjects completed a novel timeline-based recognition memory task. During encoding, subjects viewed a stream of images depicting everyday objects. During recognition, in addition to being tested on what they remembered (i.e., “Old or New?”), subjects used a “timeline” slider to indicate when they remembered recognized items as having occurred during encoding. This enabled a precise measure of temporal displacement reflecting whether temporal judgments were overly recent or overly distal relative to an item’s original position. In Study 1 and 2, we measured paranoia (Revised Green Paranoid Thoughts Scale) and schizotypy (Multidimensional Schizotypy Scale Brief; including positive, negative, and disorganized symptoms); in Study 2, we measured intensity of déjà vu experiences. Mixed-effects linear regressions assessed whether psychoticism (i.e., a composite of paranoia, positive symptoms, and disorganized symptoms) and déjà vu were associated with temporal displacement, over and above negative symptoms.

Results: Results indicated that those higher in psychoticism performed more poorly on the timeline task. Yet, instead of a pattern of general disorganization, psychoticism was associated with a tendency to misjudge recognized items as having occurred more recently than they actually did. This manifested as a main effect of psychoticism on temporal displacement in Study 1, $t(226.68)=6.31$, $p < .001$, $\eta^2=0.15$, 95% CI [0.07, 0.24], which was replicated in Study 2, $t(227.08)=5.57$, $p < .001$, $\eta^2=0.12$, 95% CI [0.05, 0.20]. A parallel effect was seen for recognition “false alarms” in both Study 1, $t(195.33)=6.77$, $p < .001$, $\eta^2=0.19$, 95% CI [0.10, 0.29], and Study 2, $t(237.78)=6.36$, $p < .001$, $\eta^2=0.15$, 95% CI [0.07, 0.23]. Notably, Study 2 revealed that déjà vu was similarly associated with hyper-recency of both correct recognitions $t(231.03)=5.51$, $p < .001$, $\eta^2=0.12$, 95% CI [0.05, 0.20], and false alarms, $t(230.71)=5.82$, $p < .001$,

$\eta^2=0.13$, 95% CI [0.06, 0.21]. Finally, across studies, negative schizotypy showed no such patterns (ps ranging from .09 to .75; with any trends leaning towards hypo-recency).

Discussion: Across two preregistered studies, psychoticism and déjà vu (but not negative schizotypy) were associated with the tendency to remember recognized items as having occurred more recently than they actually did. This “hyper-recency” bias was seen for both correct and false recognitions, was robust to alternate explanations (e.g., low attention), and replicated in an independent sample. Together, these results indicate that aberrant temporal memory may be related to challenges with reality monitoring across a continuum, creating conflicts between reality and one’s experience of it wherein remotely encountered stimuli currently in mind are perceived to have happened just recently.

37. THE EFFECT OF ANTIPSYCHOTIC DRUGS ON SOCIAL COGNITION IN SCHIZOPHRENIA – A RETROSPECTIVE COHORT STUDY

Makarand Pantoji*¹, Rakshathi Basavaraju¹, Anuradha Rao¹, Urvakhsh M Mehta¹

¹*National Institute of Mental Health and Neurosciences, Bengaluru*

Background: Social cognition is an important determinant of real-world functional outcomes in schizophrenia, and hence an important treatment target (Hajdúk et al., 2021). The effect of antipsychotic drugs on social cognition has been studied in the recent past. Most of the studies failed to show any significant difference with antipsychotic treatment (Haime et al., 2021). This could be because social cognition impairments are stable trait like impairments and are unaffected by antipsychotic drugs. This can be proven by comparing social cognition functioning with and without antipsychotic drugs using tests of equivalence, as lack of a statistically significant difference does not imply equivalence.

Hence, we aimed to examine equivalence in social cognition between two groups – treatment group: patients with schizophrenia who are on a stable dose of any antipsychotic drug, control group: individuals with schizophrenia who are not on any antipsychotic drug.

Methods: 60 patients with schizophrenia were recruited in the treatment group, and 81 were recruited in the control group. Participants in both groups were assessed at a single time point. The assessments included – socio-demographic details, illness and treatment related details, positive and negative symptoms (using PANSS), and social cognition (using SOCRATIS and TRENDS). Social cognition was examined under five domains – first and second-order theory of mind (ToM), faux pas recognition, social cue perception, emotion recognition and attribution bias. The two groups were compared with respect to the social cognition domains using two one-sided t-tests (TOST) for equivalence, with equivalence bounds for effect size (Hedge’s g) set as (-0.2 to 0.2). Correlation between social cognition, and positive and negative symptoms was examined using Pearson’s correlation coefficient.

Results: The two groups were comparable with respect to the age and severity of negative symptoms. The treatment group had a lesser proportion of females (24% vs. 56%), fewer positive symptoms (PANSS – positive score: 6.6 vs. 33) and a longer mean duration of illness (9.7 years vs. 2.9 years). Duration of illness showed no significant correlation with any social cognition domain. The two groups showed equivalence with respect to first-order ToM (TOST upper: p LESS THAN 0.001; TOST lower: p LESS THAN 0.001), second-order ToM (TOST upper: $p=0.003$; TOST lower: p LESS THAN 0.001), faux pas recognition (TOST upper: p LESS THAN 0.001; TOST lower: p LESS THAN 0.001), emotion recognition (TOST upper: p LESS THAN 0.001; TOST lower: p LESS THAN 0.001) and social cue perception (TOST upper: p LESS THAN 0.001; TOST lower: p LESS THAN 0.001). The treatment group had more personalizing bias ($p=0.01$) and lesser externalizing bias ($p=0.04$) than the control group.

In both groups, deficits in social cue perception had a negative correlation with negative symptoms (treatment group: $r = -0.469$, $p = 0.001$; control group: $r = -0.345$, $p = 0.027$). In the control group, deficits in second-order ToM showed a negative correlation with positive symptoms ($r = -0.45$, $p < 0.001$).

Discussion: Social cognition deficits are linked to positive and negative symptoms. Antipsychotic drugs though effective in reducing positive and negative symptoms, had no effect on four out of five domains of social cognition.

The treatment group had a lesser externalizing bias. Treatment with antipsychotic drugs may reduce persecutory delusions, and this may be linked to the lower externalizing bias.

None of the social cognition domains showed any significant correlation with the duration of illness, implying these could be stable trait-like impairments.

In both groups, patients with more severe negative symptoms had poorer performance in social cue perception. Poor social cue perception may be contributing to the negative symptoms of passive social withdrawal and poor rapport.

We conclude that most of the social cognition deficits remain stable and are unaffected by antipsychotic treatment. We need to further explore our understanding of the relation between social cognition deficits and positive and negative symptoms.

38. IMPAIRED REWARD REPRESENTATIONS IN SCHIZOPHRENIA AND DEPRESSION: RE-EVALUATING THE UNDERPINNINGS OF ANHEDONIA FROM A TRANSDIAGNOSTIC PERSPECTIVE

Zheng Xia^{*1}, Han-shan Jiang¹, Lan Zhou², Ling-ling Wang³, Zheng-hui Yi⁴, Su-hong Wang⁵, Chao Yan¹

¹East China Normal University, ²University of Groningen, ³Shanghai Normal University, ⁴Shanghai Mental Health Center, ⁵The First People's Hospital of Changzhou

Background: Anticipatory anhedonia, characterized by the inability to experience pleasure in anticipation, is a transdiagnostic symptom observed in both schizophrenia (SCZ) and major depressive disorder (MDD). Despite its prevalence, the underlying mechanisms remain unclear, and it is uncertain whether there are differences in anticipatory anhedonia between SCZ and MDD. This study aims to explore the activation and maintenance capacity of reward representation and its influence on anticipatory pleasure in patients with SCZ and MDD, respectively.

Methods: We recruited 63 patients meeting the DSM-5 criteria for SCZ and 60 patients meeting the criteria for MDD. An additional 77 healthy controls (HC) were enrolled from the community, with age and sex ratios matched. The Reward Representation and Maintenance Task (RRMT) was designed to measure the ability of reward representation activation and maintenance, as well as subsequent anticipatory experience. Initially, participants were presented with symbols indicating different levels of monetary reward (i.e., 1, 5, or 10 RMB). They were then required to maintain representations for varying lengths (i.e., short maintenance vs. long maintenance), and a second symbol was presented. Participants had to judge whether these two symbols representing the reward value were the same or different. The mismatch rate was calculated to reflect the ability of reward representation activation (short length) and maintenance (long length). During the anticipation phase, they were asked to press the space bar to express how much they would like to see the rewarding symbol again, with more key presses indicating a higher level of anticipatory pleasure.

Results: The interaction effect of group and maintenance level was marginally significant between the SCZ and HC groups ($F(1,135) = 2.78, p = .098$) and was significantly present between the MDD and HC groups ($F(1,136) = 3.88, p = .049$), with a larger between-group discrepancy in mismatch rate during long maintenance trials than that during short trials. Further analysis revealed that both SCZ ($F(1,135) = 27.16, p \text{ LESS THAN } .001$) and MDD ($F(1,136) = 5.63, p \text{ LESS THAN } .05$) patients were more likely to mismatch during short maintenance tasks compared to HCs, implying the dysfunction of activation of SCZ and MDD patients. Additionally, a significant group effect of mismatch rate between SCZ and MDD group was observed ($F(1, 119) = 9.07, p \text{ LESS THAN } .01$), with SCZ patients exhibiting higher mismatch rate than MDD patients.

In the anticipatory phase, a significant interaction between group and reward amount was observed between SCZ and HC groups ($F(2,270) = 17.50, p \text{ LESS THAN } .001$). The number of button presses by SCZ patients decreased as rewards increased, with a significant drop for larger rewards (10 RMB, $p \text{ LESS THAN } .001$) and an increase for smaller rewards (1 RMB, $p = .014$) compared to HCs. We did not observe a significant interaction of group and maintenance level, suggesting that impairment patterns persisted across both maintenance conditions. In contrast, MDD patients showed fewer button presses than HCs for all rewards, particularly for larger rewards ($F(1,140) = 12.65, p \text{ LESS THAN } .001$), suggesting a generally reduced anticipatory response for rewards. Moreover, SCZ patients pressed the button significantly more often than MDD patients ($F(1,119) = 11.33, p \text{ LESS THAN } .001$).

Discussion: Our research not only replicated previous observations of reduced anticipatory pleasure in both schizophrenia (SCZ) and major depressive disorder (MDD) patients but also revealed nuances in the nature of these deficits between the two groups. Additionally, both SCZ and MDD patients exhibit impairments in the activation and maintenance of reward representations, with SCZ patients displaying more pronounced difficulties. Our findings suggest that the distinct mechanisms underlying activation and maintenance contribute to the varied patterns of anticipatory pleasure in SCZ and MDD patients. These insights advance our comprehension of the cognitive foundations of anticipatory anhedonia and lay the groundwork for a transdiagnostic approach to comprehend and address anhedonia effectively.

39. DYNAMICS OF HALLUCINATION AND DELUSION EMERGENCE SUPPORT A SECONDARY ACCOUNT OF HALLUCINOGENESIS

Catalina Mourgues-Codern¹, David Benrimoh², Jay Gandhi¹, Emily Farina³, Tihare Zamorano², Deven Perekh², Jean Addington⁴, Carrie Bearden⁵, Kristin Cadenhead⁶, Ming Tsuang⁶, Barbara Cornblatt⁷, Matcheri Keshavan⁸, William Stone⁹, Daniel Mathalon¹⁰, Diana Perkins¹¹, Elaine Walker¹², Tyrone Cannon¹, Scott Woods¹, Jai Shah², Albert Powers^{*3}

¹Yale University, ²McGill University, ³Yale University School of Medicine, ⁴University of Calgary, ⁵University of California, Los Angeles, ⁶University of California, San Diego, ⁷The Zucker Hillside Hospital, ⁸Harvard University, ⁹Harvard Medical School / Beth Israel Deaconess Medical Center, ¹⁰University of California, San Francisco, ¹¹University of North Carolina At Chapel Hill, ¹²Emory University

Background: Hallucinations and delusions are commonly grouped together as the positive symptoms of psychosis, but recent evidence suggests that they may be driven by different and perhaps opposing computational mechanisms. However, most studies examining the computational underpinnings of hallucinations and delusions do so in fully-formed symptoms, which may obscure important information about the causal relationships between these

symptoms' underpinnings. By appealing to the relative timing of hallucination and delusion emergence, we may uncover dynamics informative for understanding their coexistence.

Methods: Participants at Clinical High Risk for Psychosis enrolled in the second (N = 719) and third iterations (N = 699) of the North American Prodrome Longitudinal Study were assessed for timing of CHR-P-level delusion and hallucination onset, defined as SIPS scores greater than 2 and less than 6 on SOPS P1/P2 and P4, respectively. Timing of symptom onset in first-episode psychosis patients from the Prevention and Early Intervention Program for Psychosis (PEPP-Montréal; N = 695) was assessed using the Circumstances of Onset and Relapse Schedule (CORS). Neural correlates of bottom-up and top-down information flow were examined using Dynamic Causal Modeling (DCM) for fMRI and EEG applied to resting-state fMRI data and EEG data gathered during an oddball task.

Results: In all three samples, participants were markedly more likely to report the onset of delusions prior to that of hallucinations (NAPLS 2: odds ratio (OR) = 4.09; NAPLS 3 OR = 4.14; PEPP OR = 4.04) and to present with only delusions than only hallucinations (NAPLS 2: OR = 5.6; NAPLS 3: OR = 11.11; PEPP: OR = 86.42). Across the time followed, transition from having no CHR-P-level symptoms to only delusions was much more likely than transition to having only hallucinations (NAPLS 2: Z = 2.920, P = 0.003; NAPLS 3 Z = 2.683, P = 0.007). The reverse was also true: hallucination resolution was more likely than delusion resolution from a state of having both CHR-P-level delusions and hallucinations (NAPLS 2: Z = 8.557, P LESS THAN 0.001; NAPLS 3: Z = 7.843, P LESS THAN 0.001). Hallucinations were also more volatile over the CHR-P period than delusions, with markedly higher standard deviations (NAPLS 2: T39 = 2.04, P = 0.048; NAPLS 3: T39 = 2.941, P = 0.005) and higher Lempel-Ziv complexity (NAPLS 2: T399 = 2.099, P = 0.036; NAPLS 3: T308 = 2.445, P LESS THAN 0.001). Critically, In the CHR-P samples, hallucination onset was found to be preceded by a period of high delusional intensity, which fell significantly following hallucination onset (T59 = 2.78, P = 0.007). This pattern was observed in both remitters and non-remitters.

A Bayesian model positing a causal relationship between the states underlying delusion severity and hallucination performed well and significantly explained the data observed. Preliminary results from fMRI and EEG analysis demonstrate a switch from bottom-up information flow to top-down dominance in individuals who have delusions at baseline assessment and subsequently develop hallucinations.

Discussion: Development of hallucinations follows that of delusions in most people in the earliest phases of psychosis. High delusion intensity leading up to hallucination onset that then drops after hallucination onset may support a secondary account of hallucinogenesis in which mechanisms driving hallucination onset are an attempt to compensate for the factors driving delusion formation.

Oral Session: Genetics, Genomics and Proteomics

40. EXPLORING THE LINK BETWEEN POLYGENIC RISK SCORES AND CORTICAL STRUCTURE IN YOUTH AT FAMILIAL RISK FOR SCHIZOPHRENIA AND BIPOLAR DISORDER

Irene Martínez Serrano^{*1}, Elena De la Serna², María Ortuño³, Daniel Ilzarbe⁴, Patricia Camprodón-Boadas³, Mireia Rosa², Adriana Fortea⁵, Àlex González-Segura⁶, Natalia Rodríguez⁶, Sergi Mas⁶, Inmaculada Baeza⁷, Josefina Castro-Fornieles⁷, Gisela Sugranyes⁸

Background: The etiology of schizophrenia and bipolar disorder involves a complex interplay of genetic, environmental and neurobiological factors (Jauhar et al. 2022). Given their polygenic nature, the polygenic risk score (PRS) method has been developed to capture the genetic liability of these disorders at the individual level. Additionally, brain magnetic resonance imaging (MRI) has revealed structural brain abnormalities among individuals with these disorders (Jalbrzikowski et al. 2019), an alteration that is also found, with smaller effect sizes, in first-degree relatives (de Zwarte SMC et al. 2019). Our aim is to examine the association between brain imaging measures and the polygenic burden of various psychopathological illnesses and cognitive phenotypes in children and adolescents at familial risk for psychosis.

Methods: One hundred and ninety participants, including 34 offspring of patients with schizophrenia (SzO), 74 offspring of patients with bipolar disorder (BpO), and 66 offspring of healthy controls (HcO), aged 6 to 17 years at intake, were assessed using clinical, genetic and neuroimaging methods. PRS for schizophrenia (PRS_SZ), bipolar disorder (PRS_BD), major depression disorder (PRS_MDD), general intelligence (PRS_IQ), educational attainment (PRS_EA) and cognitive performance (PRS_CP) were computed based on the latest available summary statistics from each one. The scores were constructed using a Bayesian Regression method with the PRS-Continuous Shrinkage (PRS-CS) tool. MRI was performed on a 3Tesla scanner; cortical surface reconstruction was applied to measure cortical thickness, surface area and grey matter volume on lobar brain regions. Linear mixed-effects models were used to assess the association between MRI measures and PRS, considering family as a random effect and correcting for the 5 first components of the genetic principal component analysis (PCA), age, sex and intracranial volume. Analyses were stratified by group, given the previously observed differences in SzO compared to other groups (Sugranyes et al. 2015).

Results: There was an effect of group on PRS_SZ, with SzO showing a significantly higher PRS_SZ than both HcO and BdO ($\beta = 0.69$, $\text{padj} = 0.01$; $\beta = 0.62$, $\text{padj} = 0.01$). We identified group-specific patterns of significant associations between PRS and MRI measures, specifically within the SzO group. PRS_SZ demonstrated a significant negative association with the gray matter volume of the left insula ($\beta = -0.35$, $\text{padj} \text{ LESS THAN } 0.01$), while PRS_BD was significantly positively associated with the gray matter volume of the right temporal lobe ($\beta = 0.30$, $\text{padj} = 0.04$). PRS_MDD showed a significant positive association with the surface area of the left occipital lobe ($\beta = 0.46$, $\text{padj} = 0.05$). Both PRS_IQ and PRS_CP were significantly negatively linked to the surface area and gray matter volume of the left cingulate lobe ($\beta = -0.24$, $\text{padj} \text{ LESS THAN } 0.01$; $\beta = -0.24$, $\text{padj} \text{ LESS THAN } 0.01$; $\beta = -0.30$, $\text{padj} \text{ LESS THAN } 0.01$; $\beta = -0.30$, $\text{padj} \text{ LESS THAN } 0.01$). No differences were observed between BdO and HcO across MRI measures within lobar brain regions.

Discussion: Our findings suggest a potential association between brain structure and the genetic burden of psychiatric disorders and cognitive phenotypes within SzO group. The lack of association between PRS and MRI measures in the BdO and HcO groups aligns with previous literature suggesting no overall effect of PRS on brain structure in the general

population (Van der Auwera et al., 2015) and a different brain signature of BdO versus SzO (Sugranyes et al. 2015). Future steps of this research include exploring how these factors contribute to clinical and cognitive outcomes.

This study has been funded by Instituto de Salud Carlos III co-funded by the EU (PI1800976, PI2100330, PI2100519), and by the European Union grant ID 101057529 and the Alicia Koplowitz Foundation, CIBERSAM and 2021 SGR 01319.

41. CHANGE IN POLYGENIC SCORES FOR PSYCHIATRIC DISORDERS FOR COHORTS BORN BETWEEN 1981-2008

Mette Lise Lousdal¹, Sonia Labianca², Andrew Schork², Esben Agerbo¹, John McGrath³, Bjarni Vilhjálmsson¹, Oleguer Plana-Ripoll^{*1}

¹Aarhus University, ²Institute for Biological Psychiatry, ³University of Queensland

Background: The incidence of several clinically diagnosed psychiatric disorders has increased over the last decades. This may be due to environmental risk factors or other factors (e.g., widening of diagnostic criteria, increased public and professional awareness, and changes in capacity and referrals). To describe patient characteristics over time, we propose to explore how polygenic scores (PGS) for psychiatric disorders have changed according to birth cohort. If diagnostic criteria have widened over time, we would expect PGS distributions in patients to shift toward lower values (due to the inclusion of milder cases) while the PGS distribution in the general population would be more stable. We aimed to explore changes in PGS in the general population and individuals diagnosed with specific psychiatric disorders in cohorts born in Denmark from 1981 to 2008.

Methods: iPSYCH is a population-based case-cohort sample selected from a study base consisting of all singleton births in Denmark between May 1, 1981 and December 31, 2008 (n=1,657,449). Individuals were linked to the Danish Psychiatric Central Research Register to obtain information on diagnoses of schizophrenia spectrum disorder (SSD) (ICD-10 codes: F20-F29), major depressive disorder (MDD) (F32-F33), autism spectrum disorder (ASD) (F84.0, F84.1, F84.5, F84.8, F84.9), or attention deficit hyperactivity disorder (ADHD) (F90.0). In addition to all cases of these disorders, the sample includes a subcohort that was randomly selected disregarding any diagnostic information. PGS were generated using LDpred2 based on external GWAS summary statistics (excluding the iPSYCH sample). After excluding genetic outliers, we examined the distributions of disorder-specific PGS comparing birth cohorts graphically and through linear regression models (for diagnosed individuals, we adjusted for age at diagnosis) and we used Cox regression models to estimate hazard ratios (HRs) for psychiatric disorders based on PGS, birth year, and their interaction.

Results: We included 40,501 controls and the following number of patients: SSD (10,701), MDD (28,216), ASD (15,758), and ADHD (16,686). Distributions according to birth cohorts showed no shift over time, neither in the random subcohort nor in patient cohorts. In the random subcohort, PGS showed no linear trend according to birth date, except for SSD with an average 10-year change of -0.013 (-0.025; -0.002). In individuals with a diagnosis, the average change in PGS over 10 years was: SSD (-0.083 [-0.132; -0.034]), MDD (-0.046 [-0.078; -0.013]), ASD (-0.033 [-0.076; 0.011]), and ADHD (-0.003 [-0.049; 0.043]). We found an elevated risk of diagnosed psychiatric disorders for higher PGS and more recent birth cohorts, but the association between PGS and risk of psychiatric disorders did not change according to birth year, except for SSD with a reduction of 9% (3%; 14%) and 11% (4%; 18%) in the HRs for birth years 1990-1995 and 1996-2001, respectively, as compared to 1984-1989.

Discussion: PGS were stable in the random subcohort. For individuals diagnosed with SSD and MDD, the mean PGS decreased for later birth cohorts. For ASD and ADHD, the mean was stable, but the GWAS summary statistics were based on a small sample (after excluding the iPSYCH sample). The association between PGS and the risk of psychiatric disorders did decrease according to birth year for SSD, as we would expect if milder cases were included, but we observed no differences for the other psychiatric disorders. PGS are imprecise instruments, far from fully capturing heritability. Nonetheless, studying time trends in PGS may be relevant for validating studies using all cases and disregarding potential changes over time.

42. METHYLATION IN HOXA5, HTR2A AND PRR5 GENES PREDICTS RESPONSE TO AMISULPRIDE AND IS PARTIALLY CONTROLLED BY GENETIC FACTORS IN THE OPTIMISE COHORT

Ana Lokmer*¹, Réjane Troudet¹, Delphine Bacq-Daian², Anne Boland-Auge², Caroline Barau³, OPTiMiSE Study group⁴, Jean-François Deleuze², Marion Leboyer⁵, Jamain Stéphane¹

Mondor, DMU IMPACT

Background: Replacing the time-consuming, trial-and-error based, antipsychotic (AP) switching in the process of schizophrenia (SCZ) therapy adjustment by personalized approach using predictive biomarkers would strongly benefit both the patients and health systems. Epigenetic variation represents a potentially interesting source of biomarkers, as it reflects genetic and environmental factors, while being more stable than gene expression. Here we present one of the first EWAS prospective studies designed to search for epigenetic biomarkers in the blood of patients with a first-episode psychosis and aiming to shed light on the link between genetic and epigenetic mechanisms of AP response.

Methods: We analyzed 232 blood methylomes of 116 first-episode psychosis patients from the OPTiMiSE cohort, mostly of European origin. Patients have been sampled before starting the amisulpride therapy and 4 weeks later during the follow-up visit in order to identify stable as well as treatment-induced epigenetic differences between good and bad responders. Good response to treatment was defined as at least 20% total PANSS reduction. Following the identification and functional characterization of the genomic regions differentially methylated between the good and bad responders by univariate analysis, and their correlation with gene expression, we proceeded to predictive modelling of amisulpride response using the baseline methylation values of those regions as candidates. We further examined the extent of cis-genetic control over the selected co-methylated regions, by searching for mQTLs (methylation quantitative trait loci) in a 2Mbp window. Finally, we integrated our results with publicly available data to improve our understanding of the mechanisms involved in AP response.

Results: We identified 67 regions differentially methylated between the good (N=83) and bad (N=33) responders and 197 regions with response-specific temporal dynamics. Whereas the former were primarily associated with the processes involved in synapse assembly, cell signalling (including neurotransmission) and morphogenesis, the latter were dominated by immune system functioning, inflammation, signalling and developmental processes.

Correlation with the expression revealed over-representation of the genes whose expression had been previously linked to SCZ. Baseline methylation values of three regions, within the HOXA5, HTR2A and PRR5 genes, were selected as good predictors of amisulpride response (MCC = 0.81). While we detected only two mQTLs affecting a single CpG in the PRR5 region, the majority of CpGs in the HTR2A region were influenced by dozens of SNPs, including rs6313, previously linked to AP response. Finally, we identified multiple mQTLs in the HOXA5 region, whose effect was, however, mostly constrained to two CpGs. None of the identified mQTLs or linked SNPs (R^2 GREATER THAN = 0.8) has been previously linked to SCZ according to the LDlink database, but we observed enrichment in traits related to blood cell count, weight, lipid metabolism and eyesight. Whereas most of the correlations between the gene expression and methylation of the selected regions were temporally inconsistent, HOXA5 was stably negatively correlated with the SKAP2 expression, involved in Src signalling.

Discussion: Our results indicate that AP response is shaped by interaction of genetic and epigenetic factors, many of which previously linked to SCZ or similar disorders and neurodevelopment. Prospective design, well-described cohort and focus on a single AP enabled us to identify a number of co-methylated regions associated with AP response, including three with a good predictive power and to provide promising directions for future research.

43. GENETIC VARIANTS IN ESTROGEN RECEPTOR 1 GENE AND COMT GENE PREDICT TREATMENT RESPONSE TO RALOXIFENE AUGMENTATION IN MEN AND WOMEN WITH SCHIZOPHRENIA

Bodyl Brand*¹, Anne Jetske de Boer², Janna de Boer¹, Kim Morris³, Kiyomet Bozaoglu⁴, Susan Rossell⁵, Iris Sommer²

¹University Medical Center Groningen, ²UMC Groningen, ³Swinburne University of Technology, ⁴Bruce Lefroy Centre for Genetic Health Research, Murdoch Children's Research Institute, Melbourne; University of Melbourne, ⁵Swinburne University

Background: Sex differences in schizophrenia manifest in distinct symptom profiles and treatment responses. Premenopausal women show a less severe disease course than men, which has been attributed to the protective effects of estrogens. While estrogens are unsuitable for long-term augmentation therapy, the addition of raloxifene, a selective estrogen receptor modulator (SERM), has been considered a safe alternative. Raloxifene has estrogen-like influences on brain tissue, without the increased risk of breast and uterine cancer. While studies have demonstrated beneficial effects of raloxifene on symptoms in women with schizophrenia, research on men is scarce, and existing results are inconsistent. Previous studies have indicated that genetic variations in the estrogen receptor gene (ESR1) and the UDP-glucuronosyltransferase 1A8 (UGT1A8) gene may influence the response to raloxifene. Moreover, studies suggest that activity of the enzyme Catechol-O-methyltransferase (COMT) can be influenced by estrogen receptor activation, affecting dopamine neurotransmission. The current study aimed to examine whether genetic variants in the ESR1, UGT1A8, and COMT gene can predict treatment response to raloxifene augmentation in individuals with schizophrenia.

Methods: This study seeks to explore whether genetic variations in single nucleotide polymorphisms (SNPs) of the ESR1, UGT1A8, and COMT genes can predict treatment response to 12 weeks of raloxifene augmentation in patients with schizophrenia. We utilized a sub-sample from a parallel, randomized, double-blind, placebo-controlled trial that included adult individuals diagnosed with schizophrenia spectrum disorders (SSD) across the

Netherlands and Belgium. Participants were stratified based on age, sex, and global functioning and were randomly assigned in a 1:1 ratio to either receive a 12-week add-on of raloxifene (120 mg/day) or a placebo. Symptom severity was assessed using the Positive and Negative Syndrome Scale at baseline, after 6 weeks, and after 12 weeks (end of treatment). DNA was collected from saliva during the baseline visit using GenoTek Oragene DNA OG 500 kits. Genotyping was performed for 3 SNPs of the ESR1 gene (rs2234693, rs2144025, rs9340799), 1 SNP of the UGT1A8 gene (UGT_rs1042597), and 4 SNPs of the COMT gene (rs165599, rs737865, rs4680, rs4818).

Analyses were performed using linear mixed-effect models for each SNP. These models included a random effect for patient, and fixed effects were time, treatment condition, sex, and SNP genotype. To examine whether the treatment effect was dependent on SNP genotype, we added a two-way interaction of genotype-by-treatment condition to the model and tested whether this led to a significant improvement of the overall model. Due to the limited number of women in our sample, sex-specific analyses were only conducted in men.

Results: The total group included 83 patients (28% women), which were equally distributed across the raloxifene (n=40) and placebo (n=43) group.

We found a significant effect of genotype-by-treatment for 1 out of 3 SNPs of the ESR1 gene and 2 out of 4 SNPs of the COMT gene, indicating that for these SNPs, a treatment response to raloxifene was found for specific genotypes. In TT carriers of the ESR1 SNP rs2234693, raloxifene had beneficial effects on general symptoms. In CG carriers of the COMT SNP rs4818, raloxifene had beneficial effects on positive symptoms, which was also reflected in our male-specific analysis. Furthermore, male-specific analyses revealed a beneficial effect of raloxifene on total symptom severity in CT carriers of COMT SNP rs737865.

Discussion: In summary, our findings suggest that genetic variants in the COMT and ESR1 genes can predict treatment response to raloxifene in patients with schizophrenia. We replicated and extrapolated earlier results regarding the ESR1 gene from postmenopausal women to a mixed group of patients with schizophrenia. Additionally, we have identified novel insights related to genetic variants of the COMT gene. These findings enhance our understanding of the mechanisms through which raloxifene may exert its effects on psychotic symptoms. They underscore the importance of continued research to explore personalized treatment approaches, taking into account genetic variations, to elucidate the predictive value for the effectiveness of raloxifene in men and women with schizophrenia.

44. GENE-ENVIRONMENT INTERACTION STUDY ON THE CORRELATES FOR PSYCHOTIC EXPERIENCES IN THE UK BIOBANK

Bochao Lin^{*1}, Lotta-Katrin Pries¹, Angelo Arias-Magnasco¹, Sinan Guloksuz¹

¹*School for Mental Health and Neuroscience, Maastricht University Medical Centre*

Background: The previous study has successfully identified 148 exposures associated with any psychotic experiences (PE) in UK-Biobank. In addition, the polygenic risk score for schizophrenia (PRS-SCZ) demonstrated a contributory role in the prognostication of psychosis. However, the interaction of identified these exposures with genetic underpinning for PE remains unknown.

Methods: To systematically investigate the Gene-environment interaction of PE through data-driven agnostic analyses. We conducted exposome-wide interaction studies using the logistic regression models and estimated the multiplicative and additive interaction of PRS-SCZ with

exposures on PE, with age and sex as covariates. We also investigated the correlations of PRS-SCZ with exposure with significant interaction.

Results: The study included 148 502 participants (83 830[56.5%] female; mean [SD] age, 55.95 [7.74] years). In the XWAS interaction model, we found a significant interaction between PRS-SCZ with 27 exposomes in categories of Lifestyle and environment (n=6), physical measures (n=5), psychosocial factors (n=4), Mental health (n=5), Local Environment (n=3), health and medical history (n=1), biological samples (n=1), sociodemographics (1) and population characteristics (n=1). Furthermore, minimal (r^2 LESS THAN 0.07) but significant correlations were estimated between PRS-SCZ with 13 variables, with the most significant correlation observed for townsend deprivation index at recruitment (f189, $r^2=0.07$, $P=2,6E-167$).

Discussion: These findings reveal preliminary evidence for gene-environment interaction in psychotic experiences and suggest that genetic vulnerability and exposures might represent intertwined pathways leading to psychosis.

45. EXPLORING PERIPHERAL BIOMARKERS OF WORKING MEMORY DYSFUNCTION IN EARLY PSYCHOSIS: INSIGHTS FROM PROTEOMIC ANALYSES

Javier Labad*¹, Itziar Montalvo², Meritxell Tost², Diego Palao², Antonio Armario³, Sergi Papiol⁴, Ángel Cabezas⁵, Martí Llaurador⁵, Lourdes Martorell⁵, Elisabet Vilella⁵

¹*Consorci Sanitari del Maresme, Mataró*, ²*Parc Taulí Hospital Universitari, I3PT, CIBERSAM. Sabadell*, ³*Animal Physiology Unit, Faculty of Biosciences, Universitat Autònoma de Barcelona, Spain*, ⁴*Institute of Psychiatric Phenomics and Genomics (IPPG), University Hospital, LMU Munich*; *Max Planck Institute of Psychiatry*, ⁵*Hospital Universitari Institut Pere Mata, Institut d'Investigació Sanitària Pere Virgili (IISPV- CERCA), Universitat Rovira i Virgili, Reus*

Background: Working memory deficits, characterized by difficulties in temporary information storage and manipulation, are recognized as core features in psychosis spectrum disorders and are present at early stages of the illness. Understanding the molecular underpinnings of working memory dysfunction in early psychosis is essential for unravelling the complex interplay between neurobiology and cognitive deficits. Protein biomarker detection with proteomics has demonstrated associations between neurology-related proteins and general fluid cognitive ability in later life. We aimed to study peripheral biomarkers related working memory in a sample of people with clinical-high-risk (CHR) for psychosis, first episode psychosis (FEP) and healthy controls.

Methods: We studied 44 CHR and 116 FEP aged between 18 and 45 years old who were attending an Early Intervention Service and 49 healthy controls. Visuospatial working memory was assessed with the Wechsler memory scale—Third Edition Spatial span (WMS-III-SS). A fasting morning blood sample was obtained for obtaining plasma and measuring proteins. The high-multiplex immunoassay panel Olink Target 96 Neurology (based on the proximity extension assay technology with PCR amplification) was used for detecting and quantifying the protein expression of 92 proteins related to neurology processes. Statistical analyses were conducted in R and SPSS v 25.0 (IBM Corp, USA). First, the glmnet package in R was used to conduct a Lasso Regression in all participants (N= 206) for identifying proteins associated with the studied outcome (WMS-III-SS scores), considering as significant associations those with a coefficient GREATER THAN 0.1. Second, we used multiple linear regression analyses

to explore the relationship between the identified proteins and working memory while adjusting for covariates (age, sex, education status, CHR and FEP diagnoses). Interactions between sex and diagnoses and each biomarker were tested. Significance was defined as $p \leq 0.05$. We did not correct p values for multiple comparisons as our analyses were exploratory in nature.

Results: Of all 92 proteins, the Lasso Regression identified 11 proteins that had a significant association with working memory and a coefficient GREATER THAN 0.1. Multiple linear regression analyses adjusted for age, sex, education status yielded 7 significant proteins associated with working memory: 1) P15311 (Ezrin; Beta= -0.197, $p = 0.006$); 2) P41217 (OX-2 membrane glycoprotein [CD200]; Beta= -0.228, $p = 0.001$); 3) P09919 (Granulocyte Colony-Stimulating Factor [G-CSF]; Beta= -0.151; $p = 0.035$); 4) O43157 (Plexin-B1 (PLXNB1); Beta= -0.312, $p = 0.070$, with significant interactions O43157 x FEP [Beta= 1.064, $p = 0.020$] and O43157 x CHR [Beta= 1.475, $p = 0.002$] diagnoses); 5) Q8TDQ1 (CMRF35-like molecule 1 [CLM-1]; Beta= -0.222, $p = 0.020$; with a significant interaction Q8TDQ1 x FEP: Beta= 2.111, $p = 0.001$); 6) Q08629 (Testican-1 [SPOCK1]; Beta= -0.205, $p = 0.004$); 7) Q16719 (Kynureninase [KYNU]; Beta= -0.179, $p = 0.018$).

Discussion: The identification of specific peripheral biomarkers associated with working memory in early psychosis unveils novel insights into the neurobiological basis of cognitive dysfunction at the onset of psychosis. Proteins such as Ezrin, CD200, G-CSF, SPOCK1 and KYNU emerged as significant peripheral markers related to working memory deficits, suggesting potential targets for future interventions. Intriguingly, interactions between PLXNB1 and CLM-1 with diagnostic categories (FEP and CHR) underscore the complex interplay between these proteins and the evolving stages of psychosis, warranting further exploration. These findings represent a crucial step toward the development of targeted therapeutic strategies aimed at ameliorating cognitive impairments in early psychosis.

46. USING AI TO UNCOVER GENETIC AND ENVIRONMENTAL RISK FACTORS FOR ANTIPSYCHOTIC-INDUCED METABOLIC ADVERSE EFFECTS IN THE MILLION VETERAN PROGRAM

Ayman Fanous^{*1}, Philip Harvey², Julie Kreyenbuhl³, Stephen Marder⁴, Silviu-Alin Bacanu⁵, Benjamin McMahon⁶, Sutanay Choudhury⁷, Hamed Abbaszadegan⁸, Khushbu Agarwal⁷

¹University of Arizona College of Medicine - Phoenix, ²University of Miami Miller School of Medicine, ³University of Maryland/Baltimore VAMC, ⁴University of California, Los Angeles/Los Angeles VAMC, ⁵Virginia Commonwealth University, ⁶Los Alamos National Laboratory, ⁷Pacific Northwest National Laboratory, ⁸Phoenix VA Health Care System

Background: Antipsychotic drugs are widely used to treat psychiatric disorders such as schizophrenia and bipolar disorder. However, they are known to have important adverse effects related to

metabolic syndrome (MS), which significantly impacts their effectiveness. Quantifying this effect is complicated because the temporal patterns of both antipsychotic medication usage and MS-related outcomes vary across patients. To minimize deleterious effects on patients, it is of the utmost importance to characterize and predict MS effects using genetic and non-genetic information available in electronic medical record (EMR) datasets.

Methods: In this work, we identify phenotypes and genotypes associated with adverse metabolic effects, which we characterize with, i) body mass index (BMI), ii) low density lipoproteins (LDL), and iii) hemoglobin A1c (HbA1c). Our cohort was selected on the basis of antipsychotic medication usage and completeness of the characterization of our MS outcomes,

from all 25 million patients with records in the VA EMR system, in use between 2000 to 2023. This results in a combined 12,303,200 patient-quarters of observation among 135,200 unique patients who have had at least one hundred measurements of weight and ten antipsychotic prescription fills.

For our initial analysis, we aggregate patient's EMR data into three-month intervals, and perform model selection and linear regression to identify important covariates such as age, sex, comorbid medical conditions, oral hypoglycemic, statin, and metformin usage, and hospitalization. We further develop a longitudinal deep learning model that uses high dimensional EMR data to predict MSvar trajectories and utilize SHAP (Shapely additive explanations) values to identify both temporal and polypharmacy-related patterns, predictive of adverse metabolic effects.

In addition, we utilize highly-predictive phenotypes developed on the full cohort of VA patients to perform GWAS for the rate of change in MS outcomes as a function of SNP genotype in the MVP population (currently 658,582 patients with genomic profiles) and antipsychotic type, while adjusting for 20 ancestry principal components and other biologically relevant covariates. Subsequently, we use summary statistics from GWAS to perform transcriptome/proteome/

Results: To be discussed.

Discussion: To be discussed.

47. PREDICTING NEGATIVE SYMPTOMS OF SCHIZOPHRENIA BY DISORDER SPECIFIC AND SHARED GENETIC LIABILITIES FOR SCHIZOPHRENIA, BIPOLAR DISORDER AND MAJOR DEPRESSIVE DISORDER

Ezgi Ince Guliyev*¹, EUGEI investigators², Bart Rutten³, Jim van Os⁴, Alp Ucok⁵, Sinan Guloksuz⁶

¹*Istanbul University Faculty of Medicine*, ²*EUGEI WP6*, ³*University of Maastricht, Netherlands*, ⁴*School of Mental Health and Neuroscience, Maastricht University, Maastricht, The Netherlands*, ⁵*Istanbul University Faculty of Medicine, Istanbul, Turkey*, ⁶ *University Medical Centre; Department of Psychiatry, Yale School of Medicine*

Background: Negative Symptoms (NS) are core components of schizophrenia, significantly impacting functioning but also a trans-diagnostically observed phenomenon. Currently, there is a widespread recognition of the heterogeneity seen within the NS dimension, usually partitioned as diminished expressions and as motivation-pleasure deficit domains. Understanding the neurobiological underpinnings of these domains is crucial for tailored interventions, as personalized approaches that address the specific array of NS experienced by each individual can significantly improve their quality of life and functional outcomes. This study aimed to investigate whether distinct and shared liabilities for different psychiatric disorders, as well as environmental liability for schizophrenia, predict NS and two NS subdomains of schizophrenia.

Methods: The sample comprised 949 patients from the EUGEI study, with NS severity assessed using the Schedule for Deficit Syndrome (SDS). Polygenic risk scores (PRSs) were calculated using Genome-Wide Association Study (GWAS) results for Major Depressive Disorder (MDD), Bipolar Disorder (BD), and Schizophrenia from the Psychiatric Genomics Consortium (PGC). PRSs were also derived from shared genetic variants among the three disorders, serving as an indicator of shared liability. Additionally, exposome scores, employed in prior studies, were computed within the EUGEI dataset. A series of linear regression

analyses were performed. Initially, the relationship between the total SDS score and PRSs for MDD, BD, schizophrenia, and the shared liability score was compared, adjusting for age, sex, country, ten principal component scores, and exposome scores. Subsequently, experiential deficits (ED) and motivation-pleasure deficit (MAP) subgroups of negative symptoms were analyzed separately, investigating their associations with PRSs for MDD, BD, schizophrenia, and the shared liability score, utilizing identical adjustments.

Results: Among the 949 patients, 359 (37.8%) were female, with a mean age of 32.54 (8.73) years. Total SDS score was predicted by the shared liability components ($B=0.117$; $p=0.009$), BD ($B=-0.092$; $p=0.036$), and exposome score for schizophrenia ($B=0.135$; $p=0.002$), but not with the liabilities that differentiate schizophrenia ($B=0.071$; $p=0.104$) and MDD ($B=-0.020$; $p=0.639$). After dividing negative symptoms into ED and MAP subgroups, we found that while ED severity was predicted by distinct liability components for schizophrenia ($B=0.102$; $p=0.019$) and bipolar disorder ($B=-0.114$; $p=0.009$), MAP severity was predicted by the shared liability component ($B=0.130$; $p=0.003$) and exposome score for schizophrenia ($B=0.159$; $p < 0.001$).

Discussion: The findings suggest a closer association between ED and schizophrenia genotype, while MAP appears to have a transdiagnostic relevance and may be influenced by environmental factors. Understanding the nature of this heterogeneity will be critical for identifying the different pathophysiological processes underlying NS and developing precision therapeutics.

Oral Session: Pharmacological Interventions: Novel Insights on New and Old Compounds

48. ADD ON TREATMENT WITH EVENAMIDE IN SCHIZOPHRENIC PATIENTS NOT RESPONDING ADEQUATELY TO THEIR CURRENT ANTIPSYCHOTIC: RESULTS OF A POTENTIALLY PIVOTAL, PHASE 2/3, INTERNATIONAL, RANDOMIZED, DOUBLE BLIND, PLACEBO-CONTROLLED TRIAL

Ravi Anand^{*1}, Alessio Turolla², Francesca Sansi², Giovanni Chinellato², Rodolfo Giuliani², Richard Hartman³

¹Anand Pharma Consulting, ²Newron Pharmaceuticals SpA, ³NeurWrite LLC

Background: A major cause of concern in schizophrenia is the large proportion (30-60%) of patients failing to adequately benefit from antipsychotic (AP) treatment, and up to one-third showing no response (Solanki et al., 2009; Lieberman et al., 2005). As a result, hospitalization rates, morbidity and suicidality are increased, and lifespan reduced in patients who do not benefit from AP. (Laursen et al., 2013; Pompili et al., 2017) Growing evidence supports an important role of the glutamatergic neurotransmitter system, which is not targeted by 5HT₂/D₂-blocking APs and therefore represents a promising therapeutic strategy. (Moghaddam et al., 2012; Demjaha et al., 2014; Mouchlianitis et al., 2016) Evenamide, a selective inhibitor of voltage-gated sodium channels, devoid of activity at GREATER THAN 130 CNS targets (Anand et al., 2018), has proved to reduce aberrant neuronal firing, normalizing excessive glutamate release without any effect on basal glutamate. In animal models of psychosis, the combination of ineffective doses of APs and evenamide was associated with significant benefit, suggesting synergistic mechanisms that would benefit

patients with inadequate response to APs. Preliminary evidence of efficacy of evenamide added on to an AP (except clozapine) was demonstrated in phase II trials: a placebo-controlled study in non-TRS patients (Anand et al., 2017) as well as in an open-label, long-term trial in TRS patients. (Anand et al., 2023)

Methods: Study 008A is a phase 2/3 international, randomized, double-blind, placebo-controlled, 4-week trial designed to assess the efficacy and safety of evenamide 30 mg bid as add-on in patients not adequately benefiting from their atypical AP. Patients with a diagnosis of schizophrenia (DSM-5) are eligible for the study, provided they are symptomatic despite treatment with an atypical AP for an adequate period at a therapeutic dose. Adherence to the background AP is assessed through determination of blood levels. Psychiatric inclusion criteria require that patients are moderately to severely ill (CGI-S 4-6), with a PANSS total score of 70-85 and predominant positive symptoms (core symptoms total score ≥ 20). Efficacy ratings for PANSS and CGI-S/C are performed by two different trained psychiatrists. Changes from baseline to endpoint (Day 29) for the key efficacy outcome measures (PANSS, CGI-S, LOF, MSQ) will be compared between evenamide and placebo groups using a Mixed Model Repeated Measures (MMRM) analysis. Moreover, the proportion of patients reaching a clinically important level of improvement will be compared between groups using a logistic regression model (chi-square test).

Results: Approximately 430 patients have been screened and ~270 patients have been randomized to evenamide or placebo to date. The low attrition rate (LESS THAN 4%) during the randomized treatment period and high compliance to the study medication and procedures suggest that evenamide is well tolerated. Routine interim safety analyses reviewed by an ISMB did not detect any evidence of toxicity. The mean age of the patients is ~40 years, ~75% are males, with a mean PANSS total score at baseline of 78, and mean duration of illness of ~11 years. The most common background APs are risperidone (~40%), olanzapine (~20%), and clozapine (~15%); mean duration of treatment with current AP is GREATER THAN 1-year. Although many patients (55%) had not responded adequately to multiple medications in the past, they did not meet the TRRIP criteria for TRS. Final, unblinded efficacy and safety results will be presented at the Congress.

Discussion: Study 008A represents the first placebo-controlled, double-blind trial of evenamide 30 mg bid as add-on to an AP in patients with schizophrenia. Positive results could change the treatment paradigm of patients with chronic schizophrenia and expedite the initiation of a potentially pivotal phase 3 study designed for the evaluation of evenamide add-on in the TRS population.

49. REVISITING THE BALANCE BETWEEN RISK AND PROTECTIVE EFFECTS OF CLOZAPINE ON MORTALITY: EVIDENCE FROM 2003 – 2019 CHILEAN COHORT

Horwitz Psychiatric Institute, Santiago; Finis Terrae University,* ³*School of Medicine, Universidad Finis Terrae. Santiago, Chile,* ⁴*Early Intervention in Psychosis Program at J. Horwitz Psychiatric Institute, Santiago, Chile and Finis Tearrae University*

Background: Clozapine has robust clinical efficacy in the management of treatment-resistant schizophrenia (TRS). Despite this, severe side effects – neutropenia, myocarditis, pneumonia, and others – have been extensively described with an underutilization of this medication as a

worldwide consequence. Clozapine has been also superior for prevention of all-cause mortality, especially in suicide. This protective effect is relevant considering well documented mortality gap between general population and people with diagnosis of TRS. The balance between risk and protective effects of clozapine must be better understood with clinical and population studies. Considering this, we analysed Clozapine's Chilean national cohort to explore: the mortality gap between clozapine users and general population; the main causes of death in a clozapine population in comparison with general population; and the impact on mortality of continued /discontinued pattern of clozapine treatment.

Methods: A retrospective analysis of individuals aged 15 years or older registered in the National Clozapine Pharmacovigilance Program between January 1, 2003, and June 30, 2019, was developed. Database contains relevant information, including gender, diagnosis, age of clozapine initiation, exposure time to clozapine, discontinuation date (defined by more than 30 days without blood count), age/causes of death (from death certificates). General population (GP) characteristics were obtained from Chilean National Institute of Statistics and the Chilean Ministry of Health. Causes of death were categorized as natural (ICD 10: A00- Q99), external (ICD 10: S00-Z99) and other causes (ICD 10: R00 – R99). A sub analysis for accident/assault and suicide (ICD 10: X64-X84) was performed. We estimated crude overall mortality incidence rates per 1000 person-years and 95% confidence intervals (CIs) by sociodemographic characteristics, cause of death and over time. Next, we used negative binomial regression to report mortality incidence rate ratios (IRR) for multivariable analysis.

Results: The clozapine cohort included 6063 individuals. Most of them were male (n=3905; 64.4%). Age of clozapine initiation was 34.6 + 12 years. We identified 642 deaths in the clozapine population (CP) during 58697 person-years between 2003 and 2019, corresponding to a crude mortality rate of 10.9 per 1000 person-years, in comparison with 1597378 deaths in GP during 228897703 person-years with a crude mortality rate of 7 per 1000 person-years. Pneumonia was the main cause of death in CP (17%), higher than GP (4%); malignant neoplasms was the main cause of death in GP (24% v/s 9% in CP). Adjusted by biological gender, age and time, global mortality IRR excess was 3.45 (95% CI 3.15-3.78, p LESS THAN 0.0001) in CP in comparison with GP. Between both populations, mortality IRR excess was 3.52 (CI 95%: 3.21-3.87, p LESS THAN 0.0001) for natural causes; 3.74 (CI 95%:3.09-4.53, p LESS THAN 0.0001) for external causes; and 11.58 (CI 95%: 8.71-15.42, p LESS THAN 0.0001) for other causes in CP in comparison with GP. Mortality IRR's between CP with continued use and GP decreased for global mortality (IRR: 1.83; 95% CI: 1.59-2.11; p LESS THAN 0.001), natural causes (IRR: 2.20; 95% CI:1.90-2.55, p LESS THAN 0.001) and other causes (IRR: 6.38; 95% CI 4.01-10.13, p LESS THAN 0.001); the excess of risk disappeared for external causes (IRR:0.96; 95% CI:0.62-1.47, p=0.87). In terms of suicide, there was no difference between CP with continued use and GP (IRR:0.58; 95% CI:0.21-1.54, p=0.27) increasing the risk for population with a discontinued use of clozapine (IRR:11.37; CI 95%: 8.01-16.13, p LESS THAN 0.001).

Discussion: Our findings have evidenced an important mortality gap between clozapine users and one Latin American general population, in a similar way to previous reports from the Global North. Considering pneumonia as the main cause of mortality in CP, a call to action is urgent for prevention and adequate management of respiratory infections. Differences in IRR observed remarks the importance of continued use of clozapine to reach the maximal benefits in mortality protection for this group.

50. EFFICACY AND EFFECTIVENESS OF ANTIPSYCHOTICS IN SCHIZOPHRENIA: COMBINING EVIDENCE FROM RANDOMISED CONTROLLED TRIALS AND REAL-WORLD DATA

Jurjen Luykx^{*1}, Orestis Efthimiou², Heidi Taipale³, Joaquim Radua⁴, Johannes Schneider-Thoma⁵, Justo Pinzon⁶, Jari Tiihonen⁷

¹University Medical Center Utrecht Rudolf Magnus Institute of Neuroscience, ²Institute of Social and Preventive Medicine, University of Bern, Switzerland, ³Niuvanniemi Hospital, University of Eastern Finland, ⁴Institute of Psychiatry, King's College, London, United Kingdom, ⁵School of Medicine, Technical University of Munich, ⁶Barcelona Clinic Schizophrenia Unit (BCSU), Neurosciences Institute, Hospital Clinic of Barcelona, ⁷Karolinska Institutet

Background: There is debate about the generalisability of results from randomised clinical trials (RCTs) to 'real-world' (RW) settings. Studying outcomes of treatments for schizophrenia can shed light on this issue and inform treatment guidelines. We therefore compared the efficacy (RCT) and effectiveness (RW) of antipsychotics for relapse prevention in schizophrenia and estimated overall treatment effects utilizing all available RCT and RW evidence in what we believe is the largest study examining effectiveness or efficacy of antipsychotics.

Methods: We conducted network meta-analyses (NMAs) using individual participant data from Swedish and Finnish national registries and aggregate data from RCTs. The target population was people with schizophrenia and schizoaffective disorder with stabilized symptoms. We analysed each registry separately to obtain hazard ratios (HRs) and 95% Confidence Interval (CI) for relapse within 6 months post-antipsychotic initiation as our main outcome. Interventions were antipsychotics, no antipsychotic use, and placebo. We compared HRs vs a reference drug (oral haloperidol) between registries, and between registry individuals who would be eligible and ineligible for RCTs, using the ratio of HRs (RHR). We synthesized evidence using NMA and compared results from our RW-NMA with our RCT-NMA, including oral vs long-acting injectable (LAI) formulations. Finally, we conducted a joint RW/RCT-NMA.

Results: We included 90,469 individuals from the Swedish and Finnish registries (mean age 45.9 (SD 14.6) years; of whom N=43,025 (48%) were women) and 10,091 individuals from 30 RCTs (mean age 39.6 years (SD 11.7); N=3,724 (36.9%) women). Ethnicity data were unavailable in the registries. We found good agreement in effectiveness of antipsychotics between Swedish and Finnish registries (RHR 0.97, 95%CI [0.88; 1.08]). Drug effectiveness vs no antipsychotic was larger in RCT-eligible than RCT-ineligible individuals (RHR 1.40 [1.24; 1.59]). Efficacy vs placebo in RCTs was larger than effectiveness vs no antipsychotic in RW (RHR 2.58 [2.02; 3.30]). We found no evidence of differences between effectiveness and efficacy for between-drug comparisons (RHR vs haloperidol oral 1.17 [0.83; 1.65], where RHR GREATER THAN 1 means superior effectiveness in RW to RCTs), except for LAI vs oral comparisons (RHR 0.73 [0.53; 0.99], indicating superior effectiveness in RW relative to RCTs). The RW-NMA showed clozapine was most effective, followed by olanzapine LAI. The RCT-NMA exhibited heterogeneity and inconsistency. The RW/RCT-NMA identified olanzapine as the most efficacious antipsychotic amongst those present in both RCTs and RW.

Discussion: In analyzing over 100,000 study participants, LAI antipsychotics performed slightly better in RW than according to RCTs. Otherwise, RCT evidence was in line with RW evidence for most between-drug comparisons, but RCTs may overestimate effectiveness of antipsychotics observed in routine care settings. Our results further the understanding of the generalisability of RCT findings to clinical practice and may inform preferential prescribing guidelines.

51. DEVELOPMENT OF AN INDIVIDUALIZED RISK CALCULATOR OF TREATMENT RESISTANCE IN PATIENTS WITH FIRST-EPISODE PSYCHOSIS (TRIPCAL) USING AUTOMATED MACHINE LEARNING: A 12-YEAR FOLLOW-UP STUDY

Ting-Yat Wong¹, Hao Luo¹, Jennifer Tang², Tyler Moore³, Ruben Gur³, Yi Nam Suen⁴, Christy Hui⁵, Ho Ming Edwin Lee⁶, Wing Chung Chang¹, Wai Ching Yan⁷, Eileena Chui⁸, Lap Tak Poon⁹, Alison Lo¹⁰, Koi Man Cheung¹¹, Chui Kwan Kan¹², Eric Yu Hai Chen¹, Sherry Kit Wa Chan^{*1}

¹The University of Hong Kong, ²The Chinese University of Hong Kong, ³University of Pennsylvania, ⁴University of Hong Kong, ⁵The University of Hong Kong, ⁶THE CHINESE UNIVERSITY OF HONG KONG, ⁷Kowloon Hospital, ⁸Queen Mary Hospital, ⁹United Christian Hospital, ¹⁰Kwai Chung Hospital, ¹¹Castle Peak Hospital, ¹²Pamela Youde Nethersole Eastern Hospital

Background: About 15-40% of patients with schizophrenia are treatment resistance (TR) and require clozapine. Identifying individuals who have higher risk of development of TR early in the course of illness is important to provide personalized intervention. Though multiple factors have been explored in prospective studies as possible predictors of TRS, only 12 studies have been identified in a recent systematic review and found early age of onset as the most consistent predictor reported. About half of the included studies had five years or less follow-up period. Use of integrated prediction models in TRS prediction has been advocated. However, there are only four studies attempting to develop a prognostic prediction model to predict TR development using machine learning (ML) methods with three being in patients with first-episode psychosis (FEP). Most studies used LASSO logistic regression or forced-entry models with area under curve (AUC) ranging from 0.59 to 0.67. These studies are initial attempts to establish a predictive model using ML approaches, and results suggest that more advanced ML models may be needed to improve prediction performance.

Methods: A total of 1400 patients with FEP enrolled in the early intervention for psychosis service or receiving the standard psychiatric service between July 1, 1998, and June 30, 2003, for the first time were included. Clozapine prescriptions until June 2015, as a proxy of treatment resistance (TR), were obtained. Premorbid information, baseline characteristics and monthly clinical information were retrieved systematically from the electronic clinical management system (CMS). Training and testing samples were established with random subsampling. An automated machine learning (autoML) approach was used to optimize the ML algorithm and hyperparameters selection to establish four probabilistic classification models (baseline, 12-month, 24-month and 36-month information) of TR development.

Results: This study found 191 FEP patients (13.7%) who had ever been prescribed clozapine over the follow-up periods. An automated machine learning (autoML) approach was implemented to automate the selection of ML algorithms and hyperparameters using the Tree-based Pipeline Optimization Tool (TPOT) package in Python. The ML pipelines identified with autoML had an area under the receiver operating characteristic curve ranging from 0.676 (baseline information) to 0.774 (36-month information) in predicting future TR. Features of baseline information, including schizophrenia diagnosis and age of onset, and longitudinal clinical information including symptoms variability, relapse and use of antipsychotics and anticholinergic medications were important predictors and were included in the risk calculator. Finally, the features were reduced to a reasonable number by refitting the data using the above procedures with top 10, 15 or 20 features and comparing their performance to determine an optimal number of features. A risk calculator was developed with the optimal number of features to calculate predicted probabilities of future clozapine use of FEP patients.

Discussion: Our study presented the development of a risk calculator of future clozapine use, a proxy of TR, in FEP patients (TRipCal) over 12-17 years, using both baseline and longitudinal clinical information in the first 36 months of treatment. This work demonstrated the importance of longitudinal clinical information in predicting development of future TR with acceptable accuracy using the AutoML approach and thus the possibility of establishing data-driven tools assisting clinicians for earlier detection of individuals with higher risk of future TR development. The individual calculator developed using the top 10 features identified in the current study could be used to personalize the interventions to prevent, postpone TR development and reduce the delay of clozapine use. Future validation studies in different populations and settings are required.

52. CEREBRAL BLOOD FLOW IN TREATMENT RESISTANT SCHIZOPHRENIA AND DURING CLOZAPINE TREATMENT

Junyu Sun^{*1}, Fernando Zelaya¹, Kyra-Verena Sendt¹, Grant McQueen¹, Amy Gillespie², Oliver Howes¹, Gareth J Barker¹, James MacCabe¹, Alice Egerton¹

¹*Institute of Psychiatry, Psychology and Neuroscience, King's College London*, ²*University of Oxford*

Background: Treatment resistant schizophrenia (TRS) observed in approximately one-third of individuals diagnosed with schizophrenia 1, of which clozapine is the gold-standard treatment. Previous radiotracer studies indicate decreases in cerebral blood flow (CBF) in TRS that may be altered during clozapine treatment in relation to clinical response 2-5. However, this has not yet been examined with arterial spin labelling (ASL), a more recent and MRI-based method. To address this gap, we applied ASL to investigate regional CBF in TRS and during clozapine treatment.

Methods: CBF maps were acquired from healthy volunteers (HV, N=16) and participants with TRS before commencing clozapine ('baseline', N=36), and again in the TRS group 12 weeks after clozapine initiation ('week 12', N=24). Data were analysed using a region of interest (ROI) based approach (ROIs: anterior cingulate cortex (ACC), hippocampus, thalamus, and striatum) and whole-brain voxel-wise analysis. Symptom severities were assessed using the Positive and Negative Syndrome Scale (PANSS). For cross-sectional comparison of TRS at baseline vs. HV, CBF data were analysed with/without age and global CBF as covariates by univariate linear models (SPSS) and voxel-wise two-sample t-tests (SPM). For within-subjects comparison of TRS at baseline vs. after 12 weeks of clozapine, CBF data were ascertained with/without change in global CBF as a covariate using repeated measures ANOVA (SPSS), and voxel-wise paired t-tests (SPM). Relationships between change in CBF and symptom improvement over 12 weeks, and between baseline CBF and symptom improvement over 12 weeks, were assessed by partial correlation (SPSS), voxel-wise multiple regression (SPM) with/without covarying for change in global CBF. Statistical thresholds were set at a two-tailed significance level of $p \text{ LESS THAN } 0.05$, and significant clusters were assessed at the $p \text{ LESS THAN } 0.05$ family-wise error (FWE) threshold from a cluster forming threshold of $p \text{ LESS THAN } 0.001$.

Results: Global CBF was significantly lower in TRS than in healthy volunteers ($t(50)=-2.731$, $p=0.009$). After accounting for age and global CBF, the TRS group exhibited significantly lower CBF in frontal, temporal, and parietal regions than the HV group (all $p \text{ LESS THAN } 0.05$, FWE corrected). Over 12 weeks of clozapine treatment, CBF decreased in the ACC ($F(22)=11.177$, $p=0.003$; $p=0.001$ FWE) and increased in the left postcentral area ($p=0.017$ FWE). Reductions in CBF in the ACC and thalamus during clozapine treatment were

associated with less improvement in negative (ACC, $r=-0.493$, $df=21$, $p=0.017$), positive (thalamus, $r=-0.417$, $df=21$, $p=0.048$), and total (thalamus, $r=-0.494$, $df=21$, $p=0.017$) symptoms. Higher striatal CBF at baseline was associated with greater improvements in total ($r=0.394$, $df=24$, $p=0.046$) and general ($r=0.449$, $df=24$, $p=0.021$) symptoms, and higher hippocampus CBF at baseline was associated with greater improvements in total ($r=0.510$, $df=24$, $p=0.008$) and positive ($r=0.465$, $df=24$, $p=0.017$) symptoms.

Discussion: TRS is associated with widespread reductions in CBF, and CBF may be further reduced in the ACC during clozapine treatment. Higher regional CBF may facilitate symptom improvement during clozapine treatment. ASL may have potential as a biomarker for TRS and prediction of clozapine response.

53. GLP-1 ANALOGUES AND THEIR LONG-TERM EFFECTS ON PSYCHIATRIC AND METABOLIC PARAMETERS IN INDIVIDUALS WITH SEVERE MENTAL DISORDERS

Ayala Gerberg^{*1}, Noa Menkes-Caspi², Sharon Taub³, Ofer Rahamin³, Abraham Weizman⁴, Mark Weiser⁵, Amir Krivoy⁴

¹Geha Mental Health Institution, ²Geha Mental Health Center, Petach Tikva, ³Geha Mental Health Center, ⁴Geha Mental Health Center, Sackler Faculty of Medicine, Tel-Aviv University, ⁵Sheba Medical Centre, Tel Hashomer

Background: Patients with schizophrenia have a doubled prevalence of metabolic syndrome and are twice as likely to develop type 2 diabetes mellitus, resulting in a 15-20 year reduction in lifespan compared to the general population. GLP-1 analogues, a therapeutic class of antidiabetic drugs, have proven safe for individuals with severe mental illness. However, their long-term effects, both metabolically and mentally, remain understudied. Our study aimed to assess the long-term efficacy (over one year) of GLP-1 analogues compared to shorter usage durations among individuals with severe mental illness.

Methods: We conducted a community-based, historical retrospective cohort study among Clalit Health Services (CHS) members from 2010 to 2020. Data were obtained from all CHS members diagnosed with a schizophrenia-spectrum or bipolar affective disorder who had purchased at least one prescription of a GLP-1 analogue during this period. Further inclusion criteria involved a diagnosis of type 2 diabetes and/or obesity. Patients were categorized into three groups based on GLP-1 analogue usage duration. Cox proportional hazard models were employed to analyze the effects of demographic and clinical variable adjustments on mortality, metabolic and psychiatric outcomes.

Results: We identified 3,609 relevant patients. Significant metabolic outcomes included changes in BMI and HDL levels. Extended GLP-1 analogue use demonstrated a decrease in mortality (over 12 months, adjusted HR 0.52, 95% CI [0.36-0.76]) and a reduction in psychiatric hospital admission rates (use of over 7 months, adjusted HR 0.61, 95% CI [0.42-0.91] and HR 0.59, 95% CI [0.45-0.78] in groups 7-12 months and over 12 months, respectively) compared to short-term users.

Discussion: Long-term treatment with GLP-1 analogues yielded beneficial metabolic and psychiatric outcomes. The observed reduction in psychiatric hospital admissions and mortality suggests potential revisions to disease management strategies and policies regarding medication subsidization.

54. POPULATION PHARMACOKINETIC MODELING FOLLOWING ADMINISTRATION OF OLANZAPINE FOR EXTENDED-RELEASE INJECTABLE

SUSPENSION (TV-44749) FOR SUBCUTANEOUS USE TO SUPPORT DOSE SELECTION FOR PHASE 3 CLINICAL TRIAL (SOLARIS)

Itay Perlstein*¹, Roberto Gomeni², Raphael Bilgraer³, Irina Cherniakov³, Dikla Gutman³, Anna Elgart³, Laura Rabinovich-Guilatt³, Avia Merenlender Wagner³, Rajendra Singh³

¹*Magic Wand Research, LLC*, ²*Pharmacometrica*, ³*Teva Pharmaceutical Industries, Ltd.*

Background: TV-44749 (Teva) is a long-acting subcutaneous (sc) injectable (LASCA) formulation of olanzapine based upon a novel copolymer drug delivery technology that forms a depot under the skin that ensures a controlled release of olanzapine. TV-44749's formulation and sc route of administration were also designed to eliminate the causes of post-injection delirium sedation (PDSS). A phase 1 study evaluated TV-44749 in healthy volunteers (HV) and patients with schizophrenia or schizoaffective disorder. A population pharmacokinetic (Pop-PK) model was developed and dopamine D2 receptor occupancy (D2RO) levels estimated following oral olanzapine and TV-44749 administration. Simulations were performed to guide TV-44749 dosing for the phase 3 study (SOLARIS).

Methods: PK samples were collected from participants (n=91) who received oral olanzapine (2.5 and 5mg/day for HVs; 10mg, 15mg, and 20mg/day for patients) for 7 days followed by a washout, and then received either TV-44749 single sc injection of 70mg and 105mg for HVs; single 318mg, 425mg or 531mg, or three monthly sc injections of 283mg or 566mg for patients. Different structural PK models were evaluated and Pop- PK analyses of oral olanzapine and TV-44749 were used to identify comparability in exposure over a month at steady state between oral doses 10, 15 and 20 mg/d and TV-44749 doses. The comparison focused on 3 PK parameters C_{max}, C_{ave} and C_{trough} GREATER THAN 10ng/mL to assure plasma levels are maintained over the dosing interval. Additionally using a published plasma-D2RO model, the PopPK model was utilized to assure dosing regimen would provide D2RO between the 65-80% for most of the dosing interval, which is the recommended therapeutic window for optimal antipsychotic effect with minimal side effects.

Results: The olanzapine concentration-time profile observed following oral administration was best described using a two-compartment model. The olanzapine concentration-time profiles observed after TV-44749 sc injections showed complex kinetics characterized by a double Weibull input function representing two phases of drug release: a first phase associated with an initial immediate release of a fraction of the dose, and a second phase associated with a delayed and sustained release of a second fraction of the dose. Final Pop-PK model estimates suggests the immediate first phase, with initial release of 23.6% of the associated dose (FF) peaking (TD=63.2% release) at 5 days post-dose. The second phase is associated with a delayed and more sustained release peaking at 14 days post-dose (TD1=63.2% release) of the remaining fraction of administered TV-44749 dose (76.4%). Median exposure throughout the dosing interval (C_{avg}) was identified as the main pharmacokinetic parameters with potential impact on efficacy. The trough plasma drug concentration (C_{trough}) was used as the main anchor for dose selection to ensure drug levels maintained throughout the dosing interval were similar or above C_{trough} of oral treatment to and optimize the clinical outcome of patient stability following TV 44749 administration. C_{max} was identified as a pharmacokinetic parameter with potential impact on the safety profile of TV-44749. Simulated steady state TV-44749 of monthly doses of 318mg, 425mg, and 531mg most adequately met aforementioned criteria. These doses also demonstrated comparable exposure to daily oral olanzapine doses (10, 15 and 20mg) over one month interval, and resulted in simulated D2 receptor occupancy levels within the recommended D2RO range of 65–80%.

Discussion: Based on PopPk exposure estimates and simulated D2RO, once monthly doses of 318mg, 425mg, and 531mg q1m were selected to be tested in Phase 3 efficacy and safety study of TV-44749.

Oral Session: Psychosocial Interventions and Special Populations

55. PSYCHOSIS RISKS FOR LESBIANS, GAYS AND BISEXUALS: SYSTEMATIC REVIEW AND META-ANALYSIS

Jean-Paul Selten^{*1}, Hussam Alrashed², Hans Oh³, Gabriella MA Blokland⁴

¹University of Maastricht, ²King's College London, Faculty of Life Sciences and Medicine,

³University of Southern California, ⁴Maastricht University, Amsterdam

Background: The social defeat hypothesis of schizophrenia spectrum disorders posits that low status, repeated humiliation and poor homeostatic control of dopamine neurons in midbrain and dorsal striatum increase the risk for the disorders (Selten and Ormel, 2023). The purpose of this systematic review and meta-analysis is to test the hypothesis of an increased risk of psychotic disorder and psychotic experiences for people who are lesbian, gay or bisexual (LGB people)

Methods: PubMed and Psycinfo were searched from database inception until 31 July 2023. We selected studies that compared the risk of psychotic disorder or psychotic experiences for LGB people to that for heterosexuals. The study followed MOOSE (Meta-Analysis of Observational Studies in Epidemiology) reporting guidelines. Two independent reviewers assessed the eligibility and quality of studies, extracted effect sizes and noted the results of mediation analyses. Separate analyses were conducted for psychotic disorder and for psychotic experiences. The main outcome measures were pooled Odds Ratios (ORs), based on unadjusted ORs and on ORs adjusted for a large variety of covariates, respectively.

Results: The search identified six studies of psychotic disorder and four of psychotic experiences. The quality of studies was generally high. One study reported about the sexual orientation of 582 patients with psychotic disorder; six studies were based on large, general population surveys. There was no significant heterogeneity across studies on psychotic disorder. Using a fixed effects model, both the unadjusted, pooled OR (2.04; 95% CI 1.55-2.70) and the covariate-adjusted, pooled OR of psychotic disorder (2.46; 95% CI 1.55-2.70) were increased for LGB individuals. Given the presence of significant heterogeneity across studies on psychotic experiences, we used a random effects model and found that the pooled ORs were increased (unadjusted, pooled OR= 2.07; 95% CI: 1.44-2.96; covariate-adjusted, pooled OR = 1.85; 95% CI: 1.50–2.28). Publication bias played a very small role; the pooled ORs remained significantly increased after correction for this type of bias. Two studies of psychotic experiences examined the mediating role of drug abuse and reported that the contribution of this variable was small compared to that of psychosocial stressors, like discrimination and childhood trauma.

Discussion: These findings suggest an increased psychosis risk for LGB people and support the social defeat hypothesis.

56. FINDINGS FROM A MIXED METHOD FEASIBILITY STUDY ON AN AUTOMATED VR APPLICATION FOR ANXIOUS AVOIDANCE IN PEOPLE SUFFERING FROM SCHIZOPHRENIA

Andreas Seierstad*¹, June lystad², Olivia Schjøtt-Pedersen², Helen Bull², Jan Ivar Røssberg³

¹*Oslo University Hospital, Section for Early Psychosis Intervention*, ²*Oslo University Hospital,*

³*NORMENT KG Jebsen Centre for Psychosis Research, Oslo University Hospital and Institute of Clinical Medicine, University of Oslo; Division of Mental Health and Addiction, Oslo University Hospital*

Background: People with schizophrenia experience high levels of anxious avoidance with 2/3 of the patient group meet the criteria for comorbid agoraphobia. Anxious avoidance is in turn associated with higher levels of hallucinations, hallucinations, depression, and lower levels of quality of life and meaningful activity. Alleviating anxiety symptoms may therefore be key to improving subjective and objective outcomes in people suffering from schizophrenia.

The gameChange VR program (GC), developed at the University of Oxford is an automated virtual reality application intended for individuals with psychosis experiencing anxiety in everyday social situations. The application allows individuals to enter virtual reality simulations of situations they would normally avoid in order to test out their fears and experiment with alternative behavioral coping strategies. GC has been validated in a large randomized trial in the UK.

The aim of this feasibility trial was to investigate if GC could lead to changes in anxiety, avoidance, depression and hallucinations as well as improve quality of life and functioning in people with schizophrenia spectrum disorder in Norway.

Methods: 28 participants received GC, and quantitative assessments were carried out at baseline, at 6 and 26 weeks after inclusion. Qualitative interviews were conducted at 6 weeks after inclusion. Recruitment and retention rates were calculated.

Results: GC was perceived as a novel, fun and innovative approach to therapy. Participants described the virtual environment as artificial, yet realistic. One stated “I imagine it’s like partaking in a reality show. Even though you know it’s a TV-production, at some point: you forget that the cameras are there”. VR simulations triggered anxiety by effectively mimicking every day, fear-inducing situations like taking the bus or visiting a café. Participants who experienced strong anxious avoidance in real life also tended to report improved functioning after the intervention. Several pathways of change were described: GC provided exposure training, but also a safe environment to experiment with behavior and learn new skills. Some participants noted that GC had bolstered their social agency by enabling them to for example greet a neighbor or make eye contact with strangers when using public transport.

A total of 76 % of participants were satisfied or very satisfied with the intervention, 64% found it helpful in managing everyday situations. We found reductions in anxious avoidance, depression and small reductions in hallucinations, as well as improvements in quality of life and functioning, with strong recruitment and retention rates. Retention was also good between post-intervention and follow-up assessments.

Employing a mixed method design with both qualitative and quantitative and qualitative data sources allowed us to corroborate our findings.

Discussion: VR-therapy could be a powerful tool for improving clinical and functional outcomes in psychosis as well as making effective therapy more accessible to patients. However, developing new applications are costly, time consuming and require close collaboration between users, clinicians and developers. This small feasibility trial utilized a

VR-intervention developed and validated in the UK within a Norwegian treatment setting. High participant satisfaction, reductions in key symptomological outcomes, improvements in quality of life and function, as well as good recruitment/retention rates, suggest that expensive VR applications can be efficaciously shared across borders. Findings from this feasibility study supply valuable input for a future multicenter RCT.

57. MINDFULNESS ENHANCED REAL-TIME FMRI NEUROFEEDBACK REDUCES AUDITORY HALLUCINATIONS AND MODULATES ASSOCIATED BRAIN ACTIVITY AND CONNECTIVITY

Clemens Bauer^{*1}, Jiahe Zhang¹, Francesca Morfini¹, Ann K. Shinn², Emma Andrikidis³, Emma Tusuzian¹, Lena Stone², Chelsea C. Ajunwa¹, Keara D. Greene¹, Nicholas W. Ford¹, Jude Hammound¹, Yoon Ji Lee¹, Angelina Awad⁴, Emily Quin⁴, Mia Kriksciun⁴, Zoi Urban¹, Paul Nestor⁵, Susan Whitfield-Gabrieli¹, Margaret A. Niznikiewicz⁶

¹Northeastern University, ²McLean Hospital/Harvard Medical School, ³McLean Hospital, ⁴Veterans Affairs Boston Healthcare System, ⁵Laboratory of Neuroscience, Boston VA Healthcare System, Harvard Medical School, ⁶Harvard Medical School, Veterans Affairs Boston Healthcare System

Background: Auditory hallucinations (AH) are a major and debilitating symptom of schizophrenia (SZ). AH does not respond to medications in one-third of SZ patients; hence, an urgent need for alternative therapies exists. Mindfulness-based interventions have shown promise in this regard, yet learning mindfulness can be challenging for patients with schizophrenia since they often have attentional, emotion regulation, and self-awareness impairments, which are core mechanisms of mindfulness. This study aimed to test if mindfulness-based real-time functional magnetic resonance imaging (fMRI) neurofeedback (mbNF) can boost downregulation of superior temporal gyrus (STG) activation and reduce AH in medication-resistant schizophrenia.

Methods: In this sham-controlled, single-blinded, randomized study, 23 adults (19 males) with SZ and medication-resistant AH received one session of mbNF either from STG (n=10; active mbNF) or motor cortex (n=13; sham mbNF). During mbNF, participants were instructed to (1) attend to pre-recorded sentences read by the participant (self) or (2) ignore pre-recorded sentences read by unfamiliar voices (other). Participants were trained in mindfulness to ignore other voices. Activation was displayed in the form of a thermometer. Participants were asked to reduce brain activation when listening to the other voice by using mindfulness, and increase brain activation by attending to self voice. STG and motor cortex targets were identified using a localizer scan. AH were assessed using the Psychotic Symptom Rating Scale (PSYRATS). Before and after

Results: ANOVA test on AH change contrasting active and sham groups across pre- and post-TT showed only a significant main effect of time ($F(18)=2.62$, $p=.01$), but did not reveal a significant main effect of group or group-by-time interaction. Nonetheless, compared to sham mbNF, active mbNF reduced rMTG activation (p LESS THAN .005, Cohen's $f^2=.54$), and PPI connectivity was reduced between rMTG cluster and both right dorsolateral prefrontal cortex (rDLPFC) and anterior cingulate cortex (ACC) (p LESS THAN .001, Cohen's f^2 GREATER THAN 2). Change in rMTG-rDLPFC connectivity correlated with AH-score reduction in the active mbNF group ($n=10$, $r=.45$, $p=.09$); we observed no such relationship in the sham mbNF group ($n=12$, $r=-.24$, $p=.78$). A post hoc Fisher's Z test showed a trend at $p=.06$ between the two groups. We found no correlation between rMTG-ACC and AH-score for either group.

Discussion: Mindfulness enhanced by real-time fMRI neurofeedback helps patients with medication-resistant AH to engage in mindfulness successfully. Specifically, we demonstrate that neurofeedback from STG, a region implicated in the pathophysiology of AH, in conjunction with mindfulness, indeed leads to reductions in MTG activation, and farther modulates brain connectivity in a network associated with cognitive control regions, which in turn leads to AH reduction; sham neurofeedback from the motor cortex does not achieve it.

58. SHORT-TERM PSYCHOEDUCATION GROUP REDUCING BURDEN, ANXIOUS AND DEPRESSIVE SYMPTOMS IN CAREGIVERS OF FIRST-EPISEDE PSYCHOSIS PATIENTS

Walter Soares*¹, Amann da Lima¹, Debora Medeiros¹

¹*Onofre Lopes University Hospital - Federal University (HUOL-UFRN)*

Background: The first-episode psychosis (FEP) is a life-changing experience for the patient and their family. The psychotic patient care is linked to anxious, depressive symptoms and objective/subjective burden. At the beginning of FEP, psychotherapeutic interventions for caregivers can bring more positive results than the patient approach. Psychoeducation of caregivers promotes knowledge about mental health, emotional support, reduction of burden, adherence to treatment and prevents relapses.

Methods: We recruited caregivers (N=14) for brief group psychoeducation. Each group involved 2–4 carers and had 3 sessions (90 minutes), 1 or 2 weeks apart. The discussions were guided by structure compute presentations about psychotic symptoms, diagnosis, treatment, prognosis, comorbidities, treatment adherence and relapse prevention. We assessed participants at baseline and 30 days after intervention for anxiety (GAD-7), for depression (PHQ-9), and for objective and subjective burden with the Family Burden Interview Scale for Relatives of Psychiatric Patients (FBIS-BR). The data was analysed using R software. We used Student test to compare the values of continuous variables (GAD-7, PHQ-9, FIBS-A, FIBS-B, FIBS-D and FIBS-E scores).

Results: Most of the participants were women (78.6%), was employed (71.5%), most of them formal jobs, 71.4% were one of the parents. Before the intervention of group psychoeducation sessions, family members had levels of anxious and depressive symptoms above the clinical threshold with a mean of 10.3 (GAD-7) and 9.0 (PHQ-9). Regarding the burden on family members, the FBIS-BR subscale that demonstrated the greatest commitment for caregivers was “worries about present and future life”(reaching 75% of the maximum score (MS) – mean 26.3), followed by the “impact on family routine” (59.3% of the MS – mean 21.4), “assistance in daily life” (56.7% of the MS – mean 46) and the least affected, “supervision of problematic behavior” (38% of the MS – mean 27.4). Even 30 days after the intervention, all scales means reduced. Both PHQ-9 (mean: 6.8, $p \leq 0.01$) and GAD-7 (mean: 8.3, $p \leq 0.05$) reached a level lower than or equal to the clinical threshold. Regarding the FBIS-BR subscales, the greatest reduction occurred in “worries about present and future life” (12.4% reduction – mean 21.9), followed by “supervision of problematic behavior” (7.9% reduction – 21.7), “assistance in daily life” (6.8% reduction – mean 40.4) and the “impact on family routine” (5.1% reduction – mean 19.6), $p \leq 0.01$.

Discussion: The literature demonstrates the positive impact of structured psychoeducational interventions for caregivers of patients experiencing FEP, both in terms of wellbeing and stigma reduction, as well as anxious and depressive clinical symptoms. Unlike other interventions proposed in the literature, we suggest a shorter one in small groups, which is better suited to our Brazilian reality of low availability of psychologists in the public service, especially for such specific service. However, we had qualitatively similar results, as both

depressive and anxious symptoms below clinical level. The burden on caregivers also reduced overall. As this is a first experience with a psychotic illness, less knowledge of this clinical condition is expected for caregivers. Psychoeducation work has a direct impact on knowledge about the condition, which may justify the largest proportional difference in the FBIS-BR subscale being in the “worries about present and future life” cluster. Our research reinforces the importance and short-term effectiveness of early approach to family members of FEP patients in reducing caregiver suffering at the onset of psychotic illness.

59. THE EFFECT OF MINDFULNESS-BASED GROUP THERAPY ON CORTISOL AND OXYTOCIN LEVELS AND PSYCHOLOGICAL STRESS PARAMETERS IN SCHIZOPHRENIA SPECTRUM DISORDERS

Marco Zierhut¹, Niklas Bergmann², Sarah Koop², Inge Hahne², Julia Kraft³, Alice Braun³, Josefa Wohlthan², Ingmar Conell², Thi Minh Tam Ta², Malek Bajbouj², Neil Thomas⁴, Paul Chadwick⁵, Ripke Stephan³, Eric Hahn², Kerem Böge²

¹Charité – Universitätsmedizin Berlin, Campus Benjamin Franklin, ²Charité – Universitätsmedizin Berlin, Campus Benjamin Franklin, ³Charité – Universitätsmedizin Berlin, Campus Mitte, ⁴Centre for Mental Health, Swinburne University of Technology, Melbourne, Australia, ⁵University of Bath

Background: Recent studies have shown positive effects of mindfulness-based interventions in healthy individuals and schizophrenia spectrum disorders (SSD). Positive effects in healthy individuals have been observed in healthy individuals for example in the area of stress reduction. In particular, individuals with an SSD have an increased stress level due to multiple factors. Oxytocin and cortisol levels in plasma and saliva can function as biological stress parameters according to the literature. The interplay between mindfulness, stress and the oxytocinergic system in SSD has yet to be investigated to date. Therefore, this exploratory study examined the impact of mindfulness-based group therapy (MBGT) on biological stress parameters as OXT plasma and saliva as well as cortisol saliva levels and changes in psychological stress parameters.

Methods: A blinded, randomized, and controlled study was conducted. Participants were assigned to either MBGT with four weekly sessions in addition to treatment as usual outpatient treatment (MBGT+TAU) or only treatment as usual (TAU). Venous blood and saliva samples were collected before and after the MBGT sessions to determine OXT and cortisol levels. Self-reported questionnaires measured stress via visual analogue scales before and after the MBGT sessions.

Results: In total, 48 outpatients with SSD received either MBGT+TAU (n=25) or TAU (n=23). Analyses revealed effects in form of a significant reduction in subjective stress levels during each MBGT session. After the MBGT sessions also a significant reduction in cortisol levels could be shown, which correlated significantly with the reduction in subjective stress experience. During the first session, oxytocin levels increased, particularly significantly in the saliva. In the last session, however, there was a significant decrease in oxytocin levels in both blood and saliva. In addition, the MBGT+TAU group showed a significantly lower OXT plasma level at the end of the intervention compared to TAU.

Discussion: The outcomes of this study provide insight into the potential effects of mindfulness on biological and psychological stress parameters in SSD. In line with recent research, we found strong effects on subjective stress as well as changes in oxytocin and cortisol levels in the course of the MBGT intervention. A fully powered trial is needed to determine the efficacy of current outcomes.

60. EXTENDING SUICIDE THEORY TO PSYCHOSIS RISK AMONG LGB+ AND HETEROSEXUAL BLACK AND LATINE NORTH AMERICAN ADULTS

Daisy Lopez^{*1}, Amy Weisman de Mamani², Carrie Bearden³

¹*UCLA*, ²*U. of Miami*, ³*University of California, Los Angeles*

Background: Black and Latine U.S. individuals are diagnosed with psychotic disorders at rates 3-4 times greater than White individuals (Schwartz and Blankenship, 2014). There is also recent evidence of greater rates of psychotic disorder diagnoses in LGB+ samples as compared to heterosexual samples (Jacob et al., 2019; Oh, 2021; Bolton and Sareen, 2011). LGBTQ+ ethno-racially marginalized individuals are more likely than people with only one marginalized identity to report more than one type of discrimination (Vargas, 2020). Therefore, Black and Latine LGB+ individuals are vulnerable to the combination of discrimination they face from sexual orientation and racial/ethnic background compared to Black and Latine heterosexual individuals, which is theorized to exacerbate mental health outcomes (Bowleg et al., 2003). The construct of social defeat has been implicated in both psychosis and suicide risk literatures (Selten et al., 2013; Pollak et al., 2021). Further, in suicide research the interpersonal theory of suicide (IPTS; Joiner, 2005; Chu et al., 2017) is widely cited, which posits the importance of two risk factors for suicide— thwarted belongingness (TB) and perceived burdensomeness (PB). Cohen and colleagues (2019) conducted a principal component analysis and found that TB, PB, and social defeat loaded onto a single “interpersonal” factor. However, the IPTS has not been extended to psychosis risk. Among Black and Latine individuals, the current study tested the hypotheses that 1) sexual orientation would be associated with psychosis and suicide risk such that LGB+ individuals would present with greater psychosis and suicide risk compared to heterosexual individuals and 2) greater TB, PB, and social defeat would be associated with both greater psychosis and suicide risk.

Methods: Hypotheses were tested among a sample of 211 Black and Latine LGB+ (n=105) and heterosexual (n=106) adults (M age in years=39.17, SD= 15.87) recruited from across the U.S. through Qualtrics XM who self-reported experiences in an online survey using the Suicidal Ideation Attributes Scale (SIDAS; van Spijker et al., 2014), Community Assessment of Psychic Experiences (CAPE; Koningset al., 2006), Interpersonal Needs Questionnaire (Van Orden et al., 2012), and Defeat and Entrapment Scale (Gilbert and Allan, 1998).

Results: Contrary to expectations, sexual orientation was not associated with risk for psychosis or suicidal behaviors (operationalized using the SIDAS’s cut-off score of a sum of 21 or greater and a cut-off score of 50 or greater on the sum of the CAPE’s positive symptom subscale). As hypothesized, when tested individually, greater TB, $\chi^2(8)=43.47$, $p < .001$, OR=1.05, $p < .01$, PB, $\chi^2(8)=53.70$, $p < .001$, OR=1.08, $p < .001$, and social defeat, $\chi^2(8)=47.04$, $p < .001$, OR=1.20, $p < .001$ were associated with greater risk for suicidal behaviors. Similarly, greater TB, $\chi^2(8)=19.37$, $p=.01$, OR=1.05, $p=.04$, PB, $\chi^2(2)=21.89$, $p < .01$, OR=1.06, $p < .01$, and social defeat, $\chi^2(8)=30.36$, $p < .001$, OR=1.30, $p < .001$ were associated with greater risk for psychosis.

Discussion: Results indicate that LGB+ identity may not be driving the risk of psychosis and suicide among this intersectional community and therefore requires further study. Further, TB, PB, and defeat are associated with both greater suicide and psychosis risk among LGB+ and heterosexual individuals, extending the IPTS to psychosis. Our results suggest that psychosis interventions might be enhanced by targeting TB and PB for both LGB+ and heterosexual individuals alike.

61. MOTIVATIONAL INTERVIEWING FOR LOVED ONES: RANDOMIZED CONTROLLED TRIAL OF BRIEF TRAINING FOR FIRST EPISODE PSYCHOSIS CAREGIVERS

Emily Kline^{*1}, Heather Thibeu², Beshoun Davis³, Bediha Ipekci⁴, Aliyah Simone Sanders⁵, Rachel Oblath¹, Shirley Yen⁶, Matcheri Keshavan⁷

¹*Boston University School of Medicine*, ²*Boston Medical Center*, ³*University of Maryland School of Medicine*, ⁴*Boston University*, ⁵*Georgia State University*, ⁶*Alpert Medical School, Brown University*, ⁷*Harvard Medical School*

Background: First episode psychosis (FEP) is characterized by the onset of symptoms such as hallucinations, delusions, and disorganized behavior, and often is the first stage of a more chronic illness such as schizophrenia or bipolar disorder. Typically occurring in adolescence or early adulthood, most FEP patients reside with parents and other family members. Research shows that family involvement in psychosis treatment leads to better patient outcomes. Interventions that involve and counsel family members may improve patient outcomes by addressing barriers to treatment adherence and lowering family expressed emotion, thereby creating a less stressful and more supportive home environment. Motivational interviewing is an evidence-based style of therapeutic communication used by clinical providers to support behavior change in patients. Learning to use motivational interviewing communication skills may help FEP caregivers to decrease conflict and expressed emotion and improve treatment adherence.

Methods: The current study is a pilot randomized controlled trial testing the impact of “Motivational Interviewing for Loved Ones” (MILO), a brief five-hour psychoeducational intervention for caregivers, in a sample of family members of individuals with early course psychosis (N = 40). Using a randomized crossover design, caregivers were randomized to either immediate MILO or a six-week waitlist control condition; all participants eventually received the intervention.

Results: Caregiver participants experienced large ($d = 1.08$ – 1.43) and significant improvements in caregiver

wellbeing, caregiver self-efficacy, family conflict, and expressed emotion. There was no change over time in caregiver-reported patient treatment adherence. Relative to waitlist, MILO had significant effects on family conflict and expressed emotion, a trending effect on perceived stress, and no detectable effect on parenting self-efficacy or treatment adherence at the six-week assessment.

Discussion: This randomized controlled trial demonstrates that brief motivational interviewing training for caregivers effectively targets important facets of family environment (expressed emotion and family conflict) that have been shown to predict psychosis outcomes. Longitudinal analyses also indicated that MILO may significantly impact caregiver wellness by decreasing stress and increasing self-efficacy. Observed effects on caregiver outcomes were larger than expected, which suggests that caregivers' own mental health and expressed emotion represent important treatment targets that may be overlooked in typical study designs that focus on symptom improvement in the individual with psychosis. The study also had excellent engagement and retention, likely due to our prioritization of feasibility in designing the intervention and our responsiveness to families' requests for a brief intervention that did not require participation of the individual with psychosis. Future research will confirm the impact of MILO in a larger population of caregiver while attending more carefully to outcomes relevant to the mental health and treatment participation of the individual with psychosis. We

hope to study whether caregiver involvement with MILO may indirectly impact psychosis treatment outcomes via improved treatment adherence and positive family climate.

62. SECONDARY PSYCHOSIS: A SYSTEMATIC REVIEW AND META-ANALYSIS

Graham Blackman^{*1}, Ronan Byrne², Neha Gill², Jack Fanshawe¹, Vaughan Bell³, Cameron Watson², Nikolaos Koutsouleris⁴, Paolo Fusar-Poli², Thomas Pollak², Philip McGuire¹

¹University of Oxford, ²Institute of Psychiatry, Psychology and Neuroscience, King's College London, ³University College London, ⁴Ludwig-Maximilian-University

Background: The detection of patients with psychosis due to an identifiable disease state or exogenous agent – commonly referred to as ‘secondary psychosis’ – is an essential, but challenging diagnostic task in psychiatry. Early identification is critical in ensuring appropriate care, which may include treatment for the underlying cause. Whilst it is recognized that psychosis can have a secondary basis, surprisingly little is known about the epidemiology of such cases. The proportion of patients presenting with secondary psychosis is currently unknown; we therefore sought to derive a meta-analytic estimate.

Methods: Electronic databases (MEDLINE, PsycINFO, and Global Health) were searched up to August 2022, alongside references of included articles and review articles. We selected studies that reported the number of patients with psychosis attributable to a secondary cause and calculated the meta-analytic proportion of patients with a secondary cause, along with a 95% confidence interval (CI) using a random-effects inverse variance method. We also estimated the number of patients who would need to be assessed to detect one case of secondary psychosis (numbers-needed-to-assess; NNA) and the proportion of specific types of secondary psychosis. Statistical significance was $p \leq 0.05$ for all analyses.

Results: Based on 34 independent studies ($N = 26,693$), 13% (95% CI 8% to 18%) of patients had a secondary cause, yielding an overall NNA of 8 (95% CI 6 to 12), with marked between-study heterogeneity ($I^2 = 99\%$). The proportion estimate was revised to 11% (95% CI 7% – 16%), excluding a statistical outlier. Among patients with a first episode of a psychotic disorder, 14% ($N = 4,341$, 95% CI 8% – 22%) had a secondary cause. Overall, the most common cause of secondary psychosis was drug-induced psychosis (12%; 95% CI 6 to 19%). An underlying medical cause accounted for 5% (95% CI 3% to 9%) of cases, with infection (1%; 95% CI 0% to 4%) and autoimmune disease (1%; 95% CI 0 to 2%) being the most common medical causes. Clinical setting was a significant moderator of study variability, with the proportion of secondary psychosis in a general hospital setting highest. Geographical area was also a significant moderator.

Discussion: Based on a pooled sample of over twenty-six thousand patients presenting with psychosis, an estimated 11% had a secondary cause for their symptoms. This corresponds to an average number needed to assess (NNA) to detect one case of secondary psychosis of approximately eight. This estimate increases to around 14% in patients presenting with first-episode psychosis. Estimates vary by clinical setting and geographical area. Drug-induced psychosis accounted for most cases of secondary psychosis, whilst psychosis secondary to an underlying medical condition (commonly termed “organic” psychosis) accounted for 5% of all patients.

Findings indicate that a substantial minority of patients with psychosis have a secondary cause, particularly those presenting with a first episode of psychosis, however, estimates vary substantially by context.

Oral Session: Multimorbidity, Unmet Needs and Service Development

63. THE RAPID-LEARNING HEALTH SYSTEM IN EARLY INTERVENTION SERVICES FOR PSYCHOSIS IN QUÉBEC, CANADA: QUALITATIVE EVALUATION OF BARRIERS AND FACILITATORS TO IMPLEMENTATION

Manuela Ferrari*¹, Srividya Iyer², Marc-André Roy³, Annie LeBlanc³, Amal Abdel-Baki⁴

¹McGill University and Douglas Mental Health Institute, ²McGill University and Douglas Hospital Research Institute, ³Université Laval Faculty of Medicine, ⁴Centre Hospitalier de l'Université de Montréal

Background: In 2019, SARPEP (Système Apprenant Rapide pour les Programmes de Premiers Épisodes Psychotiques), the first rapid learning health system (RLHS) for first-episode psychosis in Canada, was created. Bringing together 11 early intervention services (EIS) from urban, semi-rural, and rural areas, SARPEP aimed to determine the feasibility/acceptability of implementing a RLHS in EIS. Evaluation of the project used a mixed method design grounded in the Reach, Effectiveness, Adoption, Implementation, Maintenance (RE-AIM) framework. Stakeholder involvement was strong, with all RLHS components successfully implemented. Meaningful indicators for EIS were selected by consensus among all the stakeholders, based on an external scan and internal survey. SARPEP developed user-friendly technologies for routine real-time data collection (REDCap platform), allowing team leaders to share program-level data. These included onsite “happy or not” digital terminals with a 3-question survey on satisfaction with services, and an in-depth questionnaire for service users and family members on satisfaction with care received that covered 9 recovery dimensions (e.g., health, quality of life). Collected data were aggregated and anonymized. The REDCap platform performed data analysis and provided real-time feedback on standards to participating programs via (graphical) data visualization with tailored practice recommendations. SARPEP offered community of practice activities, generating insights for building program capacity and aligning practices with provincial standards. This presentation describes the findings from the qualitative phase, presenting barriers and facilitators to implementation.

Methods: Six focus groups were conducted, two with service users, and one each with family members, psychiatrists, managers, and team leaders to ensure multistakeholder perspectives. Participants (n=24) were asked to share their experiences with the implementation of the RLHS over two years. The focus group questions were designed using Lessard’s five dimensions for a learning health system.

Results: Participants (n=24) confirmed the value of introducing a standardized, measurement-based, digital system through SARPEP for the routine collection and sharing of program-level data provincially. SARPEP capacity-building activities met with great success in creating a learning community. Participants viewed the key indicators selected by stakeholder consensus for the SARPEP project as both relevant and recovery-oriented. They considered the technologies developed to support data collection, analysis and data sharing as effective tools. SARPEP members greatly appreciated receiving periodic graphical feedback, using these performance evaluations to celebrate good results and set new objectives based on exchanges in the community of practice and other capacity-building activities. Yet, challenges were encountered in the implementation of user-rated outcomes and satisfaction questionnaires, whether on REDCap or the “happy or not” terminals. Digital tools were new for both providers and service users, and their integration into routine EIS care was challenging. Importantly,

stakeholders identified the provision of service user and family peer support as the crucial next step for the RLHS.

Discussion: Stakeholders agreed that a RLHS can promote evidence-based care in EIS. The RLHS created a sense of belonging in a community aiming to learn and improve. Overall, implementing SARPEP proved feasible and successful, reaching targeted EIS/participants, who adopted and maintained the RLHS, improving in key program indicators despite the pandemic, and provided a new Québec database of quality care indicators. Additional strategies, such as the establishment of peer support services, are needed to attain and maintain consistent standards.

64. UTILIZING QUALITATIVE METHODS TO REFINE THE IMPLEMENTATION OF NEW APPROACHES IN EARLY PSYCHOSIS CARE DELIVERY.

Mark Savill^{*1}, Lindsay Banks¹, Regina Gemignani¹, Valerie Tryon¹, Sabrina Ereshefsky¹, Kathleen Nye¹, Christopher K. Hakusui¹, Renata Botello¹, Viviana Padilla¹, Karina Muro¹, Laura M. Tully¹, Rachel Loewy², Tara Niendam¹

¹University of California, Davis, ²University of California, San Francisco

Background: Implementing new approaches in routine healthcare delivery can be a challenging process. A key feature of successful implementation is rooted in the perception of the innovation amongst relevant community partners, including its perceived benefit, complexity, and compatibility with existing values and needs. To address this, qualitative efforts have represented a central feature of the implementation of EPI-CAL, a statewide effort to support a learning healthcare network approach to early psychosis (EP) care.

Methods: During the design phase, focus groups held in English and Spanish were conducted to support a co-design approach to the development of the assessment battery, data sharing procedures, and the creation of the data collection and presentation application (Beehive). During the implementation phase, provider and service user interviews were conducted to identify barriers and facilitators to effective implementation, with findings iteratively fed back to the implementation team to inform program delivery.

Results: To date, 33 interviews and 40 focus groups including 284 providers, service users, and family members have been completed across 15 EP programs. In the outcomes focus groups functioning, quality of life, recovery, and symptoms of psychosis were identified as key domains to assess in EP care. Participants emphasized the clinical utility of predictors of outcomes, and the importance of concrete, client reported measures. In the focus groups concerning data sharing priorities, participants reported being receptive to data sharing, but exhibited concerns regarding third-party sharing, risk of breaches, and hidden motives in user legal agreements. Increased user-level control for data, and an understandable, transparent EULA was considered key to mitigating concerns. In focus groups supporting Beehive development, participants suggested adding program demographic visualizations, modifications to the registration process to reduce service user burden, and aesthetic changes to make the tool look less “clinical”. Interviews with EP program providers and service users identified multiple facilitators to EPI-CAL implementation, including the importance of leadership buy-in, program administrative staff support, and ongoing communication with research staff. Barriers included the challenge of integrating the project alongside existing administrative requirements, the lack of clarity on the clinical utility of the data, software bugs, and high staff turnover.

Discussion: Integrating qualitative approaches to better understand community partner needs and experiences during healthcare innovation initiatives can serve the dual purpose of

improving the initial implementation, while also producing generalizable knowledge to support the more widespread adoption of these innovations should they be effective. In EPI-CAL, ongoing and systematic feedback from partners has been critical to developing an outcomes battery that meets the needs and values of users, a usable data collection and presentation system that focuses on the clinical priorities of those delivering and receiving care, and a process whereby barriers to successful implementation can be identified and addressed as they emerge. While the integration of the Beehive application has been variable, the data collected throughout the process has led to substantive changes in the development and implementation of the process, re-orienting the project direction towards community partner needs. This approach has supported the successful implementation of EPI-CAL and may serve as a template to support the implementation of other innovations in healthcare delivery.

65. ASSOCIATION BETWEEN CANNABIS USE DISORDER AND SCHIZOPHRENIA STRONGER IN YOUNG MALES THAN IN FEMALES

Carsten Hjorthøj¹, Wilson Compton², Marie Starzer³, Dorte Nordholm⁴, Emily Einstein², Annette Erlangsen³, Merete Nordentoft⁵, Nora Volkow⁶, Beth Han², Merete Nordentoft*⁷

¹Copenhagen Research Center for Mental Health - CORE, ²National Institute on Drug Abuse (NIDA), ³Copenhagen University Hospital, Mental Health Center Copenhagen, Copenhagen Research Center for Mental Health - CORE, ⁴Copenhagen Research Center for Mental Health, ⁵Copenhagen Research Center for Mental Health-CORE; Mental Health Center Copenhagen, Copenhagen University Hospital, Denmark, ⁶National Institute on Drug Abuse, National Institutes of Health, ⁷Mental Health Centre Copenhagen

Background: Previous research suggests an increase in schizophrenia population attributable risk fraction (PARF) for cannabis use disorder (CUD). However, sex and age variations in CUD and schizophrenia suggest the importance of examining differences in PARFs in sex and age subgroups.

Methods: We conducted a nationwide Danish register-based cohort study including all individuals aged 16-49 at some point during 1972-2021. CUD and schizophrenia status was obtained from the registers. Hazard ratios (HR), incidence risk ratios (IRR), and PARFs were estimated. Joinpoint analyses were applied to sex-specific PARFs.

Results: We examined 6,907,859 individuals with 45,327 cases of incident schizophrenia during follow-up across 129,521,260 person-years. The overall adjusted HR (aHR) for CUD on schizophrenia was slightly higher among males (aHR=2.42, 95% CI=2.33-2.52) than females (aHR=2.02, 95% CI=1.89-2.17); however, among 16-20-year-olds, the adjusted IRR (aIRR) for males was more than twice that for females (males: aIRR=3.84, 95% CI=3.43-4.29; females: aIRR=1.81, 95% CI=1.53-2.15). During 1972-2021, the annual average percentage change in PARFs for CUD in schizophrenia incidence was 4.8 among males (95% CI=4.3-5.3; P LESS THAN 0.0001) and 3.2 among females (95% CI=2.5-3.8; P LESS THAN 0.0001). In 2021, among males, PARF was 15%; among females, it was around 4%.

Discussion: Young males might be particularly susceptible to the effects of cannabis on schizophrenia. At a population level, assuming causality, one-fifth of cases of schizophrenia among young males might be prevented by averting CUD. Results highlight the importance of early detection and treatment of CUD and policy decisions regarding cannabis use and access, particularly for 16-25-year-olds.

66. PATTERNS OF MULTIMORBIDITY, HEALTH CARE UTILIZATION, AND MORTALITY AMONG MID- TO LATE-LIFE ADULTS WITH SCHIZOPHRENIA

Alison Hwong*¹, Yixia Li², Michael Steinman¹, Christina Mangurian³, Donna Zulman⁴, Ruth Morin⁵, Amy Byers¹

¹UCSF and San Francisco VA Medical Center, ²Northern California Institute for Research and Education, ³UCSF, ⁴Stanford and Palo Alto VA Medical Center, ⁵Hoag Hospital

Background: As adults with schizophrenia are increasingly entering older age, there is a need to better understand their risk factors for accelerated aging and premature mortality. We identified patterns of multimorbidity and their relationship to health care utilization and cause-specific mortality among mid- to late-life adults with schizophrenia to characterize how multiple chronic conditions affect this population.

Methods: The study leveraged a national, longitudinal and population-based cohort of 5 million United States (U.S.) veterans aged GREATER THAN 50 years to create a representative subcohort called the “Aging Veterans with Schizophrenia Dataset” (N=82,858). The parent dataset has linked national VA and non-VA databases to provide diagnoses, encounters, pharmacy and cause-specific death data from 2012 to 2020. Individuals were identified as having schizophrenia if they had one inpatient or two outpatient encounters associated with a primary diagnosis of schizophrenia in the two years preceding the baseline cohort.

Forty-five major comorbid conditions were selected based on their applicability to an older population with schizophrenia. These conditions were measured across the entire study period and defined using algorithms from the U.S. Centers for Medicare and Medicaid Services (CMS) Chronic Conditions Warehouse.

Latent class analysis (LCA) was used to identify latent profiles of comorbid conditions, with the best-fitting model determined by a combination of fit statistics, clinical acumen, and theoretical parsimony. Demographics, comorbidities, utilization, and mortality outcomes were assessed using means and standard deviations or frequencies and proportions, with statistical significance of differences between classes tested by F tests for continuous variables and chi-square tests for categorical variables.

Results: We identified three comorbidity profiles: Low Comorbidity (67.0% of cohort), High Medical Comorbidity and Depression (17.6%), and Substance Use Disorders and Related Conditions (SUDRC, 15.4%). The Low Comorbidity profile had low prevalence (LESS THAN 15%) of medical and psychiatric conditions. The High Medical Comorbidity and Depression profile had high prevalence (GREATER THAN 50%) of chronic obstructive pulmonary disease (COPD) and hypertension and moderate prevalence (25-50%) of diabetes, congestive heart failure, dementia, chronic kidney disease, sleep disorders, tobacco use disorder, and depression. The SUDRC profile was notable for high prevalence of alcohol use disorder, tobacco use disorder and other drug use disorder as well as COPD, hepatitis C, chronic pain, depression, and posttraumatic stress disorder.

The SUDRC profile had the highest rates of utilization of emergency, inpatient, and outpatient mental health services as well as the highest utilization rates of emergency and inpatient medical services. The Low Comorbidity and SUDRC profiles had similar utilization rates for outpatient primary care services (91.4% vs. 92.8% with a least 1 encounter, respectively).

The High Medical Comorbidity and Depression profile had the highest mortality rate (56.0%) over the study period. Primary causes of death were heart disease, cancer, chronic lower respiratory diseases, dementia, and diabetes. The SUDRC profile had the highest rates of death due to suicide, alcohol use, hepatitis and unintentional injuries.

Discussion: Older adults with schizophrenia are a heterogeneous population, consisting of profiles with distinct patterns of multimorbidity. High rates of suicide death and substance use-related deaths among those who are high utilizers of health care services may point to more opportunities for effective psychosocial and clinical intervention.

67. ESTIMATING THE PREVALENCE OF MULTIMORBIDITY IN PEOPLE WITH AND WITHOUT SCHIZOPHRENIA: A SYSTEMATIC REVIEW AND META-ANALYSIS

Sean Halstead¹, Chester Cao², Grimur Høgnason Mohr³, Bjørn H. Ebdrup⁴, Toby Pillinger⁵, Robert McCutcheon⁶, Joseph Firth⁷, Dan Siskind⁸, Nicola Warren⁹, Dan Siskind*¹⁰

¹*The University of Queensland*, ²*Royal Brisbane and Women's Hospital, Brisbane*, ³*Center for Neuropsychiatric Schizophrenia Research, Mental Health Centre Glostrup, University of Copenhagen*, ⁴*Centre for Neuropsychiatric Schizophrenia Research (CNSR), Mental Health Centre Glostrup*, ⁵*Institute of Psychiatry, Psychology and Neuroscience, King's College London*, ⁶*Institute of Psychiatry, Psychology and Neuroscience, King's College London; University of Oxford*, ⁷*University of Manchester, Manchester, UK*, ⁸*School of Medicine, The University of Queensland, Brisbane, MIRT, Woolloongabba Community Health Centre, Addiction and Mental Health Services and MIRT*, ⁹*Metro South Addiction and Mental Health Services*, ¹⁰*Metro South Addiction and Mental Health Service*

Background: People living with severe mental illness (SMI), such as schizophrenia-spectrum disorder and bipolar disorder, experience significantly poorer health outcomes, such as a significantly reduced life expectancy. One major contributor to these outcomes are the multiple chronic conditions, or 'multimorbidity', that those living with SMI experience. This term can be categorised into both 'physical multimorbidity', denoting the coexistence of multiple chronic physical conditions, and 'psychiatric multimorbidity', corresponding to the coexistence of multiple psychiatric conditions. As multimorbidity is an emerging epidemiological concept, the overall prevalence of physical and psychiatric multimorbidity in people with SMI remains unknown, as does the ratio of prevalence of physical multimorbidity between those with and without SMI. We undertook a systematic review and meta-analysis to consequently estimate the prevalence of physical and psychiatric multimorbidity in people living with SMI.

Methods: We undertook a systematic database search in CINAHL, EMBASE, PubMed, and PsycINFO from inception until January 29, 2023 with our review protocol registered on PROSPERO. Our inclusion criteria comprised observational studies that had measured prevalence of multiple physical or multiple psychiatric conditions in people with SMI. Studies with control data from a comparable population without SMI were sought but not required. For studies with control data, we undertook a random-effects meta-analysis to compare the prevalence ratio of physical multimorbidity (≥ 2 physical conditions) between people with and without SMI. We also calculated the absolute prevalence of physical and psychiatric multimorbidity (≥ 3 psychiatric conditions, including the SMI) in people with SMI using a meta-analysis of proportion. We tested whether study factors (date of publication, country of study), population demographic factors (age, sex, ethnicity), illness factors (diagnostic composition), and methodological factors (case-control matching, study quality) had an influence on our results through a series of sensitivity and meta-regression analyses.

Results: Our systematic search identified 10,219 relevant citations which were screened by two authors at title, abstract, and full-text level. Of those, 79 studies were included which featured 1,620,420 individuals with SMI (mean age 47.8 ± 16.1 , sex ratio of 37% female: 63% male, insufficient data to report pooled ethnicity demographics), of whom 1,223,278

individuals had schizophrenia-spectrum disorder. 21 studies also featured data on people without SMI, with a pooled control population of 13,235,882 individuals. The ratio of physical multimorbidity (≥ 2 physical conditions) prevalence between people with and without SMI was 2.03 ($k = 11$, 95%CI: 1.43, 2.89, $p = 0.0012$). Sensitivity analysis that stratified studies by mean age revealed that younger cohorts with SMI (mean age ≤ 40 years) had a greater prevalence ratio of physical multimorbidity compared to controls (PR=2.90, 95%CI: 1.29, 6.49) compared to older cohorts (mean age GREATER THAN 40 years; PR=1.42, 95%CI: 0.94, 2.14, $p=0.0025$). Moreover, for those with SMI, meta-analysis estimated that 25% ($k = 28$, 95%CI: 0.19, 0.32) have physical multimorbidity and 15% (≥ 3 psychiatric conditions, $k = 19$, 95%CI: 0.09, 0.25) have psychiatric multimorbidity.

Discussion: This is the first meta-analysis to estimate both physical and psychiatric multimorbidity prevalence in people with SMI. Our findings highlight that for people with SMI physical multimorbidity is twice as prevalent compared to those without SMI. Further, this gap in multimorbidity burden appears widened in younger populations. Multimorbidity is common amongst people with SMI, with estimates that one in four have two or more physical conditions, and one in six have two or more other psychiatric conditions in addition to the SMI. These prevalence estimates highlight the relevance of studying multimorbidity in people living with schizophrenia in order to characterise the burden of chronic disease faced by this cohort. These findings clarify the need for healthcare services to provide integrated care models that address intertwined physical and psychiatric health needs and risk factors for those living with schizophrenia and SMI more broadly.

68. PSYCHOTROPIC DRUG EXPOSURES DURING PREGNANCY AND DEVELOPMENT OF OBSTETRIC COMPLICATIONS: A POPULATION-BASED STUDY IN HONG KONG

Perry Bok Man Leung^{*1}, Evangelos Vassos², Marta Di Forti², Robin M Murray², Hon-Cheong So³, Pak C Sham¹, Simon SY Lui¹

¹The University of Hong Kong, ²King's College London, ³The Chinese University of Hong Kong

Background: Psychotropic drug use in pregnant women has been associated with subsequent obstetric complications. However, psychiatric diagnosis and associated factor may confound this relationship. The analysis of population-based data using causal inference methods may clarify the association of psychotropic drug use during pregnancy with increased obstetric complications.

Methods: Data were gathered from the population-based electronic health records of the Hospital Authority (HA) which provides government-funded medical care to the entire population of Hong Kong. We identified all HA birth episodes from 2004 to 2022, then retrieved each mother's ICD-10 diagnosis and medication records in the two years before and one year after the delivery date, including prescriptions for psychotropic drugs, including antipsychotics, antidepressants, benzodiazepines, and mood stabilisers. We employed Firth's bias-reduced logistic regression to investigate the associations between different psychotropic drugs used during the pregnancy period and obstetric complications. In addition, negative control analysis was performed using mothers who were exposed to psychotropic medications before conception but not during pregnancy.

Results: We retrieved data on 585,409 birth episodes involving 421,578 mothers, in which 7,245 episodes (1.2%) had exposure to psychotropic drugs during their pregnancy period. We found significant associations between antipsychotics exposure and admission to neonatal

intensive care unit for at least 24 hours (NICU admission (≥ 24 hours)) (OR = 1.39; P-FDR = 0.0001); antidepressants and gestational diabetes (OR = 1.15; P-FDR = 0.014), gestational hypertension (OR = 1.16; P-FDR = 0.034), low birth weight (OR = 1.18; P-FDR = 0.014), NICU admission (≥ 24 hours) (OR = 1.49; P-FDR = 3×10^{-15}), and premature rupture of membranes (negatively: OR = 0.9; P-FDR = 0.028). Mood stabilisers were significantly associated with gestational hypertension (OR = 1.28; P-FDR = 0.014), emergency caesarean section (OR = 1.32; P-FDR = 1×10^{-5}), low birth weight (OR = 1.39; P-FDR = 0.0001), NICU admissions (≥ 24 hours) (OR = 1.58; P-FDR = 4×10^{-15}) and neonatal major infection (OR = 1.87; P-FDR = 0.004). Weaker associations between psychotropic drug exposure and many obstetric complications were observed in negative controls compared to pregnant women who used psychotropic drugs. Besides, after adjusted for exposures of multiple drug classes during pregnancy, emergency caesarean section (OR=1.37, P-FDR=0.0003), preterm birth (OR=1.44, P-FDR=0.001), NICU admissions (≥ 24 hours) (OR=1.56, P-FDR = 6×10^{-9}) and placental abnormalities (negatively: OR=0.5, P-FDR = 0.046) were associated with a diagnosis of schizophrenia spectrum disorders in the mother. Similarly, admission to NICU (≥ 24 hours) (OR=1.13, P-FDR = 0.028) was associated with depressive spectrum disorder in the mother.

Discussion: This population-based study provides evidence that psychotropic use during pregnancy is associated with increased risk of obstetric complications, after adjustment for underlying psychiatric diagnoses and the concurrent prescription of multiple psychotropic drugs (over half of the mothers who were prescribed antipsychotics were also prescribed antidepressants). Moreover, although some exposures or outcomes were relatively rare in our sample, the use of Firth's logistic regression reduced bias and allowed full use of available data. Our findings offer valuable insights for obstetricians and psychiatrists in caring for pregnant women with significant mental health issues.

69. SCHIZOPHRENIA RECOVERY: THE IMPACT OF COMMUNITY-BASED PSYCHIATRIC REHABILITATION PATHWAYS ON RE-HOSPITALIZATION TRAJECTORIES

Sharon Florentin¹, Yehuda Neumark², David Roe³, Paola Rosca⁴, Amir Krivoy⁵, Amir Krivoy*⁶

¹Hadassah Medical Center, Jerusalem, Israel; Faculty of Medicine, The Hebrew University of Jerusalem, ²Braun School of Public Health and Community Medicine, Faculty of Medicine, The Hebrew University of Jerusalem, ³University of Haifa, Israel; Aalborg University, ⁴Ministry of Health; The Hebrew University of Jerusalem, ⁵Geha Mental Health Center, Petach-Tikva, Israel; Sckalar Faculty of Medicine, Tel-Aviv University, Israel., ⁶Geha Mental Health Center, Petach Tikva

Background: Psychiatric rehabilitation is essential to the recovery process of individuals with schizophrenia. This study examined the impact of varied psychiatric rehabilitation services on the long-term clinical trajectory of schizophrenia patients.

Methods: We utilized data from 18,684 adults diagnosed with schizophrenia and schizoaffective disorder, derived from Israel's national rehabilitation and psychiatric hospitalization case registries. The data was divided into three periods: before the enactment of the national rehabilitation law in Israel (1991-2000), rehabilitation services availability (2001-2009), and readmission follow-up (2010-2017). The association between rehabilitation and readmission risk was tested using a Cox proportional hazard model. Associations between vocational and residential rehabilitation services subtypes and annual re-hospitalization days (ARHD), were analyzed using ANCOVA.

Results: The usage of rehabilitation services was significantly associated with a lower risk to readmission (p LESS THAN 0.0001, HR 1.20, 95%CI 1.14-1.26). Median [IQR] time-to-readmission was 752 days [1454 days] for the rehabilitation group and 381 days [1096 days] for the non-rehabilitation group. Combined residential and vocational rehabilitation resulted in a mean decrease of 20 ARHD, while either residential or vocational rehabilitation led to decreases of 2 and 5 ARHD, respectively. Absence of rehabilitation was associated with a mean increase of 9 ARHD. High levels of residential support were linked with reduced ARHD. Out of the vocational rehabilitation types, supported employment and sheltered workshops showed the greatest reductions in ARHD (17 days; p LESS THAN 0.0001).

Discussion: Community-based psychiatric rehabilitation effectively lessens admission rates and re-hospitalization days. Combined vocational and residential services may optimally reduce psychiatric exacerbations, as demonstrated by fewer hospital readmissions.

70. RESEARCH GAPS IN SUICIDE PREVENTION AMONG INDIVIDUALS WITH PSYCHOSIS: A CALL TO ACTION TO ADVANCE KNOWLEDGE AND INFORM PRACTICE

Samantha Chalker^{*1}, Roxanne Sicotte², Lindsay Bornheimer³, Emma M. Parrish⁴, Heather Wastler⁵, Blaire Erhet⁶, Jordan DeVlyder⁷, Collin A. Depp¹

¹VA San Diego Healthcare System, ²Research Center, Centre Hospitalier de l'Université de Montréal, ³University of Michigan, ⁴San Diego State University/University of California San Diego, ⁵Ohio State University Wexner Medical Center, ⁶Lyra Health, ⁷Fordham University

Background: Individuals with schizophrenia spectrum disorders have an increased risk of suicide of up to 20 times that the general population. It is estimated that 30 to 50% of those experiencing psychosis will have suicide ideation in their lifetime, 20 to 50% will attempt suicide and 4 to 13% will die by suicide. Given these alarmingly high rates, a better understanding of the intersection of psychosis and suicide is needed. The overarching goal of this call to action is to provide specific action steps to address research gaps in suicide prevention among individuals with psychosis, and thus, inform research and improve clinical practice.

Methods: A group of researchers working on different aspects of suicide in psychosis has been put formed to reflect on the main research gaps to be filled. For each gap identified, a review of the literature has been conducted and key findings highlighted. Informed by the literature, several action steps were outlined to help researchers and providers fill these gaps.

Results: Four major gaps have been identified: 1) lack of research design standards, 2) unknown reliability and validity of suicide risk screening and assessment tools in a psychosis population, 3) insufficient evidence of efficacious suicide-focused psychosocial interventions and therapies for those experiencing psychosis, and 4) limited training standards and opportunities for providers to build competencies in suicide prevention and psychosis.

First, research design standards considering the heterogeneity of both psychosis and suicide thoughts and behaviors are needed to support data aggregation. This implies the recruitment of diverse samples across the psychosis spectrum (e.g., varying levels of psychosis severity and diagnoses, variety of settings, include sexual and gender diverse individuals and persons from differing racial and ethnic backgrounds), conducting theory-driven longitudinal studies and largescale, multisite research that supports data sharing.

Second, in order to determine the reliability and validity of suicide risk screening and assessment tools in individuals with psychosis, studies testing the use of established suicide

risk screening and assessment in this population are needed. Furthermore, to determine whether tailored screening or assessment tools are necessary, is it essential to better understand how the risk of suicide in this person with psychosis may be influenced by 1) unique aspects of psychosis (e.g., experience of involuntary hospitalization, cognitive impairments, internalized stigma), 2) the effect of specific symptoms, 3) the mechanisms underlying the association between psychosis and suicide.

Third, the effectiveness of suicide-focused psychosocial interventions and treatments needs to be assessed across the psychosis spectrum, which includes testing the use of existing suicide prevention interventions and novel suicide prevention intervention adaptations.

Fourth, training to prepare providers with competency and effectiveness in treating suicide risk and psychosis needs to be implemented, including, but not limited to, augmenting suicide prevention training in service settings that are designed for people with psychosis, training suicide prevention professionals in core competencies for working with individuals with psychosis and developing specific training for clinicians working with persons with psychosis beyond broad- or general population-focused suicide prevention training.

Discussion: Suicide is a critical public health issue among individuals with psychosis. Despite substantial progress in research and clinical care for persons with psychosis at risk for suicide, important gaps remain. The action steps outlined in this call to action provide a framework for addressing these gaps and improving care and prognosis in persons with psychosis at risk for suicide.

Oral Session: Structural and Neurochemical Imaging

71. GABA, GLUTAMATE AND NEUROMELANIN IN FIRST-EPISODE PSYCHOSIS: A MULTIMODAL MRI STUDY

Francisco Reyes-Madrigal¹, Pablo León-Ortiz¹, Kenneth Wengler², Xiangling Mao³, Dikoma Shungu⁴, Guillermo Horga⁵, Camilo de la Fuente-Sandoval^{*6}

¹*Instituto Nacional de Neurología y Neurocirugía, Mexico City*, ²*New York State Psychiatric Institute, Columbia University Medical Center*, ³*Weill Cornell Medical College*, ⁴*Weill Cornell Medicine*, ⁵*Columbia University and New York State Psychiatric Institute*, ⁶*Instituto Nacional de Neurología y Neurocirugía*

Background: Abnormally elevated levels of gamma-aminobutyric acid (GABA) and of Glutamate + Glutamine (Glx) in the medial prefrontal cortex (mPFC) and the striatum have been reported in antipsychotic-free patients with schizophrenia. Additionally, neuromelanin is a promising marker in psychosis, since neuromelanin-sensitive magnetic resonance imaging (NM-MRI) is proxy measure of dopamine function. Here, we examined prefrontal and striatal GABAergic and Glutamatergic metabolites, and their associations with NM-MRI in a group of first-episode psychosis (FEP) patients.

Methods: Twenty-three antipsychotic-naïve patients with FEP and 22 age- and sex-matched healthy controls completed the study. All participants underwent a 3T MRI study in which NM-MRI of the substantia nigra (SN), and proton magnetic resonance spectroscopy (1H-MRS), targeting the mPFC and the dorsal striatum, were acquired within the same imaging session. Averaged NM-MRI contrast-to-noise ratio (CNR) values of the whole SN (SN-CNR) and 4 subregions of interest (SN pars compacta –SNpc-CNR–, SN pars reticularis –SNpr-CNR–, Ventral tegmental area –VTA-CNR–, and Parabrachial pigmented area –PBP-CNR–)

were calculated. GABA and Glx levels were analyzed using XsOSNMR software, referenced to water signal and corrected to account for the tissue composition of the voxel.

Results: Higher GABA levels were found both in the mPFC and in the dorsal caudate of patients with

FEP compared with healthy control subjects ($t=3.3$, $p=.002$; $t=3.1$, $p=.004$, respectively). Glx elevations were only seen in the dorsal striatum of the FEP group ($t=3.3$, $p=.002$). Preliminary correlations were shown between SNpr-CNR and mPFC GABA levels ($r=-.33$, $p=.04$), and SNpc-CNR and age ($r=.35$, $p=.02$) across all subjects. In the FEP group, duration of untreated psychosis correlated with both SNpc-CNR ($r=0.45$, $p=.04$) and mPFC Glx ($r=0.48$, $p=.04$).

Discussion: To the best of our knowledge, this study is the first to assess a proxy measure of dopamine function, GABAergic and Glutamatergic metabolites in drug-naïve patients with FEP. Longitudinal studies are required to establish if these combine markers are a suitable biomarker for predicting treatment response in schizophrenia.

72. DOPAMINE AND DEPRESSION ACROSS THE PSYCHOSIS SPECTRUM: AN 18F-DOPA PET STUDY

Sameer Jauhar^{*1}, Robert McCutcheon², Mattia Veronese³, Matthew Mq Noue⁴, Maria Rogdaki⁵, Thomas Whitehurst⁵, Ellis Onwordi⁵, Fedrico Turkheimer⁶, Allan H Young⁵, Oliver D Howews⁵

¹*Institute of Psychiatry, King's College*, ²*Oxford University*, ³*University of Padua*, ⁴*University College, London*, ⁵*Institute of Psychiatry, Psychology and Neuroscience*, ⁶*Institute of Psychiatry, Psychology and Neuroscience*

Background: Dopamine has played a central role in hypotheses regarding the patho-aetiology of schizophrenia, a tenet of which was response to D2 blocking antipsychotics, with in-vivo neuroreceptor imaging validating this. The treatment of psychotic symptoms across most psychotic disorders (eg bipolar disorder and delusional disorder) with antipsychotics is accepted, with a modest amount of biological data from in-vivo imaging supporting this. However, in disorders such as psychotic major depression (PMD) it is unclear if, and to what extent antipsychotics exert an effect. Whilst psychotic symptoms may respond to antipsychotics in this disorder, RCT evidence is not strong (suggesting a role for both antidepressants and antipsychotics), depression itself (in the absence of psychosis) being theoretically being linked to decreased dopamine function. Depression symptoms are seen trans-diagnostically in psychotic disorders, and often occur before illness onset (in the clinical high-risk state), as well as at first episode psychosis (FEP), and more established illness. We therefore wished to assess dopamine function (specifically dopamine synthesis capacity, DSC), in people across the psychotic spectrum, across diagnostic boundaries.

Methods: 18F-DOPA PET in people at clinical high risk of psychosis, psychotic major depression and first episode psychosis (FEP).

Inclusion criteria

People with and without positive psychotic symptoms, defined by PANSS P1, 3 or 6 GREATER THAN =4, meeting diagnostic criteria for MDD (defined by SCID, or screening using the Hamilton Depression Rating Scale (HDRS) cut-off GREATER THAN =14 or Hospital Anxiety Depression Scale (HADS). Mania/mixed defined by Young Mania Rating Scale (YMRS) GREATER THAN =12 (mania) and Montgomery Asberg Depression Rating Scale (MADRS) GREATER THAN =8 (mixed).

Multiple linear regression, controlling for age and sex, was used to examine if mood state was associated with striatal dopamine synthesis capacity in individual with psychosis spectrum disorder. Mood state was coded linearly (depressed -1, euthymic 0, manic/mixed 1). The same approach was used to determine if individuals with psychosis and depression differed from healthy controls.

Results: Total participants, N=184 (92 patients with current positive symptoms, (Clinical High Risk (CHR).N=31, First Episode Psychosis (FEP), N=47, established illness, N=14), 46 controls).

In individuals with psychosis spectrum and positive psychotic symptoms at time of scanning mood state was associated with striatal Ki, coef=0.05, SE=0.02, p=0.013), with elevation in those with manic/mixed state.

In individuals with psychosis spectrum diagnosis but no positive psychosis symptoms at time of scanning (N=46) mood state was not associated with striatal ki (N=46, coef =-0.002, se=0.03, p=0.96)

No significant mood*psychosis interaction in the model was seen in the full sample (N=184) Compared to controls (N=46), individuals with psychosis and depression (N=37) showed non-significantly lower Ki (coef=-0.03, Se=0.03, p=0.3).

Discussion: These findings suggest that, across the psychosis spectrum, in those people with current positive psychotic symptoms, mood state (presence of depression, euthymia or mania/mixed state) is related to dopamine synthesis capacity. This may have implications for targeted treatments of affective disorders across the psychosis spectrum.

73. PSYCHOSIS MRI SHARED DATA RESOURCE (PSY-SHARED): A GLOBAL MRI DATASET FOR ALL PSYCHOSIS RESEARCHERS

Mariana Zurita*¹, Matthew Kempton¹, Veena Kumari², Simon Evans³, Jack Rogers⁴, Rachel Upthegrove⁴, Urvakhsh Mehta⁵, Rubaida Easmin¹, Sara Bucci¹, Paul Allen¹

¹*Institute of Psychiatry, Psychology and Neuroscience, King's College London*, ²*Brunel University London*, ³*University of Surrey*, ⁴*University of Birmingham*, ⁵*National Institute of Mental Health and Neuro Sciences (NIMHANS)*

Background: Magnetic Resonance Imaging (MRI) studies have significantly enhanced our understanding of the neuroanatomical basis of psychosis. However, persistent challenges, including underpowered datasets, recruitment difficulties, high costs, and limited diversity in patient populations, hinder progress. Furthermore, the majority of psychosis MRI research has been conducted in western populations. Multi-centre initiatives, though promising, often focus on only one or two illness or risk stages, can still feature small samples, and are generally conducted in western populations.

Here we introduce the Psychosis MRI Shared Data Resource (Psy-ShareD), a global repository that aims to address these challenges. Psy-ShareD provides curated data allowing diverse analytical approaches, including voxel-based morphometry, cortical thickness, surface area, and region of interest assessments. It also includes linked standardised clinical, demographic, and cognitive data and encompasses schizophrenia, bipolar disorder, first-episode psychosis, various at-risk cohorts, and control populations.

Methods: Psy-ShareD currently hosts 1,736 T1-weighted MRI images from 8 different sites across Europe and Asia. These datasets are expected to grow with contributions from additional

partner sites (incorporating South America) and future collaborators in China and Australia. Collaborators anonymise their data by using custom code provided by our team to de-face all structural images and create unique subject IDs (with keys only accessible by the original sites). We carefully curate the data to ensure that what will be available is of high quality. Additionally, we harmonise the data at the image and feature level to ensure reliability and consistency by reducing unwanted variation caused by differences in image acquisition. Image-level harmonisation is carried out using HACA3 (Zuo et al., 2023) and CycleGAN (Gao et al., 2019). Feature-level harmonisation is being conducted using ComBat (Fortin et al., 2018).

Clinical data is standardised using an ordinal system, regardless of the scale used. Cognitive data is standardised and harmonised across three domains: i) intellectual function, ii) working memory and executive function, and iii) verbal learning, by creating standardised z-scores and using data from respective control cohorts matched for age.

Results: Psy-ShareD's curated and harmonised T1 MRI data will be freely accessible and managed by the Psy-ShareD Partnership for researchers at all career stages. It is expected that the resource will be particularly useful for early career researchers and doctoral student projects, particularly those who would otherwise struggle to access MRI datasets in psychosis and psychosis cohorts. Therefore, the Psy-ShareD resource has the potential to significantly increase research capacity and provide opportunities for early-stage researchers to undertake MRI studies in clinical datasets that would not have previously been accessible. Furthermore, we will provide a number of tools and training materials for users to facilitate analyses.

Discussion: In conclusion, Psy-ShareD, a global MRI resource, is positioned to advance schizophrenia and psychosis research by overcoming challenges and enhancing accessibility. Data sharing not only improves reliability and reproducibility but also provides a global perspective on these conditions, emphasising the importance of cross-ethnic MRI datasets in understanding brain structure variations across diverse populations.

74. 7 T MRS REVEALS NEURAL METABOLIC DYSFUNCTION AND ASSOCIATION WITH SYMPTOMS IN PEOPLE WITH PSYCHOSIS

Caroline Demro*¹, Michael-Paul Schallmo¹, Kyle W. Killebrew¹, Małgorzata Marjańska¹, Scott Sponheim²

¹University of Minnesota, ²Minneapolis VA / University of Minnesota

Background: Altered brain chemistry contributes to distressing impairments in cognitive and perceptual functioning in people with psychosis (PwP). These alterations may extend to biological relatives, given the role of genetic factors in psychosis, but studies directly comparing PwP and relatives are sparse (1). Results of previous magnetic resonance spectroscopy (MRS) studies quantifying neurochemical concentrations in PwP are mixed, likely due to methodological differences (2,3). Previous meta-analyses in schizophrenia suggest widespread reduction of N-acetyl aspartate (NAA) (4), a marker of neuronal integrity that has been associated with neuroinflammation. Inflammatory biomarkers can be measured in blood serum and low-grade inflammation has been associated with psychosis. In this study, we addressed common methodological limitations and directly compared neurochemical concentrations and peripheral inflammatory biomarkers between PwP, their relatives, and controls.

Methods: We acquired MRS data at 7 tesla in occipital and prefrontal cortices from 43 controls, 42 first-degree biological relatives, and 64 PwP. MRS methodological limitations were addressed in the current study by: (1) using an ultra-short echo time (TE = 8 ms) sequence

to mitigate the confound of shorter T2 in PwP, (2) acquiring data at 7 tesla to provide higher SNR and separate quantification of overlapping metabolites (e.g., separating NAA from N-acetyl aspartylglutamate (NAAG)), and (3) including macromolecular signals in our basis set, fitting metabolites without soft constraints, and using a rigid baseline during fitting to avoid quantification errors reported in the literature. In addition to MRS, we collected blood serum samples (n=56 controls, 84 relatives, 138 PwP). Kruskal-Wallis tests analyzed group differences in non-normally distributed data.

Results: In a priori tests, NAA levels in the occipital lobe were lower in PwP and their relatives compared to controls (Kruskal-Wallis, $\chi^2=7.46$, $p=.024$). Lower NAAG concentrations in the prefrontal cortex were also evident in PwP versus controls and relatives ($\chi^2=8.10$, $p=.017$). In exploratory analyses, we observed markedly higher glucose levels in occipital ($\chi^2=7.99$, uncorrected $p=.018$, FDR-corrected $p=.18$) and prefrontal ($\chi^2=8.10$, uncorrected $p=.007$, FDR-corrected $p=.074$) cortices in PwP compared to controls and relatives. Hierarchical clustering analyses showed higher glucose levels were linked to higher psychiatric symptom levels and impairments in visual task performance. Serum glutathione levels were lower in PwP and relatives compared to controls ($\chi^2(2, N=241)=74.13$, $p < .001$). We also saw evidence of higher peripheral inflammatory marker levels (e.g., IL-6) for PwP compared to controls and relatives ($\chi^2(2, N=265)=15.40$, $p < .001$).

Discussion: We show when methodological issues are addressed, 7 T MRS reveals a pattern of neurometabolic dysfunction in PwP. Our findings point to a disruption in neural metabolism across multiple brain areas in PwP that is associated with impaired cognitive and perceptual functioning. Relatives showed intermediate occipital NAA levels, suggesting a role for genetic liability for psychosis in this metabolite, whereas relatives' occipital glucose and prefrontal NAAG and glucose levels were similar to controls and thus these metabolites may be more closely linked to disease processes in PwP. Our evidence of higher peripheral inflammation and lower antioxidant defense is consistent with the notion that altered neuronal integrity is associated with inflammation. Together results suggest widespread metabolic and immune dysfunction in PwP that is partly associated with unexpressed genetic liability for psychosis.

75. IN VIVO SYNAPTIC DENSITY LOSS IN SCHIZOPHRENIA IS SHAPED BY ANATOMICAL CONNECTIVITY AND SPREADS FROM REGIONAL EPICENTERS

Sidhant Chopra^{*1}, Patrick D. Worhunsky¹, Mika Naganawa¹, Gustavo A. Angarita¹, Kelly Cosgrove¹, Deepak C. D'Souza¹, David Matuskey¹, Nabeel B. Nabulsi¹, Yiyun Huang¹, Richard E. Carson¹, Irina Esterlis¹, Patrick D. Skosnik¹, Avram J. Holmes², Rajiv Radhakrishnan¹

¹Yale University, ²Rutgers University

Background: Converging genetic and post-mortem evidence suggests the loss of synapses is fundamental to schizophrenia pathogenesis. The radioligand [¹¹C]UCB-J now allows in vivo examination of synaptic density via positron emission tomography (PET), revealing widespread lower density in schizophrenia. However, the mechanisms explaining the spatial pattern of these alterations remain unknown. Here, we investigate whether the brain's axonal fibres act as conduits for synaptic density loss in schizophrenia, as observed in other neurological syndromes.

Methods: Using PET parametric images of [¹¹C]UCB-J binding potential from 117 individuals (92 healthy controls and 25 individuals with schizophrenia), we generated brain-wide voxel-level group difference maps. We derived representative functional and structural

connectivity patterns from an independent control group (N=100). We used coordinated deformation models to predict the extent of synaptic alteration in each parcellated area by the changes observed in areas to which the index region is structurally, or functionally, connected. To locate focal sources, or epicentres, from which synaptic density loss may spread, we used a network diffusion model, sequentially using each brain region as a starting seed.

Results: Our results demonstrated that regional synaptic density differences were strongly correlated with estimates predicted using a model constrained by structural, rather than functional, connectivity ($r=.58$; p LESS THAN .01). Finally, we identified the left temporal pole (p LESS THAN .05) as putative an epicentre from which the pathological spread of synaptic loss may initiate.

Discussion: Our findings highlight a robust and central role for the topology of the brain's white matter fibres in the spread of synaptic pathology in schizophrenia, mirroring findings reported in animal models and other neurological syndromes.

76. COMBINING NEUROMELANIN-MRI AND [18F]-DOPA PET TO EXPLORE MESOSTRIATAL DOPAMINERGIC CIRCUIT DYSFUNCTION IN SCHIZOPHRENIA

Luke Vano*¹, Robert McCutcheon², Grazia Rutigliano³, Stephen Kaar³, Valeria Finelli³, Giovanna Nordio³, Rong Ye⁴, Mattia Veronese³, Ian Everall³, Oliver Howes³

¹*Institute of Psychiatry, King's College*, ²*Oxford University*, ³*Institute of Psychiatry, Psychology and Neuroscience, King's College London*, ⁴*University of Cambridge, Cambridge, UK*

Background: Whilst mesostriatal dopaminergic circuit dysfunction is one of the most established findings in schizophrenia, precisely where dysfunction is most prominent and the relationship between different components of dopaminergic metabolism here has not been fully elucidated. To examine this, we first aimed to determine where dopamine overactivity was most marked in the substantia nigra (SN) and ventral tegmental area (VTA). We then aimed to explore the relationship between dopamine synthesis capacity and neuromelanin levels, produced as a product of dopamine metabolism, across the SN-VTA and striatum.

Methods: 154 subjects (74 people with schizophrenia and 80 healthy controls) underwent clinical assessments and neuromelanin-sensitive MRI (NM-MRI). 38 patients in the schizophrenia group also received [18F]-DOPA PET to measure dopamine synthesis capacity (Kicer) in the SN-VTA and striatum. First, we examined case-control differences in SN-VTA NM-MRI contrast-to-noise ratio (NM-CNR) using region of interest and voxelwise analysis. Second, we explored the relationship between SN-VTA NM-CNR, SN-VTA Kicer, and striatal Kicer in individuals with schizophrenia.

Results: We found that the schizophrenia group had significantly higher SN-VTA NM-CNR compared to controls (effect size= 0.46, $p=0.005$). This was most significant in the medial SN and lateral VTA on voxelwise analysis. In patients who underwent NM-MRI and [18F]-DOPA PET, region of interest analysis demonstrated that SN-VTA Kicer positively correlated with both SN-VTA NM-CNR ($r=0.49$, $p=0.002$) and striatal Kicer ($r=0.71$, p LESS THAN 0.001). Striatal Kicer also positively associated with SN-VTA NM-CNR ($r=0.48$, $p=0.002$). Voxelwise analysis showed that SN-VTA NM-CNR was positively correlated with striatal Kicer ($r=0.54$, $p=0.007$) and highlighted that this relationship was strongest between the ventral SN and associative striatum.

Discussion: Neuromelanin contrast in the dopaminergic midbrain is higher in individuals with schizophrenia compared to controls, with this being most significant in areas of the VTA and

nigra that project to the associative striatum, and is directly associated with dopamine synthesis capacity in both the dopaminergic midbrain and striatum. We identify specific mesostriatal dopaminergic circuits most altered in schizophrenia, with implications for novel treatment development.

77. CORTICAL FOLDING ASYMMETRY AND STRUCTURAL COVARIANCE IN AUDITORY HALLUCINATIONS: IMPLICATIONS FOR THE PSYCHOSIS CONTINUUM

Shun-Chin Jim Wu^{*1}, Héloïse de Vareilles¹, Samantha C. Mitchell¹, Atheer Al-Manea², Jane Garrison¹, Michail Mamalakis¹, Jon Simons¹, Lynn Mørch-Johnsen³, Ingrid Agartz⁴, John Suckling¹, Graham K. Murray¹

¹University of Cambridge, ²University of Birmingham, ³University of Oslo, ⁴NORMENT, Division of Mental Health and Addiction, University of Oslo, and Diakonhjemmet Hospital

Background: Cortical folding, a prenatal developmental process with a persistent pattern after the age of two, serves as a robust biomarker for early neurodevelopment. Previous studies examining the association between impaired sulcal patterns in the paracingulate sulcus (PCS) or superior temporal sulcus (STS) and hallucinations in schizophrenia patients have faced limitations such as modest sample sizes, inconsistent unilateral hemispheric findings, and categorical subject inclusion. This study addresses these issues by investigating the link between lifetime auditory hallucinations and sulcal patterns bilaterally, utilising two distinct quantitative measures, and further assessing asymmetry and structural covariance in individuals with psychotic spectrum disorders and healthy controls.

Methods: The Thematically Organized Psychosis (TOP-OSLO) study's T1-weighted MRI data were utilized, including separate examinations for schizophrenia spectrum disorders (SSD, N=194) and Bipolar spectrum disorders (BSD, N=157), as well as a combined analysis for psychotic spectrum disorders. Healthy controls (N=278) were also included. We utilized manually and automatically labelled metrics from BrainVisa, along with the automatically generated gyrification index from Freesurfer. Asymmetry of labelled metrics and structural covariances of the gyrification index were calculated to investigate interhemispheric developmental coordination within and between PCS, STS and associated networks including salience and auditory network to compare the patients with a lifetime history of auditory hallucinations (N=194), comprising of 145 with SSD and 49 with BSD, and those without such history (N=157), consisting of 49 with SSD and 108 with BSD, alongside the control group.

Results: Patients with psychotic spectrum disorders experiencing lifetime auditory hallucinations exhibited reduced leftward asymmetry in PCS length, as compared to healthy controls (nonparametric Kruskal-Wallis rank sum test statistic (χ^2) = 8.76, post hoc Dunn's test adjusted p-value = 0.03). Consistent findings were observed in SSD and BSD subgroups. Despite variabilities in the structural covariance of the psychotic spectrum disorders, both patient subgroups with hallucinations manifested augmented structural covariance in gyrification within and between sulci, and also extended networks as compared to healthy controls (χ^2 = 9.61-1416.09, post hoc adjusted p = 0.008-0.001).

Discussion: This study replicates earlier schizophrenia findings of decreased leftward asymmetry in PCS length and heightened gyrification covariance in patients with lifetime auditory hallucinations with a larger and independent dataset. The results underscore the importance of interhemispheric communication in sulcal patterns related to auditory hallucinations as enduring traits in psychosis. Differences in covariance among SSD and BSD subgroups suggest nuanced structural coordination variations across these spectra.

78. DEMONSTRATING REDOX IMBALANCE IN EARLY-STAGE SCHIZOPHRENIA USING 7-TESLA FUNCTIONAL MRS

Peter Jeon^{*1}, Michael MacKinley², Kara Dempster³, Sabrina Ford⁴, Lena Palaniyappan⁵, Jean Theberge⁶

¹Western University, ²University of Western Ontario, Lawson Health Research Institute, ³Dalhousie University, ⁴University of Western Ontario, ⁵Douglas Mental Health University Institute, ⁶St. Joseph's Health Care London

Background: Redox imbalance has been implicated in contributing to observable schizophrenia symptoms. As the brain's main antioxidant, glutathione (GSH) is expected to mount a response to redox imbalances and oxidative stress. However, traditional MRS techniques do not capture the potential dynamic or regulatory behavior of neurometabolites, which may provide a more accurate understanding of the molecular mechanisms behind schizophrenia symptoms. To this end, we propose the use of functional MRS (fMRS) to investigate potential antioxidant response abnormalities in response to short-term cognitive stress in the early stages of schizophrenia.

Methods: We recruited 33 first-episode schizophrenia (FES) and 23 patient-matched healthy control (HC) volunteers to undergo proton fMRS (1H-fMRS) using a Siemens MAGENTOM head-only 7-Tesla MRI scanner (8-Tx/32-Rx RF coil). Using a long echo-time semi-LASER pulse sequence (TR = 7500ms, TE = 100ms, 128 averages), GSH, glutamate, and glutamine concentrations were measured with a 2 x 2 x 2 cm³ voxel placed in the dorsolateral anterior cingulate cortex (ACC). The fMRS paradigm consisted of four blocks (baseline, task, recovery 1, recovery 2) with the color-word Stroop task used as the cognitive task in the second block. All transient spectra collected per block were phase- and frequency-corrected prior to averaging into a single spectrum to be used for further post-processing, spectral fitting, and quantification.

Results: A strong trend towards higher baseline GSH was observed in FES compared to HC ($t(54) = -1.829$, $p = 0.07$). No significant difference was detected between baseline glutamate and glutamine in both groups. Repeated measures ANOVA revealed an effect of time ($F(1,3) = 4.169$, $p = 0.01$), metabolite ($F(1,2) = 35.163$, $p < 0.001$), and diagnosis $\times$ metabolite $\times$ time ($F(1,52) = 5.384$, $p = 0.02$). A significant GSH level increase was observed during task activation in HC ($t(22) = -2.570$, $p = 0.03$), but not in FES ($t(32) = 0.357$, $p = 0.71$). Glutathione levels remained elevated for an additional block in HC ($t(22) = -2.570$, $p = 0.02$), even after the removal of task stimuli, before decreasing its levels in the final block. No accompanying changes were observed in glutamate or glutamine during the task period. Glutamate concentrations were significantly decreased, below baseline levels, in the final block of the fMRS paradigm for both HC ($t(22) = 3.454$, $p = 0.002$) and FES ($t(32) = 3.482$, $p = 0.001$). Additionally, a significant increase in glutamine level was detected in HC from the first to second recovery block ($t(22) = -2.194$, $p = 0.04$). Lastly, FES normalized glutamate levels in the first recovery block relative to baseline showed significant correlation to both positive ($r = 0.351$, $p = 0.045$) and general ($r = 0.404$, $p = 0.02$) PANSS-8 sub-scores.

Discussion: We note three major observations in this work. First, is the relative elevation of GSH levels in FES compared to HC, which may indicate pre-existing oxidative stress in our patient sample. Secondly, we note the difference in ability between HC and FES to significantly regulate their ACC GSH levels in response to short-term cognitive activity. Lastly, a significant reduction in glutamate levels post-task in both groups may reveal a more complex interplay among the glutamatergic metabolites in the brain. This work demonstrates the need to move

beyond using traditional MRS techniques into more dynamic tools such as fMRS when studying complex molecular mechanisms behind schizophrenia symptoms. Inability to effectively regulate antioxidants in response to stress not only supports the presence of redox imbalance in schizophrenia, but also suggests the inability to move towards redox balance in the early stages of illness.

Oral Session: Subclinical Populations, High Clinical Risk and Early Onset Psychosis

79. COMPARATIVE ANALYSIS OF CHR-P AND UHR PROFILES DERIVED FROM PSYCHS INTERVIEW: INSIGHTS FROM SIPS AND CAARMS ASSESSMENTS IN EARLY PSYCHOSIS INTERVENTION

Catalina Mourgues-Codern^{*1}, Jean Addington², Martha E. Shenton³, Barnaby Nelson⁴, Alison Yung⁵, Scott Woods¹

¹Yale University, ²Calgary University, ³Brigham and Women's Hospital, Departments of Psychiatry and Radiology, Harvard Medical School, ⁴Melbourne University, ⁵Deakin University

Background: In early psychosis intervention, the Clinical High-Risk syndrome for psychosis (CHR-P) and the Ultra-High Risk (UHR) mental state are assessed through the SIPS and CAARMS interviews. Although they are fundamentally similar in evaluating attenuated positive symptoms, various differences especially in CHR-P/UHR lead to potentially different CHR-P/UHR profiles. Few studies have conducted SIPS and CAARMS interviews in the same patients, rendering the extent of the potential differences unclear. The Positive SYMptoms and Diagnostic Criteria for the CAARMS Harmonized with the SIPS (PSYCHS) offers a unified approach to CHR-P assessment and severity scoring compatible with both CAARMS and SIPS frameworks.

Methods: The first data release from the ongoing AMP SCZ study contains screening PSYCHS data from a cohort of 339 CHR-P/UHR individuals. This cohort was drawn from the PRESCIENT (n=88) and ProNET (n=259) consortia. Participants were stratified into three groups: Group 1 (G1, n=132) consisted of individuals meeting both CAARMS UHR criteria and evidencing SIPS CHR-P progression; Group 2 (G2, n=192) included those meeting UHR criteria and SIPS CHR-P persistent, partial, or full remission; and Group 3 (G3, n=3) comprised individuals who fulfilled SIPS CHR progression criteria without meeting for UHR. A battery of clinical assessments was administered, including the PSYCHS, Brief Psychiatric Rating Scale (BPRS), Premorbid Adjustment Scale (PAS), Negative Symptom Inventory-Prodromal Risk (NSI-PR), Calgary Depression Scale for Schizophrenia (CDSS), Overall Anxiety Severity and Impairment Scale (OASIS), Social and Occupational Functioning Assessment Scale (SOFAS), Global Functioning Scale (GFS), and Global Functioning: Role (GFR).

Results: In this sample, only 3 participants were classified into G3, leading our analysis to focus on G1 (n=132) and G2 (n=192). Both groups were comparable in terms of age and sex. However, G1 exhibited substantially elevated levels of depression on the CDSS ($t(261)=2.442$, $p=.005$, $d=.306$) and anxiety on the OASIS ($\chi^2(1)=5.704$, $p=.017$). G1 was characterized by a higher incidence of BPRS total ($t(269)=2.248$, $p=.025$, $d=.274$) and specific symptoms of guilt ($t(286)=2.31$, $d=.277$) and suspiciousness ($t(285)=2.433$, $d=.291$, ps LESS THAN .05). Moreover, G1 showed higher scores than G2 in various negative symptoms, such as reduced motivation, avolition, and anhedonia, as measured by the NSI-PR ($t(269)=2.533$, $d=.306$; $t(274)=2.078$, $d=.253$; $t(190.343)=2.596$, $d=.328$; ps LESS THAN .05). G1 had higher positive symptoms on the SIPS derived from the PSYCHS ($t(321)=2.444$, $d=.277$, $p=.015$). CAARMS scores were

numerically higher for G1 than G2 ($t(321)=1.646$, $d=.192$, $p=.101$). Regarding functional outcomes, G1 displayed lower social functioning than G2 ($t(289)=2.751$, $t(311)=2.022$, $d=.327$, p s LESS THAN .05), but no significant differences were observed in role functioning between the two groups.

Discussion: In this preliminary sample, fewer than half of participants (40.7%) meeting CAARMS UHR criteria also met SIPS CHR Progression criteria. Participants meeting both criteria (G1) exhibited significantly elevated levels of depression, anxiety, and various negative symptoms and reduced social and occupational functioning compared to those meeting only CAARMS UHR criteria, but effect sizes were small. Requiring SIPS progression for ascertainment appears to produce a slightly more severely ill sample but would require exclusion of more than half of potential enrollees, relative to requiring CAARMS UHR. These trade-offs should be considered when designing and implementing CHR intervention studies.

80. THE EXPERIENCE AND ROLE OF DISSOCIATION IN SUBCLINICAL PSYCHOSIS FOLLOWING DEVELOPMENTAL TRAUMA: A MIXED-METHODS STUDY

Eirini Melegkovits^{*1}, Paul Gu-Yun Jung², Ava Mason², Tereza Bountiokou², Rui Tang², Katie Ashcroft³, Michael Bloomfield²

¹*Division of Psychiatry, UCL*, ²*University College London*, ³*Royal Holloway, University of London*

Background: Developmental trauma (DT), defined here as abuse and neglect prior to the age of 18, increases vulnerability to psychosis in adulthood. Dissociative experiences are common phenomenological characteristics and proposed candidate vulnerability mechanisms among survivors of DT with clinical psychosis. However, there is a lack of research on the phenomenology or the mediating role of dissociation among survivors of DT with subclinical psychosis. We employed a mixed-methods design to delineate the role of dissociation and phenomenological experiences in survivors of DT with subclinical psychotic experiences.

Methods: In study 1, we recruited participants based in the UK ($n=1245$) who were not receiving psychiatric medication to participate in an online survey exploring the role of DT on adult mental health. Participants were invited to complete the study if 1) they had a history of DT, 2) were hearing voices or feeling threatened, or 3) reported no difficulties with their mental health. Participants completed the Childhood Trauma Questionnaire, Dissociative Experiences Scale, the Community Assessment of Psychic Experiences, the Paranoia Scale and the International Trauma Questionnaire. In study 2, 23 participants who met threshold for subclinical psychosis (UHR) based on the CAPE-15 were invited to participate in follow-up qualitative interviews. The interviews comprised of an abridged version of the Comprehensive Assessment of At Risk Mental States (CAARMS) and an adapted version of the Intrusions Interview, focusing on the experience and impact of recent intrusive memories, images, thoughts or voices related to trauma. In study 3, 64 individuals with and without histories of DT were invited to a follow-up experimental study using the Mirror Gazing Task (MGT). We measured depersonalisation before and after the experiment using the Cambridge Depersonalisation Scale-State Version, and explored their experience using qualitative responses.

Results: In Study 1, we found that exposure to DT contributed to increased levels of total and subtypes of dissociation among participants, both with and without subclinical psychosis. Dissociative experiences mediated the relationship between DT and: 1) Frequency of positive psychotic symptoms, 2) Paranoia. The mediating role of dissociation was not moderated by the

presence of PTSD or complex PTSD based on the ITQ. In Study 2, participants meeting the threshold for UHR described various forms of dissociation, particularly experiences of detachment. Dissociation was explained in the context of DT but also as a coping mechanism for distressing emotions, interpersonal relationships, and the experience of the self relevant to both DT and psychosis. Some participants identified that dissociation served as both a cause of psychotic experiences (such as paranoia and hallucinations) and as a response to psychotic experiences. In Study 3, we observed a higher change in depersonalization among participants with DT compared to those without DT. Qualitative responses indicated that participants with DT found the MGT more distressing, more uncontrollable and inexplicable, giving rise to confusion and erroneous explanations.

Discussion: This mixed-methods study aimed to elucidate the relationship between DT, dissociation, and subclinical psychosis, as well as the role dissociation may play in giving rise to psychotic symptoms in adult survivors of DT. Primarily, trait and state dissociation appear to be common among survivors of DT and are also associated with psychotic experiences. Qualitative analyses provided rich phenomenological descriptions and supported the mediating role of dissociation in the experience of psychotic symptoms following DT, as identified in study 1. However, reverse causality needs to be taken into account, as dissociation was also described by participants meeting the UHR threshold as an automatic response to the distress of psychotic symptoms. Findings on the complex relationship between DT and psychosis are discussed, including the role of dissociation as a response peri-traumatically, but also as a way of coping with both psychotic experiences and with memories and experiences of the self following DT. Limitations of the study include the cross-sectional design, that limits causal inferences, and use of self-report questionnaires. Considering the strong association between DT, dissociation, and subclinical psychotic experiences, it is important to screen for traumatic and dissociative experiences among individuals with early presentations of psychosis and to consider them as part of formulation and treatment if necessary. Future research is needed to understand the phenomenology and mechanisms underlying the relationship between dissociation and psychosis, and to determine if dissociation is associated with a worse prognosis and treatment response in individuals with psychosis and DT.

81. IDENTIFYING MODIFIABLE BEHAVIORS THAT PREDICT TRAJECTORIES OF PSYCHOTIC-LIKE EXPERIENCES IN YOUNG ADOLESCENTS

Rebecca Cooper*¹, Maria Jalbrzikowski²

¹*Boston Children's Hospital*, ²*Children's Hospital/Harvard Medical School*

Background: While transient psychotic-like experiences (PLEs) in adolescence are common, persistent and increasing PLEs predict poorer mental health outcomes. PLEs in childhood are associated with increased risk of later developing psychosis, as well as depression and anxiety disorders, substance use disorders, functional impairment, and suicide. Emerging evidence suggests that modifiable lifestyle factors (such as quality sleep and regular exercise) can improve mental health outcomes. However, it is unclear how modifiable lifestyle factors are linked to trajectories of PLEs. Here, we sought to characterize trajectories of PLEs across early adolescence, and assess relationships between PLE trajectories and a range of modifiable behavioral and/or psychosocial predictors.

Methods: We assessed data from 10,007 children (age 9-10 years at the initial visit) from the Adolescent Brain Cognitive Development Study (data release 5.0). Yearly longitudinal data was available for four time points (2018-2021). We used data from the self-report Prodromal Questionnaire-Brief Child Version (PQ-BC) to measure PLEs. Our outcome measure was the summed total of endorsed PLEs. We used latent growth mixture models to characterize PLE

trajectories. Latent growth mixture models can identify distinct sub-groups of individuals that share similar characteristics and follow similar trajectories over time. We examined modifiable predictors available in the ABCD dataset (N=4, e.g., physical activity). For each predictor, we conducted a univariate logistic regression to predict PLE subgroups, covarying for sex at birth, ABCD site and parental education. To evaluate the goodness of fit of the regression model, we calculated Nagelkerke's R squared.

Results: Over half of young adolescents (55%, N=5493) reported persistently low levels of PLES, while the remainder (45%, N=4583) followed a persistently high PLE trajectory over time. The PLE levels in the persistently high PLE trajectory group decreased over the four year follow-up period, but still remained significantly higher than persistently low PLE group at the fourth year time point. Individuals in the elevated trajectory were more likely to be from lower socio-economic status (Nagelkerke $R^2 = 0.01$). These individuals experienced a greater amount of sleep problems (Nagelkerke $R^2 = 0.02$), participated in less regular physical activity (Nagelkerke $R^2 = 0.01$), and drank more caffeinated drinks (Nagelkerke $R^2 = 0.01$) than individuals in the low-level trajectory.

Discussion: Several modifiable behavioral variables were associated with an elevated PLE trajectory in a large sample of youth. Identification of these modifiable factors associated with PLEs provides valuable targets for future risk assessment and preventative treatments in youth. In the future, we plan to incorporate a measure of distress about the PLEs into our calculations of these developmental trajectories, as this measure may improve our ability to capture unobserved heterogeneity and better characterize youth at greatest risk for adverse mental health outcomes. We also plan to assess the predictive effect of biological variables (e.g., neuroimaging measures, polygenic risk scores) on PLE trajectories in youth, as well as moderating effects of the biological measures on the relationships between the modifiable factors and PLE trajectories. Understanding the intersection between an individual's neurobiology and their behavior may provide a comprehensive understanding of how PLEs lead to adverse mental health outcomes.

82. THE PREVALENCE OF EARLY-ONSET PSYCHOSIS AMONG CHINESE SCHOOL-ATTENDING STUDENTS AGED 6-16: A NATIONAL SURVEY

Ying Li^{*1}, Yonghua Cui², Raymond Chan³

¹*Neuropsychology and Applied Cognitive Neuroscience Laboratory, CAS Key Laboratory of Mental Health, Institute of Psychology,* ²*Beijing Children's Hospital, Capital Medical University,* ³*Institute of Psychology, Chinese Academy of Sciences*

Background: The occurrence of early-onset psychosis in Chinese children and adolescents is not yet fully understood. Drawing from a nationwide epidemiological survey focused on psychiatric disorders within this age group, this study delves into the prevalence of early-onset psychosis and associated symptoms among students aged 6-16 attending school.

Methods: We utilized the database from China's first epidemiological survey on psychiatric disorders in children and adolescents. Using the DSM-Oriented Psychotic Symptoms Scales (DOPSS, where a total score GREATER THAN 1.97 suggests the presence of Psychotic Symptoms), we screened for psychotic indicators. Furthermore, we assessed the prevalence of early-onset psychosis based on the Psychotic Disorders diagnosis as outlined in the Mini International Neuropsychiatric Interview for Children and Adolescents (MINI-KID) from this survey. We determined the prevalence of psychotic symptoms or early-onset psychosis and analyzed the influence of age and gender on these rates.

Results: In our study, we analyzed a cohort of 71,929 students aged 6 to 16 years, comprising 36,304 boys and 35,625 girls. Using the DOPSS criteria, 5,140 individuals displayed psychotic symptoms, translating to a prevalence rate of 7.15% (95% Confidence Interval: 6.96-7.34). Notably, boys exhibited a higher prevalence at 7.46%, in contrast to 6.83% in girls (p LESS THAN 0.05). As for age impact, we observed a consistent yearly rise in the prevalence of psychotic symptoms from ages 6 to 16 (p LESS THAN 0.05), peaking at 12.6% for 15-year-olds. Of the cohort, only 31 were diagnosed with early-onset psychosis, leading to a prevalence rate of 0.04% (95% Confidence Interval: 0.03-0.06).

Discussion: This study represents the inaugural epidemiological exploration into the prevalence of early-onset psychosis in China, which stands at 0.04%. Additionally, our research revealed that 7.15% of Chinese children and adolescents exhibit psychotic symptoms. Notably, these symptoms are more prevalent in boys compared to girls, with a peak incidence observed at 15 years of age. Such insights are pivotal for the refinement of early screening and intervention strategies for early-onset psychosis.

83. PROFILING THE CONTRIBUTION OF COGNITION AND PERSONALITY TO PSYCHOSIS PRONENESS COURSE IN YOUNG ADULTS VIA INDIVIDUAL ENVIRONMENTAL LOADINGS

Alessandra Raio^{*1}, Linda Antonella Antonucci¹, Julian Wenzel², Alessandro Bertolino¹, Lana Kambeitz-Illankovic², Joseph Kambeitz², Giulio Pergola³

¹University of Bari Aldo Moro, ²University of Cologne, ³John Hopkins University

Background: Lifetime estimates of transient psychotic-like experiences (PLEs) involve about 15% of the healthy population. While clinically significant psychosis onset peaks in young adulthood, PLEs decrease from childhood onwards. Their persistency after childhood is associated with a fourfold increased risk of psychosis onset within the age stage from early adolescence to young adulthood. Neurodevelopmental changes in this time window may shape behavioral development, resulting in dysfunctional personality traits and low cognitive functioning. Here, we investigated how specific cognitive and/or personality patterns are intertwined over time with the cumulative exposure to environmental factors contributing to psychosis risk. We derived cognitive and personality functioning profiles in a longitudinal study. We assessed the influence of the individual cumulative load of environmental-related psychosis risk on adult PLEs measured in a naturalistic cohort.

Methods: Based on data availability, a sample of 666 participants recruited by the IMAGEN consortium was selected and included 313 males and 353 females assessed across 4 time points (Baseline-BL: 13-15 years; Follow-Up 1-FU1: 16,17 years; FU2: 18-20 years; FU3: 21-24 years). K-means clustering algorithms were separately applied to cognitive and personality data collected at BL and FU2 to identify time-specific profiles of behavioral functioning. The selected features included 22 performance scores evaluating decision-making (DM) subdomains for cognition, and 14 scores evaluating personality and temperament traits. Longitudinal cluster stability was evaluated via permuted Jaccard Index (JI) computation. We modeled the cumulative environmental risk load on PLEs levels, assessed at FU3, via Random Forest Regression (RFR), including 41 sum predictors, each evaluating substance use and stressful life events occurrence across FU1, FU2, and FU3. ANOVA and correlation analyses served to test the association of cluster assignments and cluster prototypicality, respectively, with RFR individual predictions and with the feature most contributing to RFR performance.

Results: At both BL and FU2, two cognitive clusters grouped individuals for good or poor DM scores. Three personality clusters separated “easy-going” (prone to sociability), “impulsive explorers” (novelty-seekers), and “self-focused” individuals. Although individuals changed

cluster assignments over time (all real JIs: 0.29-0.52), the overall clusters' membership reproducibility was above the chance level for all subgroups (p LESS THAN 0.001). The RFR model based on the longitudinal predictors of environmental risk predicted FU3 PLEs severity with an accuracy of 81% (Mean Percentage Absolute Error=0.19). Cumulative distress was the feature most contributing to predictive performance. At BL and FU2, only a main effect of personality cluster assignment on both PLEs environmental risk load and cumulative distress (all p LESS THAN 0.01) was significant. Environmental risk load on adult PLEs was also negatively associated with individual prototypicality for the easy-going cluster at BL ($\rho=-0.154$; $p=0.02$) and positively for the self-focused cluster at FU2 ($\rho=0.31$; p LESS THAN 0.001).

Discussion: Our data-driven behavioral subtyping of adolescent behavioral functioning at different age stages revealed a differential role of specific personality patterns in contributing to the longitudinal life stressors- and substance use-related burden on adult PLEs. No significant effect of DM styles was found. Personality functioning may therefore be a potential target of early intervention aimed at softening the environmental contribution to subthreshold symptoms' severity.

84. REGIONAL SPECIFICITY OF MORPHOMETRIC SIMILARITY NETWORK ALTERATIONS IN SUBGROUPS OF YOUTH AT CLINICAL HIGH RISK FOR PSYCHOSIS

Gil Hoftman^{*1}, Jakob Seidlitz², Jennifer K. Forsyth³, Charles Schleifer¹, Dylan Hughes¹, Jean Addington⁴, Kristin S. Cadenhead⁵, Barbara A. Cornblatt⁶, Daniel H. Mathalon⁷, Diana O. Perkins⁸, Ming T. Tsung⁵, Scott W. Woods⁹, Elaine F. Walker¹⁰, Tyrone D. Cannon⁹, Carrie E. Bearden¹

¹*Semel Institute for Neuroscience and Human Behavior at UCLA*, ²*Children's Hospital of Philadelphia; University of Pennsylvania*, ³*University of Washington*, ⁴*University of Calgary*, ⁵*University of California, San Diego*, ⁶*The Zucker Hillside Hospital*, ⁷*University of California San Francisco, California*, ⁸*University of North Carolina*, ⁹*Yale University*, ¹⁰*Emory University*

Background: Given increasing recognition that psychosis onset is a late stage of a neurodevelopmental illness, and the importance of early intervention, efforts are focused on understanding the pathophysiology of early stages of psychosis. Here we characterize morphometric similarity networks (MSNs), which measure within-subject structural similarity between cortical areas, using baseline structural brain imaging measures in subjects at clinical high-risk (CHR) who converted (CHRC; "converters") or did not convert (CHRCnc; "non-converters") to psychosis, relative to unaffected comparison subjects. We further investigate those subjects who did not convert but remained symptomatic (CHRCncs; "sustainers") and those whose symptoms remitted (CHRCncr; "remitters"). We incorporate postmortem transcriptomic data from the Allen Human Brain Atlas (AHBA) to relate transcriptomic and MSN cortical spatial patterns.

Methods: MRI data were available for 757 subjects from the NAPLS2 cohort at baseline, including 71 CHRC, 467 CHRCnc, and 219 unaffected comparison subjects (Age [Mean, SD]: 19.2 +/- 4.4 years old; Sex: M=58%, F=42%). For CHRCnc subgroup analysis, data were available for 220 CHRCncs and 87 CHRCncr subjects. In one analysis to increase the sample size of symptomatic CHR subjects, the 71 CHRC and 220 CHRCncs were combined to form the CHRCs group (converters and sustainers). MSNs, which represent the sum of inter-regional associations, were constructed from 7 structural MRI measures including volume, cortical thickness, surface area, and 4 curvature indices. MSNs were adjusted for site effects using

neuroCombat. MSN group differences were determined using ANOVA with FDR correction for multiple comparisons and accounting for covariates of age, sex, and site. Microarray data from the AHBA were related to MSNs using partial least squares (PLS) regression and gene ontology (GO) pathway analysis was used to annotate correlated gene groups. We used a modified granular version of the Desikan-Killiany cortical surface parcellation, consisting of 308 regions of interest.

Results: Baseline difference maps between CHR vs. unaffected comparison subjects showed significant increases in MSN degree in 17 posterior visual areas and decreases in 14 anterior frontal and temporal areas in CHR youth (all FDR $p < 0.05$). CHRcs showed significant increases in 3 posterior visual areas and decreases in 4 anterior frontotemporal areas, relative to unaffected comparison subjects (all FDR $p < 0.05$). No significant differences were observed between CHRnc vs. CHRc or between CHRcs vs. CHRncr. For the PLS regression analysis, we modeled effect sizes across cortical regions to examine regional differences in MSNs between CHR vs. unaffected comparison subjects and related them to regional gene expression from the AHBA. PLS component 1 (PLS1) for the MSN model explained 13.5% of the covariance between regional CHR vs. unaffected comparison subject MSN effect sizes and gene expression. Key markers of synaptic neurotransmission, including parvalbumin, GABAA receptor subunit delta, and sodium and potassium channel subunits were in the top 2% of PLS1 loadings. Functional annotation of all genes in the top 5% of loadings on PLS1 were associated with synaptic signaling, including glutamate, GABA and endocannabinoid signaling.

Discussion: These findings suggest that baseline differences in MSN topology between individuals at CHR for psychosis and unaffected comparison subjects cluster in specific cortical areas, are identifiable at the baseline MRI scan, and associate with markers of GABA neurotransmission and synaptic transmission-related biological pathways.

85. COURSE OF CLINICAL HIGH-RISK SYMPTOMS FOR PSYCHOSIS IN THE COMMUNITY: A LATENT CLASS ANALYSIS WITH A FOCUS ON MOVEMENT BETWEEN SUBGROUPS OVER TIME

Miriam Stübke¹, Naweed Osman², Giulia Rinaldi³, Benno G. Schimmelmann⁴, Jochen Kindler³, Frauke Schultze-Lutter⁵, Chantal Michel³

¹University of Bern, ²Medical Faculty, Heinrich-Heine-University Düsseldorf, ³University Hospital of Child and Adolescent Psychiatry and Psychotherapy, University of Bern, ⁴University Hospital of Child and Adolescent Psychiatry and Psychotherapy, University of Bern, University Hospital of Child and Adolescent Psychiatry, University Hospital Hamburg-Eppendorf, ⁵University Hospital of Child and Adolescent Psychiatry and Psychotherapy, University of Bern, Medical Faculty, Heinrich-Heine-University Düsseldorf, Airlangga University, Surabaya

Background: Typically, studies of the longitudinal course of clinical high-risk (CHR) for psychosis symptoms have focussed on transition rates to manifest psychosis (mostly in help-seeking samples). However, more recent research considers clinical presentation over time, regardless of transition. Moreover, given the heterogeneity in clinical presentation of CHR symptoms, it is important to identify homogenous clinical profiles. The aim of this study was to ascertain clinical profiles of individuals in the community presenting with CHR symptoms and to examine them longitudinally.

Methods: Participants (N=829) comprised individuals from a Swiss community sample. Latent Class Analysis was applied to baseline and follow-up (FU) CHR symptom data, and class profiles were characterised across demographic and clinical variables.

Results: The best fit was the 3-class solution for both time points. Baseline: Class 1 (n=19; most impaired, persecutory ideas, cognitive basic symptoms, derealisation); Class 2 (n=25; intermediate impaired; unusual thought content, disorganized communication); and Class 3 (n=785; least impaired; low CHR probability). Follow-up: FU Class 1 (n=27; most impaired; unusual thought content, attenuated hallucinations, derealisation); FU Class 2 (n=52; intermediate impaired; perceptual abnormalities and cognitive basic symptoms); and FU Class 3 (n=750; least impaired, low CHR probability). Overall, there was some movement between all groups over time.

Discussion: Findings provide a more nuanced view of CHR symptoms in the community and their associated clinical presentation and course over time. Findings can also be used to inform psychoeducation regarding the course of CHR and associated symptoms.

Oral Session: New Pharmacological Treatments and Assessments

86. LINGUISTIC RISK SCORE FOR SCHIZOPHRENIA: APPLYING A POLYGENIC RISK APPROACH TO SYNTHESIZE MULTIVARIATE FEATURES FROM COMPUTATIONAL SPEECH AND LANGUAGE ANALYSIS

Sunny Tang*¹, Amir Nikzad¹, Michael Spilka², Yan Cong¹, Leily Behbehani¹, Sarah Berretta¹, John Kane¹, Anil K. Malhotra¹

¹Zucker Hillside Hospital, ²Winterlight Labs

Background: Computational speech analysis offers powerful methods to objectively quantify linguistic signals which can reflect the mental state of the speaker. A wide range of features can be generated to describe linguistic content: e.g., parts of speech, phrase structure, semantic coherence, graph metrics, tempo, and lexical properties, among others. These features can be analyzed in different ways, e.g., with moving windows of varying sizes, verbatim vs. filtered content, etc., and using language collected from different tasks, e.g., picture description, open-ended narratives, fluency tasks, etc. Taken together, studies employing computational speech and language analysis can easily accumulate thousands of features. Understanding and accounting for this large feature space is a prominent challenge in this field. Here, we take an analogous approach to the calculation of polygenic risk scores to first identify candidate features associated with schizophrenia diagnosis, and then calculate a single weighted sum to represent the individual's "Linguistic Risk Score" (LRS). We hypothesized that the LRS would demonstrate intermediate effects in non-psychotic psychiatric disorders, and that within individuals with schizophrenia spectrum disorders (SSD), the LRS would demonstrate both state and trait-like characteristics.

Methods: Three samples were included. Sample 1 was the training sample and included 52 healthy control (HC) and 85 SSD participants, with no significant differences in age, gender, race, or ethnicity between groups. Sample 2 was an independent cross-diagnostic test sample, including 21 randomly set-aside SSD participants, 81 participants with unipolar depression, 40 with bipolar disorder, and 22 with mood disorders with psychotic features. Sample 3 included an overlapping sample of 62 participants with SSD with up to 4 timepoints of longitudinal follow-up. Psychosis symptoms were assessed dimensionally with the Brief Psychiatric Rating Scale (BPRS).

To calculate the LRS from 1227 computational speech and language features, we first selected features which were significantly different between groups in Sample 1 and calculated a weighting factor based on the effect size. Because many features were non-parametric, the group comparison was conducted using the Mann-Whitney U test, and the effect size was calculated using Cliff's Delta. Next, for each feature in each subject, a normalized rank score ranging from -1 to 1 was computed relative to the HC training sample, such that the test subject received a -1 if they scored lower than all HC subjects, 0 if they scored at the median, +0.50 if they scored at the 75%, and +1 if they scored higher than all HC subjects, etc. The normalized rank score was multiplied by the weighting factor for each feature, then summed across all features for each participant.

Group comparisons were made using ANOVA with pairwise effects calculated with t-tests (p values corrected using FDR). Between-subject dimensional relationships to psychosis symptom dimensions were calculated with linear regressions. To assess within-individual relationships between psychosis symptoms and LRS, we examined linear mixed models with random slopes and random intercepts by participant.

Results: LRS was calculated for p-value thresholds of 0.01, 0.05 and 0.10. In each case, we first verified that the HC LRS was centered at 0 and the SSD training sample produced a significantly elevated LRS. Comparing the HC sample to the independent cross-diagnostic test samples, we found elevated LRS for all of the psychiatric groups at all of the p-value thresholds, with marginally larger effect sizes for p LESS THAN 0.01. Here, LRS in all groups was significantly elevated relative to HC with p LESS THAN 0.001 (Cohen's d: Unipolar = 1.45, Bipolar = 1.75, Mood with psychosis = 2.18, SSD = 2.33). LRS in the psychosis groups were significantly elevated relative to unipolar depression (Mood with psychosis: p=0.02, d=0.61; SSD: p=0.03, d=0.61). There was no difference in LRS between the SSD and mood with psychosis groups, and trend level differences between these and the bipolar disorder group. Cross-sectionally, higher BPRS total score was associated with higher LRS between subjects (Std. Beta = 0.28, p=0.03). Longitudinally, accounting for random effects in slope did not improve the prediction of LRS based on BPRS total score over the random intercept model. Here, we found significant values for the overall intercept (i.e., LRS when there are no active psychosis symptoms; Beta=4.06, p LESS THAN 0.001), the fixed effect of BPRS score (i.e., average relationship between LRS and BPRS; Beta=0.08, p LESS THAN 0.001), and the random effects for subject (95% CI of standard deviation: 0.96-2.29).

Discussion: We successfully calculated a LRS to summarize SSD-related effects across 1227 computational speech and language features at p-value thresholds of 0.01, 0.05 and 0.10. The LRS demonstrated expected cross-diagnostic group differences, with the highest scores in SSD and mood disorders with psychotic features, and intermediate scores in unipolar depression. For individuals with SSD, LRS appears to demonstrate both state- and trait-like effects: LRS is elevated at baseline (i.e., even when psychosis-free), and further increases with greater psychosis severity.

87. DETECTING SCHIZOPHRENIA, BIPOLAR DISORDER, PSYCHOSIS VULNERABILITY AND MAJOR DEPRESSION FROM 5 MINUTES OF ONLINE COLLECTED SPEECH

Julianna Olah^{*1}, Win Lee Edwin Wong², Atta-ul Raheem Rana Chaudhry³, Sunny X Tang⁴

¹King's College London, ²King's College London, Psyrin Ltd., ³Psyrin Ltd., ⁴Institute of Behavioral Science, Feinstein Institutes for Medical Research; Donald and Barbara Zucker School of Medicine at Hofstra/Northwell

Background: Psychosis, characterised by a disconnection from reality, hallucinations, and delusions, poses substantial social and healthcare burdens. The analysis of speech is a promising approach for the diagnosis and monitoring of psychosis, capturing symptoms like thought disorder and flattened affect. Recent advancements in Natural Language Processing methodologies enables the automated extraction of informative speech features, which has been leveraged for early psychosis detection and assessment of symptomology. However, critical gaps persist, including the absence of standardized sample collection protocols, small sample sizes, and a lack of multi-illness classification, limiting clinical applicability.

Methods: We adopted online data collection methods to collect 20 minutes of speech and demographic information from individuals. Participants were given labels of “healthy”, schizophrenia, bipolar, depression, and prodromal psychosis based on self-reported clinical diagnosis and responses to the PHQ-8 and PQ-16 screening questionnaires. Text-based and paralinguistic features were extracted and ensemble learning algorithms were used to train models. A mix of cross-validation approaches and a 70%-30% test-train split were used.

Results: The final analysis sample comprised 1140 individuals and 22,650 minutes of speech. Using 5-minutes of speech, our model could discriminate between healthy individuals and psychosis individuals with 90% accuracy (AUC = 0.94, Recall = 0.83, Precision = 0.96). Furthermore, our model could discern between healthy, prodromal, bipolar and schizophrenia groups with 86% accuracy (F1 macro = 0.855, Recall Macro = 0.86, Precision Macro = 0.86). Finally in a 5-class discrimination task including individuals with depression, our model had 76% accuracy (F1 macro = 0.757, Recall Macro = 0.758, Precision Macro = 0.766).

Discussion: In summary, our ML pipeline demonstrated disorder-specific learning, achieving excellent accuracy across several classification tasks. We demonstrated that the screening of mental disorders is possible via a fully automated, remote speech assessment pipeline. First in literature, we tested our model on the highest number of classes of conditions (5 classes) and in a stratified sample of healthy control, psychosis vulnerability and two types of psychotic disorders (4 classes). We tested our model on the largest sample in the literature (N = 1150) and demonstrated best-in-class accuracy with remotely collected speech data in the psychosis spectrum.

88. THE IMPACT OF KARXT ON COGNITIVE IMPAIRMENT IN ACUTE SCHIZOPHRENIA: REPLICATION IN POOLED DATA FROM PHASE 3 TRIALS

William Horan^{*1}, Colin Sauder¹, Philip D. Harvey², Ian S. Ramsay¹, Steven M. Paul¹, Stephen K. Brannan¹

¹Karuna Therapeutics, Inc., ²University of Miami Miller School of Medicine

Background: KarXT is an M1 /M4 preferring central muscarinic receptor agonist based on xanomeline, which has been shown to improve cognition in psychiatric populations. The phase II EMERGENT-1 (NCT03697252) trial demonstrated that KarXT monotherapy improved cognition in a subgroup of acute schizophrenia inpatients with clinically significant cognitive impairment, but not in the entire sample. We sought to replicate this finding using pooled data from two similarly designed phase III trials.

Methods: The EMERGENT-2 (NCT04659161) and EMERGENT-3 (NCT04738123) studies were randomised, double-blind, placebo-controlled, 5-week inpatient trials of KarXT monotherapy in schizophrenia participants experiencing acute psychosis. Cognition was

assessed at baseline, week-3, and week-5 using the CANTAB computerised battery. Pre-specified analyses compared change from baseline on cognitive composite scores between KarXT and placebo in the full sample and, based on phase II findings, in a subsample of participants performing at least 1 standard deviation below healthy comparison norms on the CANTAB at baseline. Linear regression assessed the relation between change in cognition and Positive and Negative Syndrome Scale (PANSS) scores.

Results: There was no significant treatment effect for KarXT (N=150) vs. Placebo (N=157) in the full sample. However, in the impaired subgroup, participants taking KarXT (N=71) again showed significantly greater improvement in cognition compared to Placebo (N = 66; LSM Difference $\pm$ SE=0.31 $\pm$ 0.10; p = .004; d = 0.54). A significantly larger proportion of those who received KarXT (45.2%) compared to placebo (17.2%) achieved a 0.50 SD improvement (X^2 [1, N = 120] = 10.80, p LESS THAN .001). Change in cognition did not significantly relate to improvement in PANSS total, positive, or negative symptom scores (p s GREATER THAN 0.15).

Discussion: These clinical studies with KarXT constitute the first time that a cognitive benefit found in a phase II trial has been replicated in phase III. The KarXT benefit in a subgroup of acute schizophrenia participants with clinically significant cognitive impairment was not attributable to changes in clinical symptoms, despite substantial evidence of efficacy for psychosis. The replicable findings across phase II and III trials warrant further prospective investigation in clinically stable patients, enriched for cognitive impairment, to fully characterize the effects of KarXT on cognitive impairment associated with schizophrenia (CIAS).

89. LONG-TERM SAFETY AND EFFICACY OF OLANZAPINE/SAMIDORPHAN: RESULTS OF A 4-YEAR OPEN-LABEL STUDY

Jacob Ballon¹, Rene Kahn², Christina Arevalo³, Martin Dunbar³, David McDonnell⁴, Christoph Correll⁵, René Kahn*²

¹Stanford University, ²Icahn School of Medicine at Mount Sinai, ³Alkermes, Inc., ⁴Alkermes, ⁵Zucker Hillside Hospital; Donald and Barbara Zucker School of Medicine at Hofstra/Northwell, Hempstead; Charité Universitätsmedizin

Background: This study evaluated the long-term safety, tolerability, and durability of effect of olanzapine/samidorphan (OLZ/SAM).

Methods: This phase 3, multicenter, open-label extension study assessed the long-term safety and efficacy of up to 4 years of OLZ/SAM in patients who completed the following OLZ/SAM trials: 52-week open-label studies NCT02873208 and NCT02669758, which were rollover extensions of phase 3 pivotal randomized controlled trials in adults with schizophrenia (SZ), and NCT03187769 in young adults with recent-onset SZ, schizophreniform disorder, or bipolar I disorder (BD-I). Depending on geography and enrollment date, patients in the current long-term study had the opportunity to receive up to 2 to 4 years of treatment. Safety assessments included the incidence of adverse events (AEs) and changes from baseline in body weight and waist circumference. Changes in lipid (high-density lipoprotein [HDL], low-density lipoprotein [LDL], and total cholesterol and triglycerides) and glycemic (glucose and glycosylated hemoglobin [HbA1c]) parameters were also evaluated. Antipsychotic efficacy was assessed with the Clinical Global Impressions–Severity (CGI-S) scale.

Results: Of 524 patients enrolled in the study, 523 received ≥ 1 dose of OLZ/SAM. 188 (35.9%) patients completed between 2 to 4 years of treatment. The mean (SD) duration of exposure was 652.4 (454.8) days. Among 451 patients who were eligible to receive at least 2

years of treatment, 242 (53.7%) received ≥ 2 years of treatment. Among 335 patients who were eligible to receive 4 years of treatment, 109 (32.5%) received 4 years of treatment. In the treated population, patients were mostly male (61.6%) and White (72.7%), with a mean (SD) age of 35.1 (12.2) years. Overall, 60.0% of patients reported at least one AE; the most common were weight increased (9.8%), headache (7.1%), anxiety (6.1%), insomnia (5.9%), somnolence (5.9%), nausea (5.7%), and weight decreased (5.7%). For patients who contributed data to the 2-year assessment (n=238), mean (SD) change from baseline in body weight was 0.84 (6.84) kg and waist circumference was -0.56 (6.24) cm. For patients who contributed data to the 4-year assessment (n=108), the mean (SD) change from baseline in body weight was 2.65 (8.12) kg and waist circumference was 1.37 (8.65) cm. Lipid and glycemic parameters were generally stable over the treatment period. Patients' symptoms remained stable—for patients contributing data at 2 years, mean (SD) change from baseline in CGI-S was -0.18 (0.67) and for those at 4 years was -0.24 (0.65).

Discussion: In this 4-year open-label extension study, treatment with OLZ/SAM resulted in a safety profile consistent with previous short-term studies and was associated with small changes in body weight and minimal changes in waist circumference and lipid and glycemic parameters. Similarly, OLZ/SAM maintained symptom control during long-term treatment. Based on these results, OLZ/SAM maintained long-term antipsychotic efficacy while mitigating the weight gain and metabolic dysfunction associated with olanzapine.

This study was funded by Alkermes, Inc. Medical writing and editorial support were provided by Peloton Advantage, LLC, an OPEN Health company, and funded by Alkermes, Inc.

90. EFFICACY AND SAFETY OF BREXPIPIRAZOLE IN ADOLESCENTS (AGED 13–17 YEARS) WITH SCHIZOPHRENIA: A PHASE 3, 6-WEEK, RANDOMIZED, DOUBLE-BLIND, PLACEBO-CONTROLLED AND ACTIVE-REFERENCED TRIAL

Caroline Ward^{*1}, Milica Pejović Milovančević², Eva Kohegyi¹, Marianne Dragheim³, Catherine Aurang¹, Dalei Chen¹, Klaus Groes Larsen³, Mary Hobart¹, Christoph Correll⁴

¹Otsuka Pharmaceutical Development and Commercialization Inc., ²Faculty of Medicine, University of Belgrade; Institute of Mental Health, Belgrade, ³H. Lundbeck A/S, ⁴The Zucker Hillside Hospital; The Donald and Barbara Zucker School of Medicine at Hofstra/Northwell; Charité-Universitätsmedizin Berlin, Corporate Member of Freie Universität Berlin, Humboldt-Universität zu Berlin, and Berlin Institute of Health

Background: Schizophrenia onset in childhood/early adolescence can be associated with more chronic and severe symptoms, and poorer prognosis, compared with adult onset. Brexpiprazole is approved for the treatment of schizophrenia in adults and in adolescents aged ≥ 13 years (US and other countries). Existing approvals of brexpiprazole in adolescents were based on data extrapolation from adult studies, pharmacokinetic data, and interim data from a long-term, open-label adolescent study (includes patients from the present trial). This 6-week trial evaluated the efficacy and safety of brexpiprazole in adolescents with schizophrenia.

Methods: This was a Phase 3, 6-week, randomized, double-blind, placebo-controlled, active-referenced trial of brexpiprazole in adolescents with schizophrenia (NCT03198078), conducted June 2017 – April 2023 at 62 sites in 10 countries. Eligible patients were aged 13–17 years, with a diagnosis of schizophrenia (DSM-5 criteria; for ≥ 6 months prior to screening; confirmed by the Kiddie Schedule for Affective Disorders and Schizophrenia-Present and Lifetime version), and a Positive and Negative Syndrome Scale (PANSS) Total score ≥ 80 at screening and baseline. Patients were randomized 1:1:1 to brexpiprazole 2–4 mg/day, placebo, or

aripiprazole 10–20 mg/day (active reference to validate study methodology and patient population). The primary efficacy endpoint was change from baseline to Week 6 in PANSS Total score. Safety assessments included treatment-emergent adverse events (TEAEs), discontinuations due to AEs, and body weight. The safety sample comprised all randomized patients who received ≥ 1 dose of assigned treatment. The efficacy sample comprised all safety sample patients who had a baseline and ≥ 1 post-baseline PANSS Total evaluation.

Results: 316 patients were randomized to brexpiprazole (n=110), placebo (n=104), or aripiprazole (n=102); completion rates were 97.3%, 88.5%, and 95.1%, respectively. The safety sample comprised all 316 randomized patients. The efficacy sample comprised 314 patients (brexpiprazole, n=110; placebo, n=103; aripiprazole, n=101). Baseline characteristics were similar between groups (mean [SD] PANSS Total scores: brexpiprazole, 101.1 [14.9]; placebo, 102.1 [16.3]). The least squares (LS) mean (standard error) change from baseline to Week 6 in PANSS Total score (primary endpoint) was -22.75 (1.49) with brexpiprazole and -17.42 (1.58) with placebo (LS mean difference: -5.33 [95% confidence interval: -9.55, -1.10]; $p=0.0136$). The aripiprazole group also separated from placebo on the primary endpoint at Week 6, thus validating the study methodology and patient population. Over 6 weeks, the incidence of TEAEs was 40.0% (brexpiprazole), 40.4% (placebo), and 52.0% (aripiprazole). The most common TEAEs with brexpiprazole (incidence $\geq 5\%$) were headache (6.4%; placebo, 4.8%; aripiprazole, 4.9%) and nausea (6.4%; placebo, 3.8%; aripiprazole, 3.9%). With aripiprazole, the most common TEAEs were somnolence (10.8%; brexpiprazole, 4.5%; placebo, 4.8%), fatigue (7.8%; brexpiprazole, 1.8%; placebo, 0.0%), and akathisia (6.9%; brexpiprazole, 3.6%; placebo, 2.9%). There were no discontinuations due to AEs with brexpiprazole (placebo, n=2; aripiprazole, n=1). The mean (SD) change from baseline to last visit in body weight (kg) was 0.8 (2.6), 0.0 (2.2), and 0.5 (2.7) with brexpiprazole, placebo, and aripiprazole, respectively.

Discussion: In this 6-week, Phase 3 study of adolescents aged 13–17 years with schizophrenia, treatment with brexpiprazole 2–4 mg/day was associated with greater reduction in symptom severity versus placebo. The safety profile of brexpiprazole was consistent with that observed in adults with schizophrenia.

91. A PHASE 3, RANDOMIZED, DOUBLE-BLIND, PLACEBO-CONTROLLED STUDY TO EVALUATE THE EFFICACY AND SAFETY OF PIMAVANSERIN AS ADJUNCTIVE TREATMENT FOR THE NEGATIVE SYMPTOMS OF SCHIZOPHRENIA (ADVANCE-2)

Dragana Bugarski-Kirola*¹, I-Yuan (Cathy) Liu², Celso Arango³, Stephen R. Marder⁴

¹ACADIA Pharmaceuticals, Inc., ²ACADIA Pharmaceuticals Inc., ³Child and Adolescent Psychiatry Department, Hospital General Universitario Gregorio Marañón School of Medicine, Universidad Complutense, IiSGM, CIBERSAM. Madrid, Spain, ⁴University of California, Los Angeles, Semel Institute for Neuroscience

Background: Negative symptoms of schizophrenia (NSS) are associated with substantial burden and adverse clinical outcomes, yet few treatments are available. Evidence suggests 5-hydroxytryptamine (5-HT) 2A receptor inverse agonism may be an effective mechanism to treat NSS. Pimavanserin is a selective 5-HT_{2A} receptor inverse agonist/antagonist with low affinity for 5HT_{2C} and no affinity for dopaminergic, adrenergic, muscarinic, or histaminergic receptors. The phase 3 ADVANCE-2 study evaluated the efficacy and safety of pimavanserin as an adjunctive treatment for NSS.

Methods: ADVANCE-2 (NCT04531982) is a 26-week, phase 3, randomized, double-blind, placebo-controlled, multicenter, multinational, outpatient study in patients with schizophrenia and predominant NSS (i.e., negative symptoms of greater severity than positive symptoms). Operationally, negative symptoms were defined at Screening and Baseline based on the Positive and Negative Syndrome Scale (PANSS) Marder negative factor items as a score ≥ 20 on the sum; a score ≥ 4 on at least 3, or ≥ 5 on at least 2 of the items; and a Clinical Global Impression of Schizophrenia Scale–Severity (CGI-SCH-S) negative symptom score ≥ 4 (moderately ill or worse). Minimal positive symptoms were defined at both Screening and Baseline based on the PANSS Marder positive factor items as a score ≤ 22 on the sum and a score where ≤ 2 of the following items have a score of 4 and none had a score ≥ 5 : P1 (delusions), P3 (hallucinatory behavior), P4 (excitement), P6 (suspiciousness/persecution), and P7 (hostility).

Eligible patients were adults with a diagnosis of schizophrenia (≥ 1 year prior to Screening) according to the DSM-5 criteria and confirmed using the Structured Clinical Interview for DSM-5, Clinical Trials Version (SCID-5-CT). Patients were required to have a caregiver to ensure study compliance and to have been receiving an adequate dose of an antipsychotic from a select list (not including clozapine) for ≥ 8 weeks prior to Screening. Patients with a concurrent psychiatric diagnosis other than schizophrenia were excluded. After screening (≤ 6 weeks), patients were randomized (1:1), stratified by geographic region, to receive pimavanserin (34 mg/day) or placebo. The study's primary objective was to evaluate the efficacy of adjunctive pimavanserin versus placebo for the change from Baseline to Week 26 in the Negative Symptom Assessment–16 (NSA-16) total score.

The key secondary endpoint was the change from Baseline to Week 26 for the CGI-SCH-S negative symptom score. Other secondary endpoints included the Clinical Global Impression of Schizophrenia Scale–Improvement (CGI-SCH-I) negative symptom score at Week 26 and the change from Baseline to Week 26 for the Personal and Social Performance (PSP) scale score, PANSS total score, PANSS negative subscores, and PANSS Marder factor (negative symptoms) score. Week 26 responder analyses included the proportion of negative symptom responders defined using CGI-SCH-I (i.e., negative symptoms score of 1 or 2) and NSA-16 (i.e., $\geq 20\%$ and $\geq 30\%$ reduction in total score). Safety and tolerability were also assessed.

Results: As of August 15, 2023, a total of 671 patients have been screened and 454 have been randomized to treatment. A total of 217 (32.3%) patients failed screening. Results for the primary and secondary study endpoints will be available in March 2024 and will be presented for the first time at the Schizophrenia International Research Society (SIRS) 2024 meeting.

Discussion: ADVANCE-2 has recruited and randomized a sufficient number of patients (i.e., per power analyses) to detect a true treatment difference in the primary efficacy variable. Results will be presented at the upcoming 2024 SIRS congress.

92. INITIATION REGIMENS FOR LONG-ACTING INJECTABLE ANTIPSYCHOTICS REQUIRING ORAL SUPPLEMENTATION: IMPACT ON SUBSEQUENT MAINTENANCE TREATMENT ADHERENCE AND PERSISTENCE

Stephen Thompson¹, Handing Xie¹, Robert DiEgidio¹, Sangtaeck Lim¹, Kelli R. Franzenburg², Stephen Thompson*³

¹Teva Branded Pharmaceutical Products R and D, Inc., Global Medical Affairs, ²Teva Branded Pharmaceutical Products R and D, Inc., ³Teva Pharmaceutical Industries, Ltd.

Background: Medication adherence and persistence are major challenges in the management of schizophrenia. Nonadherence is a modifiable risk factor for relapse and contributes to poor health outcomes. Long-acting injectable antipsychotics (LAIs) with complex initiation regimens may result in reduced treatment adherence and persistence (Semahegn A, et al. Syst Rev. 2020;9:17). This analysis characterized maintenance treatment adherence and persistence for patients who followed the initiation regimen (requiring oral supplementation) versus patients who did not, based on FDA-approved prescribing information for an intramuscular (im) LAI formulation of risperidone microspheres administered once every 2 weeks (q2w).

Methods: Patients diagnosed with schizophrenia in the United States (US) were identified using the MarketScan® Commercial and Medicare Supplemental claims databases during the study period between January 1, 2013, and June 30, 2021. Patients were included if they were aged ≥ 18 years with ≥ 1 im risperidone microspheres q2w claim during the study period (date of the first claim was defined as the index date). Patients were excluded if they had any LAI claims during the 12-month pre-index period. Prescribing information for im risperidone microspheres q2w requires supplementation with 21 days of an oral antipsychotic during initiation. Patients were regarded as not following the initiation regimen if they were not treated according to the prescribing information. Propensity score matching (1:1) was used to match patients who followed the initiation regimen and those who did not. Patients were matched on gender, age, major depression diagnosis, number of antidepressant claims, US region, and payer type. Adherence with LAI treatment was measured using medication possession ratio (MPR) and proportion of days covered (PDC). Patients were considered adherent if MPR or PDC was ≥ 0.80 . One-year persistence was defined as the duration of index LAI treatment during the 12 months post index, allowing gaps of ≤ 15 days.

Results: Among 1958 patients with ≥ 1 im risperidone microspheres q2w claim, 278 met inclusion criteria. Of those patients who met criteria, 137 (49.3%) followed the initiation regimen based on the prescribing information. Propensity score matching identified 117 matched pairs of patients. Baseline characteristics were well balanced between those who followed the prescribing information and those who did not after matching: 68.4% versus 63.3% were male, respectively, and mean ages were 36.4 versus 38.8 years. Treatment adherence of index LAI (MPR; PDC) was higher among patients who followed the initiation regimen (mean [SD], 0.42 [0.36]; 0.39 [0.34]) versus those who did not (0.38 [0.34]; 0.35 [0.32]). In addition, MPR and PDC adherence rates were greater for patients who followed the prescribing information (26.5% and 22.2%, respectively) versus those who did not (21.4%, 16.2%). Mean (SD) persistence duration with maintenance treatment through the first year was also longer for those who followed the prescribing information (122.7 [126.3] days) versus those who did not (98.4 [115.8]).

Discussion: Following an LAI initiation regimen is found to be potentially associated with better maintenance treatment adherence and persistence. LAIs with less complex initiation regimens may increase adherence and persistence, and subsequently improve health outcomes (ie, prevent relapse and extend life expectancy) and help manage patients' schizophrenia symptoms more effectively.

93. LONG-TERM METABOLIC OUTCOMES ASSOCIATED WITH KARXT (XANOMELINE AND TROSPIUM): INTERIM RESULTS FROM POOLED, LONG-TERM SAFETY STUDIES EMERGENT-4 AND EMERGENT-5

Amy Claxton^{*1}, George Konis², Inder Kaul¹, Andrew C. Miller¹, Steven M. Paul¹, Stephen K. Brannan¹, Ronald Marcus¹

¹Karuna Therapeutics, ²Woodland International Research Group

Background: A high unmet medical need exists for more effective, better tolerated treatments for schizophrenia with novel mechanisms of action. Currently approved treatments for schizophrenia are associated with a variety of metabolic disturbances, including weight gain, hyperlipidemia, and increased risk of diabetes. All currently approved treatments for schizophrenia have D2 dopamine receptor blocking activity. KarXT, an investigational medication, combines the dual M1/M4 preferring muscarinic receptor agonist xanomeline and the peripherally restricted muscarinic receptor antagonist trospium chloride without blocking the D2 dopamine receptor. The efficacy and safety of KarXT in schizophrenia was demonstrated in the 5-week, randomized, double-blind, placebo-controlled EMERGENT-1 (NCT03697252), EMERGENT-2 (NCT04659161), and EMERGENT-3 (NCT04738123) trials. In these trials, KarXT was not associated with weight gain or adverse metabolic side effects compared to placebo. Long-term safety and tolerability of KarXT is currently being assessed in the Phase 3, multicenter, 52-week, outpatient, open-label extension EMERGENT-4 (NCT04659174) study and open-label EMERGENT-5 (NCT04820309) study in de novo participants without prior exposure to KarXT.

Methods: EMERGENT-4 and EMERGENT-5 trials enrolled participants with a diagnosis of schizophrenia. Participants had either rolled over from the short-term, pivotal trials (EMERGENT-4) or had stable symptoms of schizophrenia appropriate for outpatient care (EMERGENT-5). Eligible participants were dosed with KarXT (xanomeline/trospium) starting at 50 mg/20 mg twice daily (BID) and increased to a maximum of 125 mg/30 mg BID. Data from EMERGENT-4 and EMERGENT-5 trials were pooled and analyses were conducted in the safety population, defined as all participants who received ≥ 1 dose of KarXT. Participants had to discontinue previous antipsychotics prior to receiving KarXT. At the time of the data cut, 275 (41%) subjects remained ongoing in the study.

Results: At baseline, participants had a mean BMI of 29.7 and Hemoglobin A1c (HbA1c) of 5.8%, indicating that some baseline metabolic dysfunction was present. Participants had a mean reduction in weight after 24 weeks of treatment with KarXT, and a further mean reduction after 52 weeks of treatment. More participants experienced potentially clinically significant (PCS) decreases in weight ($\geq 7\%$ decrease) versus PCS increases in weight ($\geq 7\%$ increase) over the course of long-term treatment. Cholesterol remained stable, and fewer participants had PCS high cholesterol at their last assessment compared with baseline. Mean triglycerides decreased over the course of long-term treatment, with fewer subjects experiencing PCS high triglycerides at their last assessment compared with baseline. HbA1c remained stable over the course of treatment, with fewer participants reporting high HbA1c at their last assessment compared with baseline. Data are continuing to be recorded in these ongoing studies, and updated analyses will be available at the time of the meeting.

Discussion: The findings from pooled, long-term, open label studies of KarXT provide evidence that the promise of the short-term studies appears to hold up and treatment with KarXT is not associated with long-term metabolic disturbances in participants with schizophrenia. KarXT exhibits a long-term favorable metabolic profile, as participants experienced improvements or stability in all metabolic parameters over 52-weeks of treatment, including weight, cholesterol, and HbA1c.

Lunch and Poster Session I

T1. ASSOCIATIONS OF ANXIOUS, AVOIDANT, AND DISORGANIZED ATTACHMENT WITH MULTIDIMENSIONAL SCHIZOTYPY: FINDINGS FROM A MEXICAN SAMPLE

Tamara Sheinbaum*¹, Tecelli Domínguez¹, Ana Fresán¹, Lourdes Nieto¹, Rebeca Robles¹, Neus Barrantes-Vidal²

¹*Instituto Nacional de Psiquiatría “Ramón de la Fuente Muñiz”,* ²*Universitat Autònoma de Barcelona*

Background: A growing research literature has supported the relevance of attachment theory for understanding the risk for schizophrenia-spectrum psychopathology. In this context, the study of schizotypy is valuable since it encompasses a broad continuum of clinical and subclinical manifestations and shares a common multidimensional structure with schizophrenia. Although several studies have investigated links between attachment styles and schizotypy dimensions, few studies have included the assessment of disorganized attachment and disorganized schizotypy. Furthermore, the literature would be enhanced by a greater diversity of study populations since most work has been conducted with samples from high-income countries. Guided by these considerations, the present study examined the unique associations of anxious, avoidant, and disorganized attachment with multidimensional schizotypy in a Mexican sample.

Methods: Participants were 1,550 individuals (79.2% female; age range=15-45 years; mean age=29.5 years) from the Mexican general population who voluntarily agreed to participate in an online survey administered via Qualtrics software. Measures included the Revised Psychosis Attachment Measure, which measures anxious, avoidant, and disorganized attachment, and the Multidimensional Schizotypy Scale—Brief, which measures positive, negative, and disorganized schizotypy.

Results: Linear regressions were computed for each schizotypy dimension, with anxious, avoidant, and disorganized attachment subscales entered simultaneously as predictors to examine their unique contribution. These analyses indicated that anxious attachment was positively associated with positive and disorganized schizotypy and inversely associated with negative schizotypy; avoidant attachment was positively associated with negative and disorganized schizotypy; and disorganized attachment was positively associated with the three schizotypy dimensions.

Discussion: The results revealed differential links between attachment and schizotypy that are consistent with theory and prior evidence from the attachment and psychosis fields. Furthermore, although the study's cross-sectional nature limits inferences concerning developmental course, the findings align with theoretical models highlighting disorganized attachment as a prominent vulnerability factor for the development of schizophrenia-spectrum phenomenology. Overall, the results support the utility of the multidimensional model of schizotypy and the notion that attachment may provide a promising psychological mechanism for understanding the development and expression of the schizotypy dimensions across different cultural contexts.

T2. GREY MATTER MICROSTRUCTURE AT THE EARLY STAGES OF PSYCHOSIS

Mauricio Serpa*¹, Luciano Sanchez², Leonardo Queiroz³, Tania Maria Alves³, Leonardo de Jesus³, Natalia Haddad³, Julio de Andrade³, Andrea Jafet³, Arlete Modelli³, Naomi Antunes², Fabio Duran², Mario Louza⁴, Martinus van der Bilt³, Alexandre Loch³, Wagner Gattaz³, Geraldo Busatto²

¹*Institute of Psychiatry, University of Sao Paulo*, ²*Laboratory of Psychiatric Neuroimaging (LIM21), Department and Institute of Psychiatry, Faculdade de Medicina FMUSP, Universidade de Sao Paulo*, ³*Laboratory of Neuroscience (LIM27), Department and Institute of Psychiatry, Faculdade de Medicina FMUSP, Universidade de Sao Paulo*, ⁴*Schizophrenia Research Program (Projesq), Department and Institute of Psychiatry, Faculdade de Medicina FMUSP, Universidade de Sao Paulo*

Background: Abnormalities of grey matter (GM) morphology have been consistently reported across all phases of psychotic disorders and seem to intensify with their progression. However, less is known about GM tissue architecture in such medical conditions. We sought to study differences in GM microstructure in a cohort of clinical high-risk for psychosis (CHR) subjects and first-episode psychosis (FEP) patients using a new modelling tool applied to diffusion-weighted images (DWI) known as Neurite Orientation Dispersion and Density Imaging (NODDI).

Methods: In this preliminary analysis, we studied a total of 55 subjects, comprising 40 CHR subjects and 15 patients with first-episode psychosis (FEP). DWI data was acquired using a 3T MRI scanner and a multi-shell sequence. Following the preprocessing steps, which included distortions correction and semi-automated quality control of DWI, we extracted the average NODDI indexes from the whole GM compartment for each subject. Using GLM with FDR correction for multiple comparisons, we then run between-group comparisons of such metrics: Neurite Density Index (NDI), Orientation Dispersion Index (ODI) and Isotropic Volume Fraction (IVF). We also assessed the influence of symptom severity, global functioning, IQ, and potential confounding covariates (biological sex, age, and handedness) on GM microstructure.

Results: The groups differed in the Global Assessment of Functioning (GAF) scores (mean: CHR 64.6; FEP 46.2; $p < 0.001$). Between-group comparisons of NODDI metrics showed a reduction of ODI in the FEP relative to the CHR group. Results did not change when including the covariates in the analyses. ODI was directly associated with GAF scores in the whole-sample analysis ($R^2=0.112$, $pFDR < 0.05$), and such correlation was stronger when assessing the FEP group alone ($R^2=0.532$, $pFDR < 0.05$). Total PANSS scores were inversely correlated to ODI ($R^2=0.219$, $pFDR < 0.05$) in the FEP group.

Discussion: Our findings suggest that the GM microstructure might differ between the at-risk state and the first episode of psychosis. The extent to which this finding can be applied as a marker of transition in subject-level classification algorithms should be further investigated.

T3. BURDEN OF PHYSICAL ILLNESS IN SCHIZOPHRENIA: EXPLORING THE IMPACT OF SOCIODEMOGRAPHIC FACTORS ON RISK OF MULTIMORBIDITY

Brittany Gouse*¹, Tithi Baul², Sarah Syed³, Elijah Boliver⁴, Jennifer Lancet⁵, Hannah Brown²

¹*Boston University School of Medicine*, ²*Boston University School of Medicine*, ³*Tufts University*, ⁴*Boston University*, ⁵*Boston Medical Center*

Background: While the mortality rate due to suicide has decreased over the past 30 years among individuals with schizophrenia, mortality due to cardiovascular disease and cancer has moderately increased in this population during this time period. Factors such as antipsychotic-related cardiometabolic disease, higher rates of nicotine use, and reduced preventative healthcare use due to internalization of healthcare-associated stigma contribute to the high burden of chronic physical illness in schizophrenia spectrum disorders (SSD). Individuals with multiple serious chronic physical health conditions face a high risk of mortality. To close the premature mortality gap in schizophrenia, the identification of the populations at greatest risk of severe physical comorbidity is needed to inform the design of targeted interventions.

Methods: We retrospectively analyzed a cohort of patients with a SSD (defined as International Classification of Disease Code 10th edition codes of F20, F25, F28, F29) who had an outpatient, inpatient, or emergency department visit at an urban safety-net hospital in the Northeast United States between 2016-2022. The primary outcome of multi-morbidity was defined as a Charlson Comorbidity Index score of 2 or greater. Chi-squared analyses were used to assess differences in rates of multimorbidity between demographic groups. A series of bivariate correlation analyses was used to assess for multicollinearity between demographic factors. We used multivariable logistic analyses to further explore the associations between demographic factors and multimorbidity.

Results: A total of 7,960 patients (median age of 48, 37.9% female, 50% non-Hispanic/Latino Black, 16.9% Hispanic/Latino) met the inclusion criteria. In bivariate analyses, a higher proportion of female (24.3% vs. 19.5% male, $p < .001$), unhoused (22.4% vs. 19.4% housed, $p < .001$), and had multimorbidity. A higher proportion of non-Hispanic/Latino Black and Hispanic/Latino patients had multimorbidity compared to non-Hispanic/Latino white patients (23.1% vs. 22.3% vs. 20.3%, respectively, $p < .001$). There was no association between neighborhood deprivation and multimorbidity. In fully adjusted multivariable logistic regression models, only the association between non-Hispanic/Latino Black (OR 1.65 95% CI 1.32-2.07) and Hispanic/Latino race/ethnicity (OR 1.75 95% CI 1.30-2.35) with multimorbidity remained.

Discussion: Non-Hispanic/Latino Black and Hispanic/Latino individuals living with an SSD were at higher risk of multimorbidity compared to other racial/ethnic groups. Further work is urgently needed to explore the precipitating and perpetuating factors driving this health disparity. Interventions focused on promoting the physical health of individuals with a SSD are needed to advance health equity.

T4. UNDERSTANDING THE MEDIATING INFLUENCE OF CONTROL BETWEEN THOUGHT SUPPRESSION AND SYMPTOM SEVERITY

Phillip Angelos*¹, Boris Epie¹, Catalina Mourgues-Codern¹, Albert Powers¹

¹*Yale University*

Background: Auditory verbal hallucinations (AVH), the experience of hearing voices that others cannot, are most often associated with psychosis but experienced by individuals across the general population. While many individuals seek help due to the distress they experience from their voice-hearing experiences and its consequences, some do not. Past work has demonstrated that one important predictor of help-seeking is the ability to exert voluntary

control over these voices. We sought to examine the relationship between thought suppression, degree of voluntary control over AVH, and symptom severity. We hypothesized that an individual's propensity to engage in thought suppression would be positively associated with the severity of their symptoms and that this relationship may be mediated by the individual's ability to exert control over their voices, which would attenuate the severity of their symptoms, further suggesting that individuals with higher degrees of control may experience less severe symptoms.

Methods: Data were extracted from the Control Over Perceptual Experiences (COPE) study. Our final sub-sample consisted of 650 (79% F) participants who reported hearing voices at least monthly in the past six months (17% Psychic Mediums, 21% diagnosed voice hearer's). Using the following measures: White Bear Suppression Inventory (WBSI), Launay Slade Hallucination Scale (LSHS), Auditory Hallucinations Rating Scale (AHRS) and the Yale Control over Perceptual Experiences Scale (COPE) score, bivariate correlations were conducted and two mediation models were performed in which WBSI was the independent variable, COPE was the mediator, and for Model 1 the dependent variable was LSHS and for Model 2 AHRS. The effects were assessed by the confidence intervals of 5000 bootstrapped samples, in which an interval crossing zero is considered not significant.

Results: Correlations indicated a significant relationship between these variables. All correlation coefficients were significant at $p < .001$. Positive correlations were found between the WBSI and LSHS $r(n) = .455$ and WBSI and AHRS was $r(n) = .395$. COPE scores were negatively correlated with $r(n) = -.437$ (WBSI), $r(n) = -.185$ (LSHS), and $r(n) = -.389$ (AHRS). In the first model, we found that WBSI had a direct effect on LSHS of $\beta = .4572$, [CI95: .9034, 1.2846] and had an indirect effect on LSHS through COPE of $\beta = -.0059$, [CI95: -.3790, .5150]. Greater model variance was explained by the inclusion of individuals' COPE scores ($R^2 = .1888$, $R^2 = .2038$). In the second model, we found that WBSI had a direct effect on AHRS of $\beta = .2730$, [CI95: .4607, .7859] and had an indirect effect on AHRS through COPE of $\beta = -.2651$, [CI95: -1.7612, -.9719]. Again, greater variance was explained by the introduction of COPE ($R^2 = .1909$, $R^2 = .2081$).

Discussion: Thought suppression independently predicts the propensity to hallucinate and AVH severity. Voluntary control over voice hearing mediated the effect of thought suppression on AVH severity in AHRS, but not in LSHS. We propose that the primary explanation for these results is the high percentage of the high-control group being mediums who desire voice hearing experiences, leading to greater propensity to hallucinate but with less resultant distress. Future research could benefit from further exploring bidirectional relationship between these variables. To increase understanding of what role an individual's degree of control plays in mediating the relationship between symptom severity and suppression, we plan to explore other exploratory pathways such as thought suppression as the mediator between control and distress.

T5. SUBJECTIVE AND OBJECTIVE STRESS DIFFERENTIALLY MEDIATE EFFECTS OF CHILDHOOD MALTREATMENT ON SUBCLINICAL PSYCHOSIS SPECTRUM FEATURES

Jacqueline Nonweiler^{*1}, Tamara Sheinbaum², Thomas R. Kwapil³, Neus Barrantes-Vidal⁴

¹Universitat Autònoma de Barcelona, ²Universitat Autònoma de Barcelona, ³University of Illinois at Urbana-Champaign, ⁴Departament de Psicologia Clínica i de la Salut, Facultat de Psicologia, Universitat Autònoma de Barcelona,

Background: Stress is an important psychosocial risk factor which can be perceived differently depending on subjective and objective perception of the experience. Objective stress is characterized through the experiencing of external events (stressors) which require adaptation due to the increase in demands on an individual. Subjective stress, alternatively, takes an individual's perception of stress into account. These two differential understandings of stress may have contrasting effects on a range of mental health outcomes; nonetheless, understanding of subjective and objective stress' roles in psychosis spectrum features remains limited. This study aimed to analyze whether i) objective and subjective stress are associated with subclinical psychosis, ii) the impact of childhood adversity on subclinical psychosis is mediated by objective and subjective stress, and iii) whether this impact is moderated by attachment style.

Methods: This study is part of the Barcelona Longitudinal Investigation of Schizotypy (BLISS). The sample consisted of $n = 168$ university students who completed a childhood maltreatment measure at baseline and were re-assessed 7.8 years later for life events, attachment, and subclinical outcome (positive and negative schizotypy, suspiciousness, ideas of reference) measures.

Results: Results show that subjective stress is associated with all subclinical psychotic phenomena, while objective stress was only associated with positive schizotypy and ideas of reference. Subjective stress mediated the association of childhood maltreatment with all subclinical psychotic phenomena, while objective stress mediated the association with positive schizotypy and ideas of reference. Effect sizes of mediation coefficients for subjective stress were between two and three-times larger than those for objective stress effects. Moderated mediation by attachment style was not supported; however, several conditional indirect effects of childhood maltreatment on subclinical psychotic phenomena via subjective stress were significant at different levels of the five attachment styles.

Discussion: The current findings bolster understanding of psychosocial models of psychosis and provide support to the notion that childhood maltreatment may be related to psychosis through both objective and subjective stress appraisals.

T6. PSYCHOSIS CONTINUUM IN A SAMPLE OF BRAZIL NORTHEAST

Amannda Lima^{*1}, Dayse Cunha¹, Selma Jeronimo¹, Walter Soares²

¹Federal University of Rio Grande do Norte, ²Federal Hospital Onofre Lopes - UFRN

Background: Unlike most diseases, psychosis exists as a continuum of severity rather than an all-or-nothing phenomenon. The mere expression of symptoms is not sufficient for a diagnosis of a psychotic disorder. There is a relationship between psychotic symptoms and variables as age, level of education, and psychiatric diagnosis. Many individuals experience hallucinations in their lives, but do not seek medical evaluation because they do not consider a cause of functional impairment.

Methods: Individuals evaluated were part of a study aiming to identify mental disorders at a community level at the time of the COVID19 pandemic, in the Northeast Brazil. This sample was selected randomly, with 111 subjects from a poor region of the capital (recruited in 2021) and 383 from a rural city in the same state (recruited in 2023). The sample was assessed using general questionnaire and the Mini International Neuropsychiatric Interview (MINI), which contains questions about psychotic symptoms. Individuals were considered to have screened positive for psychotic symptoms when they answered could be (0.5 points) in at least one of the 3 questions: 1) Have you ever heard voices or sounds that no one else could hear? 2) Have you ever seen things other people couldn't see? 3) Have you ever

thought that people might be following or spying on you? Possible answers are: yes, definitely (1 point); can be (0.5 point); and No, never (0 points). Using a chi-square test, we compared city samples for the occurrence of psychotic symptoms.

Results: The prevalence in the entire sample of at least one psychotic symptom was 27.3%. 24.7% reported seeing things that no one else could see; 7.6% said they heard sounds and voices that no one else could hear, and 6.5% said they might be being stalked or spied on. The subsample of individuals from urban areas had a higher percentage of general and specific psychotic symptoms than those from rural areas, but the difference was only significant when screening for visual hallucinations (17% x 7.6%) and delusional ideas (18.2% x 5.2%) (p LESS THAN 001).

Discussion: To our knowledge, this study is the first to evaluate the presence of psychotic symptoms in a community sample from northeast Brazil, exploring the psychotic continuum idea at the time of COVID19 pandemic. The presence of psychotic symptoms in our sample was similar to that presented in the general population 9-11, considering that paranoid thinking and hallucinatory experiences are common in the general population (20-30%)¹², but without sufficient clinical relevance to conclude the diagnosis according to the DSM-5 criteria. Despite the socio-economic vulnerability faced by this population, as social inequality, low income, and violence, the prevalence of psychotic symptoms reported remained similar to those found in the literature.

T7. VIA FAMILY 2.0 – A RANDOMIZED CLINICAL TRIAL EVALUATING A MULTIDISCIPLINARY TEAM INTERVENTION FOR FAMILIES WITH PARENTAL MENTAL ILLNESS

Anne Amalie Elgaard Thorup^{*1}, Anne Ranning², Jan Sandberg³, Sidsel Ingversen⁴, Signe Heuckendorff⁵, Marlene Lauritsen⁶, Lene Falgaard Eplov⁷, Merete Nordentoft²

¹*Child and Adolescent Mental Health Center, Capital Region of Denmark*, ²*Mental Health Centre Copenhagen*, ³*Center for Relatives*, ⁴*Child and Adolescent Mental Health Center, Capital Region of Denmark*, ⁵*Mental Health Services, North Region Denmark*, ⁶*Child and Adolescent Mental Health Center, North Region of Denmark*, ⁷*Copenhagen Research Center for Mental Health - CORE*

Background: Children born to parents with mental illness have consistently been shown to have increased risks for a range of negative life outcomes including increased frequencies of mental disorders, somatic disorders, poorer cognitive functioning, social, emotional and behavioral problems and lower quality of life. Further they are often overlooked by both society and mental health services, although they represent a potential for prevention and early intervention.

A collaboration between researchers and clinicians from two regions, the Capital Region and the North Region Denmark has been established as the Research Center for Family Based Interventions. The research center will be an umbrella for a series of activities, all focusing on children in families with parental mental illness.

Methods: Method: We will conduct a large randomized, controlled trial for families with parental mental illness in order to evaluate the effect of a two-year multidisciplinary, holistic team intervention (VIA Family 2.0) against treatment as usual. Inclusion criteria will be biological children 0-17 of parents with any mental disorder treated in the secondary sector within the previous three years. A total of 870 children or approx. 600 families will be included from two sites. Primary outcomes will be Strength and Difficulties Questionnaire¹,

Family Assessment Devise², Parental Stress Scale³ and quality of the home environment, measured by interview and observation from the HOME Inventory⁴.

Results: The RCT will start including families from Jan 1, 2024, to Dec 31, 2025, and data collection will last for four years since all families will be assessed at baseline and again at end of treatment, i.e. after 24 months. Baseline data will inform the intervention team about each family's needs, problems, and motivation. A pilot study indicated good acceptability but no significant findings due to small sample size.

Discussion: Recruitment of families can be challenging but we have decades of experience. Since both the target group, their potential problems and the intervention is complex, primary outcome is hard to determine.

T8. FUNCTIONAL CONNECTIVITY AND GRAPH-THEORY MEASURES CHARACTERISE THE IMPACT OF SCHIZOTYPY AND PSYCHOTIC-LIKE EXPERIENCES ON DIFFERENTIAL MODULATION OF RESTING-STATE NETWORK IN NON-CLINICAL SUBJECTS

Igor Nenadic^{*1}, Clara Lundberg², Jonas Hoffmann², Tina Meller²

¹*Philipps-Universität Marburg / UKGM*, ²*Philipps-Universität Marburg*

Background: Conceptualising psychotic disorders as a spectrum that includes schizophrenia (and other disorders with psychotic features) as well as non-clinical or subclinical manifestations of risk traits or symptoms has impacted on our neurobiological understanding. The notion of a continuum ranging from healthy / non-clinical subjects with different degrees of psychosis proneness or minute symptoms to those with at-risk stage and manifest psychosis is paralleled by recent studies implying gradual changes of brain function and structure, e.g. in the hippocampus or medial temporal lobe. While schizotypy and psychotic-like experiences are well-established paradigms, there is still limited data on how variation of these phenotypes across individuals is related to underlying neurobiology, esp. the functional connectome of the brain. In this study, we analysed a community samples, phenotyped for trait-level and state-level risk factors for psychosis to identify associations with functional connectivity in main resting-state networks (RSN).

Methods: We analysed n=330 healthy subjects (age 18-40; 214 female, 116 male) from the local community. Phenotype characterisation included the schizotypal personality questionnaire – brief version (SPQ-B) and the prodromal questionnaire (PQ-16), capturing psychotic-like experiences. The SPQ-B provides three main factors (cognitive perceptual, interpersonal, disorganised), capturing trait-level loading for positive, negative, and disorganised schizotypy, resp., while the PQ-16 provides both frequency as well as distress ratings for psychotic-like experiences (PLE), which are typically used in early detection screening / research. Using 3T MRI, we obtained resting-state time series, which were pre-processed and analysed using the CONN toolbox. We applied independent component analysis (ICA) within CONN to extract, by means of data-driven separation, multiple RSNs. For subsequent analysis, we focussed on the default mode network (DMN), salience network (SN), fronto-parietal network (FPN), and executive control network (ECN). ICA results for RSNs were segmented into regions (as implemented in CONN toolbox), which were then used for analysis of intra-network connectivity, as well as inter-network connectivity. Correlations using general linear models were corrected for age and gender. We used FDR cluster-level correction implemented in CONN for correction of multiple comparisons. In a second analysis, we applied graph theory measures to characterise network properties.

Results: Our analysis demonstrated a significant correlation of schizotypy (SPQ-B) facets as well as PQ-16 distress levels with intra-network connectivity: positive schizotypy with intra-ECN connectivity (p-FDR=0.045), negative schizotypy with intra-DMN connectivity (p-FDR=0.004), disorganised schizotypy with intra-FPN (p-FDR=0.043); most of these intra-network correlations were positive (except for negative schizotypy). PQ-16 distress correlated with intra-DMN connectivity (p-FDR=0.04). Graph-theory analyses showed that for positive schizotypy a small cluster in the insular cortex within the SN showed significant correlation (p-FDR=0.041) with the clustering coefficient, while a left temporoparietal cluster in the FPN showed significant (p-FDR=0.044) correlation of with global efficiency. Contrastingly, for disorganised schizotypy, a mid-cingulate cluster was correlated with global efficiency (p-FDR=0.00076), and a cerebellar cluster with local efficiency (p-FDR=0.001).

Discussion: Our results demonstrate differential impact of schizotypy, a trait-level marker for psychosis proneness, vs. psychotic-like experiences (state-level, captured as prodromal symptoms). These findings suggest, that at least in the sub-clinical spectrum of schizophrenia risk markers, different facets (positive, negative, disorganised) are associated with different regional RSN connectivity – both for functional connectivity as well as network-level graph-theory measures. This provides a framework for understanding the risk antecedents manifesting as functional dysconnectivity in schizophrenia. Although our sample is larger than previous studies, we relied on an unfiltered community sample without enrichment for subjects with higher scores of schizotypy. Future analyses might also consider the interaction of schizotypy facets, as non-linear effects might result in disproportionately higher (or lower) effects when high loading on particular schizotypy facets occurs. Additional analyses will include moderation through polygenic risk (and resilience) to schizophrenia. Our findings underline that even in the absence of clinical psychotic symptoms, sub-clinical variation in the psychosis spectrum might manifest in changes of particular brain network functional connectivity parameters.

T9. USE OF ALL CAUSE MORTALITY AS AN OUTCOME TO CHARACTERIZE TREATMENT PATTERNS FOR SCHIZOPHRENIA

Sayera Dhaubhadel¹, Silviu-Alin Bacanu², Khushbu Agarwal³, Colby Ham³, Sutany Choudhury³, Ayman Fanous⁴, Benjamin McMahon*¹

¹Los Alamos National Laboratory, ²Virginia Commonwealth University, ³Pacific Northwest National Laboratory, ⁴VA Phoenix Medical Center

Background: We have used US Veterans Administration (VA) longitudinal electronic medical records (EMR) to predict 15-year all cause mortality from demographic information, the 1000 most prevalent ICD9 codes (Dx), generic medication names (Rx), and CPT procedure codes (CPT). We find roughly half of the population attributable mortality is due to cardiovascular disease and half to behavioral health related codes. Since only one of the top ten causes of death in the United States (suicide), is behavioral-health related, these risk factors should be thought of as contributors to other causes of death. Furthermore, we observe a cluster of fifty related Dx, Rx, and CPT codes, including schizophrenia (295.x), that are intertwined in their co-occurrence across typical 20-year long patient trajectories.

Methods: We performed retrospective analysis of 20 years of VA EMR data including outpatient diagnosis, pharmacy, and procedure codes on a population of two million veterans for whom up to five years of data were available prior to 2005 and an outcome of death or follow-up care was noted in the medical records. Several predictive modeling methods were applied to these data, including logistic regression on interval outcome, time-to-event (Cox)

modeling, random forest, and a simple neural network. Relationships among coded conditions and treatments were characterized with k-means and PCA on the matrix describing co-occurrence of medical codes. An ensemble of models predicting all cause mortality was constructed from the four techniques and fine tuned with the fifty codes clustering with schizophrenia to predict a variety of outcomes, including adverse outcomes, usage of psychotropic medications, and metabolic changes, from which balancing of cohorts for comparative analysis can occur.

Results: In this work, we use the artificial intelligence (AI) strategy of ensemble transfer learning to fine tune an all cause mortality prediction model to isolate the contributions attributable to schizophrenia and psychotropic medication usage. We are able to attribute risk of 15-year mortality to individual conditions without detailed feature engineering.

Discussion: Schizophrenia and other indicators of behavioral health conditions contribute forty percent of 15-year all cause mortality risk when computed from thousands of prevalent outpatient Dx, Rx, and CPT codes. These codes are, however, co-occur with complex temporal dependencies, complicating attempts to attribute outcomes and metabolic side effects to specific conditions. Since quantification of severity of behavioral health conditions is difficult, we present a process to attribute the substantial all cause mortality risk to individual conditions and treatments.

T10. OPEN BOARD

T11. ASSESSING SOCIAL BEHAVIOR AND SOCIAL COGNITION IN INDIVIDUALS AT CLINICAL HIGH RISK FOR PSYCHOSIS: IS A STANDARDIZED PERFORMANCE TASK SENSITIVE ENOUGH?

Erica Karp^{*1}, Jill Laquidara¹, Taylor Johnson², Madeline Ward¹, Lindsay Banks¹, Sarah Hope Lincoln¹

¹Case Western Reserve University, ²Sam Houston State University

Background: Social cognition and social behavior are both important for an individual's social functioning, well-being, and quality of life. However, both are impaired in individuals with schizophrenia. Additionally, evidence suggests that these deficits are also present in individuals at clinical high risk for psychosis (CHR-P). Yet there is limited understanding of how these abilities connect and how best to assess social behaviors in CHR-P individuals. High-Risk Social Challenge (HiSoc) is one task that was developed specifically to look at social behaviors in individuals at genetic high risk for psychosis. While it has been validated for use with CHR-P individuals, limited studies have explored whether it is targeting deficits specific to the high-risk groups or more general difficulties with social behaviors.

Methods: The current study clarifies whether the HiSoc task is sensitive enough to identify relationships between social behavior and social cognition across CHR-P and controls (HC). CHR-P individuals (N=23) and HC (N=28) were combined and their performance on social and emotional processing tasks and questionnaires was assessed. HiSoc task, a 45 second mock-audition for a reality show, and Multicultural Emotion Identification Task (RMET), an adaptation of the Reading the Mind in the Eyes Test, Social Comparison Scale (SCS), Davos Assessment of Cognitive Bias Scale (DACOBS) social cognition subscale, and Interpersonal Reactivity Index (IRI) were completed. Structured Interview for Prodromal Symptoms (SIPS) positive symptoms, Structured Clinical Interview for DSM-5 (SCID), and Weschler Abbreviated Scale of Intelligence II (WASI) were also administered. Finally, Global Functioning Scale: Social (GF-S) assessed current social functioning. The summary score for the HiSoc was adjusted to include three domains: social-interpersonal, affect, and odd

language and behavior. Correlation analyses were conducted to assess relationships between social behavior and social cognition. We hypothesized that social behavior would be significantly positively correlated with self-reported social cognition and social cognitive abilities. Partial-correlation tests were also used to control for IQ, verbal IQ, and SIPS positive symptoms total. Finally, a Bonferroni correction was used to adjust for multiple comparisons.

Results: Group differences were assessed prior to combining and contrary to our hypothesis, no statistically significant differences were found between CHR-P and HC for measures of social cognition or behavior (p GREATER THAN .10). Across the sample, participants performance on HiSoc task had no significant relationship with the SCS, IRI, or DACOBS social cognition subscale (p GREATER THAN .20). HiSoc summary score was significantly correlated with RMET total score ($r = .57$, p LESS THAN .01) with higher performance across domains on the social task associated with higher overall performance on the emotion recognition task. This finding held even when controlling for IQ ($r = .53$, p LESS THAN .01), verbal IQ ($r = .57$, p LESS THAN .01), and positive symptoms ($r = .55$, p LESS THAN .01). A similar pattern was shown across the three HiSoc domains with higher social-interpersonal skills ($r = .50$, p LESS THAN .01), better affect ($r = .49$, p LESS THAN .01), and more normative behavior and language ($r = .55$, p LESS THAN .01) significantly correlated with higher RMET total scores.

Discussion: Few studies have assessed the utility of a standardized, social behavior task designed specifically for individuals at risk for psychosis; thus, the current study begins to fill the gaps. While the domains targeted by HiSoc are established areas of social impairment in CHR individuals, results indicate that the task identifies social performance abilities across groups of people regardless of clinical profile. There was not a clear difference between CHR-P and HC on overall social performance ability. This finding may be due to the relatively low sample size in each group or the use of the task virtually, due to COVID-19, rather than in-person as previously implemented, which warrants consideration for future studies that include HiSoc. Combining the two groups, could have resulted in clusters significantly around two distinct poles, with the CHR-P clustering around lower scores and healthy controls around higher, yet this was not the case. There was no significant relationship between HiSoc and any of the self-report social cognitive measures. Although there were significant correlations between the RMET and HiSoc, enough participants from both groups scored high and low that it points more so to the relationship between social cognition and social behavior regardless of clinical profile. Previous work suggests that social cognitive abilities underscore social behavior, our work supports this theory. Of note, positive symptoms had no impact on the relationship between HiSoc performance, both overall and on subdomains, and RMET performance. Potentially negative symptoms would be more likely to drive variability in social cognitive and social behavior abilities than positive symptoms, future work should examine this hypothesis. The current study points to the potential to use HiSoc as a measure of social behavior, while demonstrating a need for further research with larger sample sizes and more complete symptoms profiles.

T12. CONNECTING THE DOTS: ABERRANT SALIENCE, DEPRESSIVE SYMPTOMS AND THE COMPLEX DYNAMICS OF PSYCHOSIS PRODROME

Federico Fiori Nastro^{*1}, Martina Pelle¹, Alice Clemente¹, Giuseppe Albanesi¹, Diego Cichetti¹, Giulia Ambrosi¹, Stefano Garofalo¹, Chiara Maimone¹, Emanuele Rizzo¹, Francesco Scrima¹, Alberto Siracusano¹, Cinzia Niolu¹, Giorgio Di Lorenzo¹

Background: The inclination to ascribe greater significance to irrelevant stimuli is referred to as 'aberrant salience' (AS). Based on empirical evidence, AS tends to occur as early as the prodromal stages of schizophrenia, and nowadays it has been increasingly recognized as a pertinent psychopathological characteristic in the early detection of At-risk mental states. Despite the primary role of positive symptoms in the definition of Clinical High-risk (CHR) states, depressive and anxiety symptoms are common in the early prodromal phase and they have been described as the primary reason for help-seeking in CHR individuals. Recent literature suggests that depressive symptoms (DS) may predict poorer global functioning and increase the risk of transitioning to psychosis. This study aims to explore the presence of AS in a cohort of young university students utilizing our counseling psychological service, examining its correlation with both DS and psychotic-like experiences.

Methods: A cross-sectional analytical study was conducted. 366 young adult help-seekers (70.2% female, median age= 23) were administered a self-report questionnaires battery, including the Aberrant Salience Inventory (ASI), the Beck Depression Inventory-II (BDI-II) and the Prodromal Questionnaire-16 (PQ-16). The relationships between the measured variables have been analyzed using a correlation matrix. Then, a multivariable regression linear model, adjusted for age and gender, was performed to establish the effect of AS and DS on psychotic-like experiences (PLE).

Results: The median self-report scores were BDI-II= 15 (IQR=12), PQ-16= 4 (IQR=5), ASI=13 (IQR=10). About 130 subjects (37.7%) screened positive for a prodromal condition, as shown by a PQ-16 T/F score ≥ 6 . Correlational analysis revealed a significant relationship between ASI total scores and ASI subscales with both PQ-16 total scores and BDI-II ($p < .001$). Multiple linear regression analysis showed that higher BDI and ASI scores act as significant predictors of higher rates of PLEs. In particular, three ASI subscales ("sharpening of senses", "heightened emotionality" and "heightened cognition") showed significant predictive value. Age and gender were not statistically significant. This model explained about 52.4% of the variance of the explored outcome.

Discussion: In accordance with our previous findings, this study confirms that the interconnection between AS and DS may provide useful insights into the psychosis continuum. In our study, higher rates of DS predicted more severe PLEs. This finding substantially confirms the significance of affective symptoms in young CHR patients. Recent literature highlights that depressive symptomatology may play a crucial role in psychosis, determining an increased state of vulnerability and potentially leading to poorer clinical outcomes. The statistically significant predictive efficacy of the ASI domains of "heightened emotionality" and "heightened cognition" may be construed as suggestive evidence that these dimensions bear a more proximate psychopathological association with the emergence of psychotic experiences. As the original 'at-risk mental state' approach evolves to encompass a broader array of pluripotent transdiagnostic outcomes, additional longitudinal investigations are necessary to deepen our comprehension of the association between AS and DS and to evaluate different psychopathological trajectories that the subjects will follow.

T13. THE STRUCTURE OF SELF- AND OTHER-SCHEMAS IN INDIVIDUALS WITH PSYCHOSIS

Robert Aidelbaum^{*1}, Lynn Rutledge¹, Sylvia Romanowska¹, Talia Leibovitz¹, Shreya Jagtap², Jessica D'Arcey³, Michael Best¹

¹University of Toronto Scarborough, ²Centre for Addiction and Mental Health, University of Toronto, ³University of Toronto Scarborough, Centre for Addiction and Mental Health

Background: Schemas have been linked to psychotic symptoms, with elevated negative schema charge predictive of profile. Research to date exploring the potential role of schemas as maintenance factors for psychotic symptoms has predominately focused on the self-reported charge of the endorsed schema. No research to date has analyzed the structure of such schemas and whether this characteristic predicts schema charge and symptoms. This study sought to explore the utility of the measurement of schema structure in a sample of individuals managing psychosis. This study is the first to measure schema structure in a psychotic population and to apply this methodology to measuring the structure of other-schemas in addition to self-schemas. The potential predictive capacity of schema structure for psychotic symptom severity was investigated to clarify the possible role schemas may play in the maintenance of psychosis.

Methods: The computerized Psychological Distance Scale Task (PDST) was used to measure schema structure. Eighty adjectives were rated by participants. Self/other descriptiveness was rated along an x-axis using a scale from not at all like me/others to very much like me/others. Valence was rated along a y-axis, ranging from positive to negative. The PDST produced eight scores reflecting the average interstimulus distance (ISD) between the adjectives for each of four conditions (interpersonal positive, interpersonal negative, achievement positive, and achievement negative). Schema charge was assessed via the Brief Core Schema Scale (BCSS) and psychotic symptoms via the Positive and Negative Syndrome Scale for Schizophrenia (PANSS). Associations between the PDST subscales and the BCSS were examined. Multiple regression analyses were conducted predicting PANSS pentagonal factors as a function of the PDST subscales.

Results: Correlations amongst the PDST subscales demonstrated a valence-dependent effect. Consolidated positive/negative schemas predicted more consolidated similarly-valenced schemas. Self-referent negative achievement ISD significantly correlated with the BCSS negative self-schema ($r_s = -.50$), self-referent positive achievement ISD significantly correlated with the BCSS positive self-schema ($r_s = -.44$), and self-referent positive interpersonal ISD significantly correlated with the BCSS positive self-schema ($r_s = -.49$). Significant interaction effects between self-referent positive and negative achievement ISDs in the prediction of positive ($F(3, 56) = 2.26, p = .01, R^2 = .108, t = 2.36, p = .022$) and emotional symptoms ($F(3, 56) = 2.26, p = .002, R^2 = .230, t = 2.84, p = .006$) were observed. Similarly, self-referent positive and negative-interpersonal schema ISDs significantly interacted in the prediction of negative symptoms ($F(3, 58) = 3.52, p = .021, R^2 = .110, t = 2.44, p = .018$).

Discussion: These novel findings highlight the potential utility of schema structure as a means of assessing schemas and their covariance within the psychosis population. Evidence suggests PDST-derived structural indices of self-referent schemas measure a similar construct to that being measured by the BCSS Self-Schema subscales. Furthermore, results highlight the importance of the interaction between the structure of positive and negative schemas in the prediction of positive, negative, and emotional symptoms. In contrast, more work is needed to validate the measurement of other-referent schema structures, as these subscales returned non-significant correlations. These results highlight a novel method of assessing the role of schemas in the manifestation of psychosis and provide evidence highlighting negative and positive schemas as distinct constructs whose interactions relate to symptom profiles.

T14. STUDY OF THE PSYCHOMETRIC PROPERTIES OF THE SPANISH MULTIDIMENSIONAL SCHIZOTYPY SCALE-BRIEF (MSS-B) IN TWO NONCLINICAL SAMPLES

Karen Fagián Núñez^{*1}, Jacqueline Nonweiler², Pilar Torrecilla³, Valeria Lavín⁴, Thomas R. Kwapil⁵, Neus Barrantes-Vidal⁶

¹*Autonomous University of Barcelona*, ²*Universitat Autònoma de Barcelona*, ³*Departament de Psicologia Clínica i de la Salut, Universitat Autònoma de Barcelona*, ⁴*Department of Health and Clinical Psychology, Autonomous University of Barcelona*, ⁵*University of North Carolina at Greensboro*, ⁶*Departament de Psicologia Clínica i de la Salut, Facultat de Psicologia, Universitat Autònoma de Barcelona*

Background: Schizotypy is a multidimensional construct that represents the phenotypic expression of vulnerability to psychotic disorders. Strong evidence supports the existence of positive, negative and disorganized dimensions of schizotypy. While various measures to evaluate schizotypy exist, the Multidimensional Schizotypy Scale-Brief (MSS-B) stands apart for its brevity, content coverage and psychometric properties. In this study, we aimed to evaluate the underlying factor structure of this self-report measure in European Spanish, and to obtain evidence of its validity in a nonclinical population.

Methods: This cross-sectional study is formed of two large independent samples. Confirmatory factor analysis using maximum likelihood estimates was performed to examine the factor structure in Sample 1 ($n = 1,049$; Mean age = 23.40, SD = 5.99). Several fit indices including Comparative Fit Index (CFI), Tucker-Lewis Index (TLI), Root Mean Square Error of Approximation (RMSEA), and Standardized Root Mean Residual (SRMR) were estimated. Convergent validity was assessed using Sample 2 ($n = 352$; Mean age = 25.41, SD = 5.89). To analyze convergent validity, participants completed two additional questionnaire measures of schizotypy: the Schizotypal Personality Questionnaire-Brief (SPQ-B) and the Wisconsin Schizotypy Scales-Short Forms (WSS-SF). A series of zero order correlations and linear regressions were performed between the different dimensions/factors comprising the different measures.

Results: Results of the confirmatory factor analysis showed that the three-factor model presented best goodness-of-fit (CFI = .91; TLI = .91; RMSEA = .04; SRMR = .09), corresponding to the positive, negative and disorganized subscales. Associations between MSS-B subscales and their corresponding dimensions/factors on measures of convergent validity were in the expected direction, presenting moderate to strong correlation values and medium to large effect sizes.

Discussion: To our knowledge, the present study was the first to assess the psychometric properties of the Spanish version of the MSS-B. Findings provide supporting evidence of a three-factor structures of the MSS-B with strong validity and robust psychometric properties. Thus, the MSS-B is a promising brief measure that allows for the screening of positive, negative, and disorganized schizotypy dimensions in large, nonclinical samples. The reliable identification and measurement of these dimensions is essential for parsing out the heterogeneity of schizotypy and psychosis spectrum disorders. Expanding the scope of investigation using the MSS-B in the future to include clinical populations will provide a more comprehensive understanding of the applicability and utility of the measure in a broader range of individuals and enhance its clinical relevance.

T15. ASSOCIATION BETWEEN INTELLIGENCE QUOTIENT AND CORTICAL STRUCTURE IN CHILDREN AND ADOLESCENTS AT FAMILIAL HIGH-RISK FOR SCHIZOPHRENIA AND BIPOLAR DISORDER

Patricia Camprodon-Boadas*¹, María Ortuño², Inmaculada Baeza³, Elena De la Serna⁴, Josefina Castro-Fornieles⁴, Gisela Sugranyes⁵

¹*Fundació de Recerca Clínic Barcelona-Institut d'Investigacions Biomèdiques August Pi i Sunyer (IDIBAPS)*, ²*Fundació Clínic Recerca Biomèdica - Institut d'Investigacions Biomèdiques August Pi i Sunyer, Clinical and Experimental Neuroscience*, ³*Child and Adolescent Psychiatry and Psychology Department, Hospital Clinic de Barcelona*, ⁴*Department of Child and Adolescent Psychiatry and Psychology, Hospital Clinic of Barcelona, 2014SGR489, CIBERSAM.*, ⁵*Department of Child and Adolescent Psychiatry and Psychology, Institute of Neuroscience, Hospital Clinic of Barcelona, 2014SGR489, CIBERSAM, CERCA-IDIBAPS*

Background: Previous studies have consistently showed a positive significant correlation between Intelligence Quotient (IQ) and cortical neuroimaging measures, both in adult and pediatric healthy populations. This study aims to analyze the relationship between IQ and cortical brain structural imaging measures, specifically gray matter volume and surface area, in a sample of children and adolescent's offspring of patients with bipolar disorder (BpO), schizophrenia (SzO) or community controls (CcO).

Methods: The study involved a total of 403 data acquisitions, which included longitudinal assessments from 51 SzO, 84 BpO, and 86 CcO at different time points. Participants were matched for age and sex. All participants completed an IQ assessment using the Wechsler Intelligence Scale for Children or Adults depending on age and underwent a structural magnetic resonance imaging scan on a 3Tesla scanner. Cortical surface reconstruction was applied to measure gray matter volume and surface area for each cortical lobe. Multilevel mixed-effects linear regression models were conducted, with cortical structural measures as dependent variable, including group, IQ, IQxgroup interaction, age, sex, and total intracranial volume as fixed factors. Additionally, random effects were incorporated for family relatedness (considering subjects who were siblings) and the subject code (accounting for different number of assessments).

Results: No significant differences were observed in age or sex between groups. SzO group exhibited a significantly lower IQ ($F = 22.636$; $p < 0.001$) compared to both the BpO ($p < 0.001$) and the CcO ($p < 0.001$) groups. No differences were observed in IQ between BpO and CcO groups. Overall, IQ had an effect on the left frontal lobe cortical gray matter volume ($F = 5.781$; $p = 0.017$) and surface area ($F = 11.650$; $p = 0.001$), right frontal lobe surface area ($F = 9.508$; $p = 0.002$), left ($F = 4.818$; $p = 0.029$) and right ($F = 5.024$; $p = 0.026$) insula gray matter volume, and right temporal lobe gray matter volume ($F = 4.847$; $p = 0.028$) and surface area ($F = 6.896$; $p = 0.009$). There was also a significant IQxgroup interaction in the right cingulate lobe gray matter volume ($F = 3.929$; $p = 0.021$) and surface area ($F = 3.354$; $p = 0.036$) and in the right parietal lobe gray matter volume ($F = 3.238$; $p = 0.04$) and surface area ($F = 3.462$; $p = 0.033$). However, subsequent pairwise comparisons did not reveal significant differences between groups in these interactions.

Discussion: Our findings suggest that IQ may have a significant effect in some cortical structures of children and adolescents at familiar high-risk for schizophrenia or bipolar disorder. Moreover, it appears that IQ may exert distinct effects depending on group, particularly on the right cingulate lobe and in the right parietal lobe. However, the absence of

statistical significance in pairwise comparisons was likely constrained by the small sample size. Our results have the potential for tailored interventions targeting structural brain changes characterizing youth at genetic high-risk of psychosis. Recognizing IQ as a measure of cognitive reserve, our results imply its significant role in aiding individuals to cope with neuroimaging abnormalities associated with these populations. Further research is warranted to elucidate the underlying mechanisms and implications for early intervention strategies.

T16. UNEXPECTED FEMALE PREPONDERANCE IN A RECENT SAMPLE OF INDIVIDUALS AT A CLINICAL HIGH RISK FOR PSYCHOSIS (CHR-P)

Emily Farina^{*1}, Catalina Mourgues-Codern², Karlos Mate², Gabriel Hosein², Adrianisse Vega-Reyes², Joshua Kenney², Jean Addington³, Carrie E. Bearden⁴, Kristin S. Cadenhead⁵, Tyrone D. Cannon⁶, Barbara Cornblatt⁷, Lauren Ellman⁸, James Gold⁹, Matcheri Keshavan¹⁰, Daniel H. Mathalon¹¹, Vijay A. Mittal¹², Diana O. Perkins¹³, Jason Schiffman¹⁴, Steven Silverstein¹⁵, Gregory P. Strauss¹⁶, William S. Stone¹⁷, Elaine F. Walker¹⁸, James Waltz¹⁹, Philip Corlett², Albert Powers², Scott W. Woods²

¹Yale University, ²Department of Psychiatry, Yale University, ³University of Calgary, Department of Psychiatry, ⁴Departments of Psychiatry and Biobehavioral Sciences and Psychology, University of California, Los Angeles, ⁵Department of Psychiatry, University of California San Diego,, ⁶Department of Psychology, Yale University, ⁷Department of Psychiatry, The Zucker Hillside Hospital Zucker Hillside Hospital, Long Island Jewish, ⁸Temple University, Department of Psychology, ⁹Maryland Psychiatric Research Center, ¹⁰Beth Israel Deaconess Med. Ctr. and Harvard Medical School and Harvard Medical School, ¹¹Department of Psychiatry, University of California, San Francisco, United States and Psychiatry Service, ¹²Northwestern University, ¹³Department of Psychiatry, University of North Carolina, ¹⁴University of California, Department of Psychological Science, ¹⁵University of Rochester Medical Center, , ¹⁶University of Georgia, ¹⁷Harvard Medical School Department of Psychiatry, Beth Israel Deaconess Medical Center, ¹⁸Departments of Psychology and Program in Neuroscience, Emory University, ¹⁹Maryland Psychiatric Research Center, University of Maryland,

Background: Historically, many large CHR-P samples have been male predominant, which is consistent with incidence rates of psychotic-spectrum diagnoses, while few had a female preponderance. However, in the recent Computerized Assessment for Psychosis Risk (CAPR) sample we have noted increased rates of female enrollment. We aimed to systematically examine the observed female preponderance in the CAPR sample and to describe sex differences in the clinical profiles of CHR-P between CAPR and two waves of the North American Prodrome Longitudinal Study (NAPLS). All three projects ascertained CHR-P using the SIPS.

Methods: Sex differences were examined in the baseline data between CAPR (2020-2023, n = 651, 272 CHR), NAPLS 2 (2009-2012, n = 1043, 764 CHR), and NAPLS 3 (2015-2018, n = 806, 710 CHR). Chi-square and two-way ANOVA were used to investigate differences between sex and sample in age, and clinical characteristics [CHR symptom severity (SOPS domain scores), social and role functioning (GF:S and GF:R), and prevalence of non-psychotic comorbidities (SCID-IV and V diagnostic criteria).

Results: The sex predominance in the three CHR samples (NAPLS 2, 43% female $\chi^2(1) = 15.267$, p LESS THAN 0.001; NAPLS 3 46% female, $\chi^2(1) = 5.07$, p = 0.02; CAPR 68%

female, $\chi^2(1) = 33.88$, $p < 0.001$) differed significantly ($\chi^2(2) = 51.34$, $p < 0.001$). The female preponderance pattern in CAPR was not significantly different across the six data collection sites (53% to 82% female) and was not present in control groups.

CHR females across all three studies were consistently older, had less negative symptoms, more general symptoms, higher social functioning, and higher role functioning [age: $F(1, 1745) = 6.00$, neg: $F(1, 1681) = 4.33$, gen: $F(1, 1680) = 31.13$, GF:S: $F(1, 1701) = 4.36$, GF:R: $F(1, 1694) = 19.83$, $p < 0.05$].

Discussion: These prominent sex differences across samples may affect estimates of clinical characteristics. An important difference between the studies is that CAPR does not require in-person participation but can be completed completely on-line, whereas both NAPLS studies required in-person participation. Future directions will examine effects of recruitment strategies and treatment histories across studies, will consider possible time-limited (i.e. pandemic) effects, and will expand comparisons to other recent samples and longitudinal outcomes (including conversion rates, distress, functioning, and other indicators of a need for early identification and care).

T17. GRAY MATTER ALTERATION AND ITS ASSOCIATION WITH POSITIVE AND NEGATIVE SYMPTOM IN THOSE AT CLINICAL HIGH RISK OF PSYCHOSIS

Shuqing Si^{*1}, Emily P. Hedges¹, Stefania Tognin², Gemma Modinos¹, Mark van der Gaag³, Lieuwe de Haan⁴, Patrick D. McGorry⁵, Barnaby Nelson⁵, Anita Riecher-Rössler⁶, Rodrigo Bressan⁷, Neus Barrantes Vidal⁸, Marie-Odile Krebs⁹, Merete Nordentoft¹⁰, Stephan Ruhrmann¹¹, Gabriele Sachs¹², Bart P Rutten¹³, Jim Van Os¹³, Anthony James¹⁴, Gareth J. Barker¹, EU-GEI High Risk Study¹⁵, Steven Williams¹, Lucia R. Valmaggia¹, Philip McGuire², Matthew J. Kempton¹

¹King's College London, ²King's College London, ³VU University Amsterdam, ⁴Academic Medical Center, University of Amsterdam, ⁵University of Melbourne, ⁶University of Basel, ⁷Universidade Federal de Sao Paulo - UNIFESP, ⁸Universitat Autònoma de Barcelona, Spain, ⁹University Paris Cité - INSERM -, ¹⁰Mental Health Centre Copenhagen, ¹¹University Hospital - University of Cologne, ¹²Medical University of Vienna, ¹³Maastricht University Medical Centre, ¹⁴Highfield Unit, Warneford Hospital, Oxford, UK, ¹⁵EU-GEI High Risk Study

Background: The clinical high-risk (CHR) phase is a critical period for early intervention in psychosis, a period where brain volume abnormalities are already present. However, the extent to which brain volume is altered and its association with symptoms and later transition to psychosis is unclear. Attenuated positive symptoms and negative psychotic symptoms have also showed greater association with the transition to psychosis. In this study, we investigated differences in brain structure between individuals at CHR and healthy controls (HC) and determined whether gray matter (GM) volume at baseline is associated with later transition to psychosis. Additionally, we examined the relationship between positive and negative symptoms and brain volume at baseline.

Methods: As a part of the EU-GEI high-risk study, CHR participants with MRI scans were recruited from 9 sites (London, Amsterdam, The Hague, Basel, Cologne, Melbourne, Vienna, Copenhagen, Paris) and HC were recruited from 4 of these sites (London, Amsterdam, The

Hague, and Melbourne). Participants were scanned and assessed at baseline and followed up to 24 months. Structural 3T MRI scans were acquired using the Alzheimer's Disease Neuroimaging Initiative (ADNI-2) protocol and regional brain volumes were determined using the FreeSurfer v6.0.0 pipeline. Negative symptoms were assessed using the Scale for the Assessment of Negative Symptoms (SANS), and positive symptom severity was determined from the Comprehensive Assessment of At-Risk Mental States (CAARMS). Five key brain regions associated with psychosis and/or CHR from previous meta-analytical studies were selected a priori: anterior cingulate cortex (ACC), fusiform gyrus, insula, hippocampus, and total gray matter (GM). Regional brain volumes were statistically adjusted for age, site, total intracranial volume, and sex. When comparing CHR to HC, we limited the analysis to the 4 sites that recruited both groups, and associations with clinical variables used the entire sample. Linear regression was used to examine the differences between CHR and HC and to assess the relationship between brain volume and symptom severity. Logistic regression was applied to investigate the association of brain volume and symptoms at baseline with later transition to psychosis.

Results: Our study comprised 65 HC and 226 CHR individuals, 48 of whom later transitioned to psychosis. There were no differences in age and gender between CHR and HC, as well as between subjects who transitioned to psychosis (CHR-T) and those who did not transition (CHR-NT). Compared with HCs, CHR subjects had significantly smaller volumes of the anterior cingulate cortex (ACC), fusiform gyrus, insula and total gray matter (GM). No differences were observed in hippocampal volume between CHR and HC. None of the brain regions at baseline were associated with later transition to psychosis. At baseline, individuals who later transitioned to psychosis had a significantly higher SANS score than those who did not transition. However, no association was found between baseline brain volume and baseline negative symptoms or positive symptoms.

Discussion: Our study revealed that CHR individuals had decreased regional brain volumes compared to HC at baseline, however no volumetric differences at baseline were associated with later transition to psychosis. CHR-T individuals presented more negative symptoms, but symptom severity was not associated with brain volume. Future longitudinal MRI studies may be a more effective way to reveal the different trajectories between transition and non-transition individuals and examine the association of symptoms and brain volume.

T18. EXAMINING MODEL STABILITY ACROSS STATIC AND DYNAMIC MODELLING APPROACHES TO PREDICTING OUTCOMES FOR INDIVIDUALS AT-RISK OF PSYCHOSIS

Yanakan Logeswaran^{*1}, Dominic Oliver¹, Matthew Kempton¹, Mark van der Gaag², Lieuwe De Haan³, Barnaby Nelson⁴, Anita Riecher-Rössler⁵, Rodrigo Bressan⁶, Neus Barrantes Vidal⁷, Marie-Odile Krebs⁸, Merete Nordentoft⁹, Stephan Ruhrmann¹⁰, Gabriele Sachs¹¹, Bart Rutten¹², Jim van Os¹², Lucia Valmaggia⁴, Philip McGuire¹³, Paolo Fusar-Poli¹, Daniel Stahl¹, EU-GEI High Risk Study¹⁴

¹*Institute of Psychiatry, Psychology and Neuroscience, King's College London*, ²*VU University Amsterdam*, ³*AMC Amsterdam*, ⁴*Orygen, The National Centre of Excellence in Youth Mental Health*, ⁵*University of Basel*, ⁶*UNIFESP*, ⁷*Universitat Autònoma de Barcelona*, ⁸*University Paris Descartes*, ⁹*University of Copenhagen*, ¹⁰*University of Cologne*, ¹¹*Medical University of Vienna*, ¹²*University of Maastricht*, ¹³*University of Oxford*, ¹⁴*International*

Background: Primary indicated prevention in individuals at Clinical High Risk for psychosis (CHR-P) may improve the trajectory of psychotic disorders, and potentially prevent a full-blown illness. However, psychosis risk in individuals at CHR-P is highly heterogeneous, with a 5% to 20% probability of transition to psychosis. Clinical prediction models may improve our ability to prognosticate outcomes. More recently, studies have used dynamic modelling approaches, which incorporate symptom dynamics over time, and have observed improved overall prognostic accuracy relative to static modelling approaches. However, there are concerns that the individual model predictions of psychosis risk may be unstable, given the use of small development datasets with relatively small numbers of outcome events and greater model complexity in such dynamic modelling. Thus, this study aims to compare model performance and instability across static and dynamic clinical prediction models for predicting transition to psychosis in CHR-P individuals.

Methods: CHR-P individuals were recruited as part of the EU-GEI study, a prospective 11-site observational study. Participants were followed up for two years, and the outcome (transition to psychosis) was determined by the CAARMS. Data will be checked for missingness and imputed using k-nearest neighbours where necessary. We will develop each model utilising cumulative blocks of candidate predictors: (i) age, gender, age*gender, ethnicity, CHR-P subgroup; (ii) total positive symptoms, total negative symptoms, global functioning, symbol coding, verbal learning; and (iii) childhood trauma, stressful life events, living status, employment status, and migrant status. Various static (i.e. Cox proportional hazards regression, random survival forests [RSF]) and dynamic models (i.e. joint modelling, Cox landmarking, and RSF landmarking) will be developed using a 10-fold cross-validation framework to predict transition to psychosis. We will assess the models' performance using internal validation, indexed by discrimination (area under the curve, sensitivity, specificity, balanced accuracy, and Brier score) and calibration (calibration slope and Brier score). Using bootstrapping, we will examine model instability of individual predictions through (i) prediction instability plots, (ii) classification instability plots, (iii) calibration instability plots, and (iv) the mean absolute prediction error (MAPE) between original and bootstrap model predictions.

Results: 343 CHR-P individuals (mean [SD] age at study entry = 22.4 [4.9] years; 184 [53.6%] male; 246 [71.7%] non-white ethnicity) were included in the study. Of these, 57 (17%) transitioned to psychosis within two years (median [IQR] days from baseline to transition = 195 [105-359] days). Regarding CHR-P intake groups, 25 (8%) met criteria for Brief Limited Intermittent Psychotic Symptoms, 256 (84%) met Attenuated Psychotic Symptoms criteria, and 24 (8%) met criteria for genetic risk vulnerability. Regarding comorbid psychopathology at baseline, 109/331 (33%) had a current major depressive episode, 169/326 (52%) had any anxiety disorder, and 45/303 (15%) had a personality disorder. Further, 89/282 (32%) had been prescribed antidepressants, 31/282 (11%) anxiolytics, and 31/277 (11%) antipsychotics, and 90/334 (27%) were current cannabis users.

Discussion: This study may emphasise the importance of reporting model stability in this field and perhaps emphasise the importance of harmonisation of measures across consortia to provide larger datasets for more stable, better performing clinical prediction models that can improve care for CHR-P individuals.

T19. PERCEIVED SOCIAL REJECTION IN REAL LIFE (ESM) AS A PREDICTOR OF INCREASED PARANOID THOUGHTS IN EXPERIMENTAL VR SETTINGS IN A NON-CLINICAL PARANOIA SAMPLE

Background: Paranoid thoughts are suggested to be built on increased vulnerability. Individuals with heightened rejection sensitivity have been shown to be more prone to actively seek out and selectively respond to threatening stimuli while anticipating harm or rejection from others. Despite extensive research on paranoid thoughts in the context of social rejection, experimental studies attempting to establish a potential causality are inconsistent. The purpose of this study is to apply gold-standard, ecologically valid methods to investigate whether inducing feelings of social rejection in a fully immersive virtual reality (VR) environment contributes to increased paranoid thoughts in non-clinical subjects, and whether real-time feelings of social rejection (collected through Experience Sampling Method) predict paranoid thoughts both in real-time (ESM) and under experimental conditions (VR).

Methods: A total of 103 participants (aged 18-40 years) were allocated to one of two groups: LP - low paranoia (n = 79) and HP - high paranoia (n = 24). Those scoring ≤ 1 on The Revised Green et al. Paranoid Thoughts Scale (R-GPTS) were placed in the LP group, and those scoring ≥ 35 were assigned to the HP group. First, participants were asked to complete 8 short surveys per day for 7 days, comprising of questions about emotions experienced at the time, perceived social rejection, and current paranoid thoughts. The ESM stage was followed by the Cyberball game in a VR setting. Participants were randomly assigned to one of two conditions - social inclusion or social rejection. Levels of paranoid thoughts were measured before and after Cyberball. Multilevel regression analyses were performed on the ESM data. The data were also aggregated at the subject and group levels to integrate with data obtained from the baseline measurements and VR experimental procedures.

Results: A three-way repeated measures ANOVA revealed a significant interaction of time x group x Cyberball condition ($F(1,99) = 22.935$, $p < 0.001$). HP group showed a significant increase in paranoid thoughts after social rejection and a significant decrease following social inclusion. LP subjects showed a slight, but insignificant, increase in paranoid thoughts following social rejection and no change after social inclusion. Rejection sensitivity significantly correlated with baseline paranoid thoughts ($r = 0.590$, $p < 0.001$), as well as momentary (ESM) paranoid thoughts ($r = 0.369$, $p < 0.001$) and feelings of social rejection ($r = 0.262$, $p < 0.001$). The results revealed that HP group spent significantly more time alone than with others compared to LP ($p < 0.05$), which was further associated with an increased sense of rejection ($p < 0.01$). Feeling accepted while with others predicted lower paranoid thoughts ($b = -0.09$, $p < 0.001$) and feeling threatened predicted higher paranoia ($b = 0.25$, $p < 0.001$). Momentary feelings of social rejection significantly predicted paranoid thoughts ($b = 0.2$, $p < 0.001$), and paranoia predicted feelings of rejection over time ($b = 0.52$, $p < 0.001$). Momentary negative emotions predicted increased paranoid thoughts after Cyberball manipulation ($p = 0.05$), but this effect was not significant for feelings of social rejection alone or momentary paranoia.

Discussion: Experiencing social rejection in immersive VR and momentary feelings of rejection may play an important role in fostering paranoid thoughts. Negative emotions in daily life, including but not limited to rejection, predict experimental responses, highlighting the role of ongoing daily stress in paranoia. Increased rejection sensitivity and prolonged periods of solitude contribute to increased feelings of rejection and thus paranoid thoughts, suggesting potential targets for therapeutic interventions. However, these are only preliminary analyses based on currently collected data, and the results should be interpreted with caution.

T20. THE 'STRESS-SENSITIVE SELF' IN PSYCHOSIS: PRELIMINARY RESULTS OF A CHALLENGE (STRESS) TEST OF SENSE OF AGENCY IN PSYCHOSIS PRONENESS

Yonatan Stern^{*1}, Roy Salomon¹, Dan Koren¹

¹*Haifa University*

Background: Psychosis often involves 'basic self-disturbances', impairing one's fundamental identification with their actions, body, and thoughts. This includes disrupted Sense of Agency (SoA), affecting control and recognition of one's actions, common in full-blown psychosis. Neurocognitive tests associated with self-disturbances have been shown to moderately improve early identification of psychosis and its differentiation from other psychopathologies. However, the associations between neurocognitive tests and basic self-disturbances have been mild at best in most studies. We hypothesize that bridging the gap between neutral testing settings and stressful real-world conditions can enhance early psychosis identification. Similar to stress tests in general medicine, , such as examining cardiac activity under physical exertion, we developed the 'Stress-sensitive Self' neurocognitive test, assessing SoA under psychosocial stress.

Specifically, we examined two pre-registered hypotheses (<https://osf.io/ubjeq>):(1) Increased psychosis-proneness and self-disturbances will be associated with impaired SoA and its metacognition. (2) Psychosocial stress will impair SoA more prominently in individuals with increased risk for psychosis.

Methods: To ecologically examine SoA we developed the 'Virtual Hand' (VH) task in immersive virtual reality to examine SoA. Participants' movements were mirrored by VH, either synchronously or with a temporal delay. Participants then judge whether the VH's movement is identical to their actual movement (i.e. agency question) and rate their confidence (i.e. metacognition question). The task was performed under two conditions; a neutral block, and following a psychosocial stress induction in a 'stress' block. To assess for psychosis proneness and self-disturbances the Structured Interview for Psychosis-Risk Syndromes and Examination of Anomalous Self Experiences were respectively administered. Three groups of participants were included: clinical high risk (CHR) for psychosis (N = 13), participants with non-psychotic psychopathology (N= 29) and healthy controls (N = 47).

Results: Contrary to our first hypothesis and previous work, no significant correlation was found between SoA and psychosis proneness ($r = .10$, $p = .35$) or self-disturbances ($r = .05$, $p = .9$). Likewise, metacognition was not significantly correlated to psychosis proneness ($r = .08$, $p = .50$) and self-disturbances ($r = .08$, $p = .52$). Furthermore, there was no significant difference between groups in their SoA ($F_{2,82} < 1$, $p = .78$) and metacognition ($F_{2,82} = 1.3$, $p = .28$). Regarding the effect of stress on SoA, stress caused a significant change in participant's criteria resulting in decreased self-attribution of actions ($t_{82} = 3.2$, $p = .002$, Cohen's $d = 0.35$). However, this criteria shift was not different between groups ($F_{2,82} = 1.4$, $p = .25$).

Discussion: Our findings, using clinical assessments and neurocognitive tests, unexpectedly contradict previous links between psychosis and self-cognition impairments across the psychosis spectrum. A possible explanation is the low number of CHR individuals in the current sample. Likewise, measurement of SoA may provide additional insight regarding conversion to full-blown psychosis, a measure currently being collected. Despite these caveats, the current results point to a more complex relation between clinically measured psychosis-proneness and self-related neurocognitive measures, that may have been previously under-reported in the literature.

T21. GENDER DIFFERENCES IN THE ASSOCIATIONS BETWEEN EXPOSOME AND PSYCHOSIS EXPRESSION IN A GENERAL POPULATION TWIN SAMPLE

Melike Karaçam Doğan*¹, Thanavadee Prachason², Claudia Menne-Lothmann³, Jeroen Decoster⁴, Ruud van Winkel⁵, Dina Collip³, Philippe Delespaul³, Marc De Hert⁶, Catherine Derom⁷, Evert Thiery⁸, Nele Jacobs⁹, Bart Rutten³, Jim van Os¹⁰, Laura Fusar-Poli¹¹, Sinan Guloksuz¹²

¹Karadeniz Ereğli State Hospital, ²Faculty of Medicine Ramathibodi Hospital, Bangkok, Thailand; School for Mental Health and Neuroscience, Maastricht University Medical Center, ³School for Mental Health and Neuroscience, Maastricht University Medical Center, ⁴Psychiatric Care Sint-Kamillus, Bierbeek, ⁵School for Mental Health and Neuroscience, Maastricht University Medical Center, ; University Psychiatric Centre KU Leuven, ⁶University Psychiatric Centre Katholieke Universiteit Leuven, Kortenberg, Belgium; Centre for Clinical Psychiatry, Katholieke Universiteit Leuven, Belgium; Leuven Brain Institute, Katholieke Universiteit Leuven, Antwerp Health Law and Ethics Chair, University of Antwerp, ⁷Centre of Human Genetics, University Hospitals Leuven, KU Leuven, Leuven, Belgium; Ghent University Hospitals, Ghent University, ⁸Ghent University Hospital, Ghent University, ⁹Maastricht University Medical Centre; Faculty of Psychology and Educational Sciences, Open University of the Netherlands, ¹⁰School for Mental Health and Neuroscience, Maastricht University Medical Center, ; Brain Centre Rudolf Magnus, University Medical Centre Utrecht, ; Institute of Psychiatry, King's Health Partners, King's College London, ¹¹University of Pavia, ¹²School for Mental Health and Neuroscience, Maastricht University Medical Center, Maastricht, the Netherlands; Yale School of Medicine

Background: Several environmental factors and coping styles are associated with psychosis expression (PE). However, available literature regarding gender differences in these connections remains inconsistent and limited. Therefore, we aimed to investigate the aforementioned gender differences in the general population.

Methods: Individuals comprising our sample were recruited from the TwinssCan study, a longitudinal examination of twins and siblings within the general population cohort. There were 791 participants aged between 18 and 35 years old. Linear regression models, considering PE as the dependent variable, were used in separate analyses for women and men. The regression coefficients of the analysis between men and women were compared using the Chow's test. PE was assessed with the Community Assessment of Psychic Experiences (CAPE). Winter birth, childhood trauma (CT), being bullied, and coping styles were independent variables. The following scales were used to assess the independent variables: The Childhood Trauma Questionnaire-Short Form for CT, Retrospective Bullying Questionnaire for bullying, the Life Events Questionnaire for negative life events, and the Utrecht Coping List for coping styles.

Results: Physical abuse, emotional abuse, and bullying, but not winter birth, were significantly associated with CAPE total and subscale scores in both genders. Emotional neglect was significantly associated with CAPE total, negative, and depressive scores in both genders, but with CAPE positive scores only in women. Physical abuse and sexual abuse were significantly associated with CAPE total, positive, and depressive scores in both genders, but with CAPE negative scores only in women. However, gender differences were not statistically significant in direct comparisons, Negative life events were associated with

CAPE total, negative, and depressive scores in both genders, but with CAPE positive scores only in women. Direct comparisons revealed significantly stronger associations of negative life events with CAPE positive and CAPE total scores in women ($\chi^2=6.54$, $P=0.010$; and $\chi^2=5.25$, $P=0.021$, respectively). Different types of coping styles were associated with CAPE scores in women and men. Particularly, the positive associations between expression of emotions and CAPE total and negative scores were stronger in women ($\chi^2=4.60$, $P=0.032$; and $\chi^2=5.64$, $P=0.018$, respectively) and negative associations between seeking social support and CAPE total, positive and depressive scores were also stronger in women ($\chi^2=9.82$, $P=0.002$; $\chi^2=11.45$, $P < 0.001$; and $\chi^2=6.25$, $P=0.012$, respectively).

Discussion: Our study investigated gender differences in the association of psychosis expression with environmental risk factors and coping strategies. Negative life events and specific coping styles, particularly expressing emotions and seeking social support, were associated with psychosis expression in women more strongly than men. Our findings emphasize the role of gender-specific associations of exposures with psychosis expression. Further exploration is needed to develop gender-informed public health measures to decrease modifiable exposures linked with psychosis.

T22. FETAL AND NEONATAL HEAD GROWTH IN OFFSPRING OF MOTHERS WITH PSYCHOTIC DISORDERS AND POPULATION-BASED CONTROLS

Lisanne van Houtum^{*1}, Dogukan Koc², Sterna Grundeman², Hans Duvekot², Hanan El Marroun², Neeltje Van Haren², Hilmar Bijma²

¹*Erasmus MC, University Medical Centre Rotterdam – Sophia, Rotterdam, the Netherlands,*

²*Erasmus Medical Center Rotterdam*

Background: Offspring of parents with severe mental illness (SMI), such as psychotic disorders, have a more than 50% increased risk for developing mental illness themselves, and over 30% develop SMI by early adulthood. There is evidence for an association between poor prenatal maternal mental health and decreased fetal head growth, suggestive of a link between high familial risk for mental illness and altered early neurodevelopment. This study aims to investigate differences in brain development, reflected in head circumference (HC) at birth and fetal HC growth trajectories, between offspring of mothers with a psychotic disorder and population-based controls. First, we investigate if offspring of mothers with a psychotic disorder have a smaller HC at birth compared to offspring of population-based control mothers. Second, we explore differences in fetal HC growth trajectories among both groups. Elucidating factors that accurately detect risk as early in life as possible is urgently needed to inform interventions to prevent mental illness in offspring at familial high risk.

Methods: In this retrospective observational study, we collected data from medical records of $N = 170$ pregnant women, who had a diagnosis of a psychotic disorder. As a control population, all pregnant women and their offspring participating in the Generation R study, having a singleton pregnancy with at least one HC measurement of their child will be included ($N = 8184$). Women who self-reported having a psychiatric disorder will be excluded from analyses. For our clinical cohort, fetal ultrasonography assessments were performed at approximately 20, 30, and 36 weeks of gestational age (GA). For controls, assessments were done around 13, 20, and 30 weeks GA. HC was additionally measured at birth with measuring tape. Multilevel modelling will be used to examine differences in neonatal HC between groups, while taking sibling data into account. To analyze how fetal HC growth varied as a function of group, we will use Generalized Additive Mixed Models. In both analyses, GA at assessment, child's sex, maternal national origin, maternal age, pre-

pregnancy BMI, parity, smoking, and psychotropic medication use will be included as potential confounders.

Results: We performed preliminary analyses on our clinical cohort data, comparing offspring of mothers diagnosed with schizophrenia or schizoaffective disorder (schizophrenia spectrum disorder (SSD) offspring; n=76) with offspring of mothers diagnosed with brief psychotic disorder or psychotic disorder not otherwise specified (PNOS offspring; n=65). Compared to PNOS offspring, SSD offspring exhibited significantly smaller fetal HC in the third trimester, i.e., both at 30 weeks GA ($F(1,136) = 8.591, p = .004$) and 36 weeks GA ($F(1,136) = 6.568, p = .011$), while controlling for GA, infant's sex, and maternal age. However, no significant differences in fetal HC at 20 weeks GA ($F(1,136) = .412, p = .522$) or HC at birth ($F(1,135) = .064, p = .801$) were found between the groups.

A next step will be to compare our clinical cohort with population-based controls. Findings will be presented as differences in HC at birth, as well as the trajectories of fetal HC change with GA.

Discussion: Preliminary findings may imply altered fetal neurodevelopment during the third trimester in offspring of mothers with SSD compared to PNOS. Comparison to population-based controls is necessary to confirm these findings and will be done in the next few months. Potential differences between groups will increase our knowledge about aberrant perinatal brain development in children at risk for SMI, and give us directions for possible underlying neural mechanisms related to the intergenerational transmission of mental illness.

T23. PROTOCOL: CHARACTERISTICS OF STUDY SAMPLES USED FOR THE DEVELOPMENT AND EVALUATION OF WEB-BASED WEIGHT LOSS PROGRAMS: A MENTAL HEALTH PERSPECTIVE

Naiiri Ghazari¹, Irina Papazova², Alkomiet Hasan²

¹*Psychiatry and Psychotherapy Faculty of Medicine University of Augsburg*, ²*Psychiatry and Psychotherapy Faculty of Medicine University of Augsburg*

Background: Weight gain is one of the main undesirable side effects of antipsychotic treatment leading to health complications, higher mortality and lower treatment compliance in people with schizophrenia. Web-based weight loss programs are a feasible way to address this issue. However, little is known about the strategies for the development and evaluation of these programs, specifically about their inclusion and exclusion criteria and applicability for patients with mental illness. This may lead to an inadequate prescribing for the excluded patient samples and therefore be stigmatizing for vulnerable groups who are specifically in need of such programs. This review attempts to access the characteristics of study samples used for the development and evaluation of web-based weight loss programs viewed from a mental health perspective with a focus on people with schizophrenia. Moreover, we will analyze the pros and cons of different web-based models regarding weight loss programs for people with severe mental illnesses.

Methods: We will conduct a search of peer-reviewed articles including the terms “web-based program”

“app*” AND “body mass index”, “weight reduc*” with focus on the exclusion and inclusion criteria in development and evaluation. We will search electronically for studies in English via the following databases: PubMed, PsycINFO, Embase and Cochrane Library database. Studies on other weight loss programs or combined interventions (web-based and in person) will be excluded.

Results: Ongoing systematic review, results will be provided by the time of the conference.

Discussion: Analysis of exclusion and inclusion criteria for a study population to test an intervention is essential. Excluding patients with schizophrenia in the development and the following evaluation of such programs could potentially neglect them. Therefore, an examination whether such supply gap exists is of importance as it may harm and reduce access to such programs for this vulnerable population.

T24. GENDER MODERATES THE ASSOCIATION BETWEEN BIRTH WEIGHT AND COGNITIVE BIASES IN A COMMUNITY SAMPLE OF ADOLESCENTS

Elena Estefania Gago Quintela^{*1}, Meritxell Tost Bonet², Montse Pamias³, Sara Perez⁴, Berta Blasco³, Itziar Montalvo Aguirrezabala⁵, Javier Labad⁶

¹Hospital del Mar, ²Parc Taulí Hospital Universitari, I3PT, Universitat Autònoma de Barcelona. CIBERSAM. Sabadell, Barcelona, ³Department of Mental Health, Parc Taulí Hospital Universitari, Sabadell, Spain., ⁴Translational Neuroscience Research Unit I3PT-Inc-UAB, Institut d'Innovació i Investigació Parc Taulí (I3PT), Institut de Neurociències, Universitat Autònoma de Barcelona, Spain., ⁵Hospital Universitari Parc Taulí, I3PT, Universitat Autònoma de Barcelona. CIBERSAM. Sabadell, SPAIN, ⁶Consorti Sanitari del Maresme, Mataró, Spain

Background: Genetic and environmental factors are involved in the pathogenesis of psychosis (Lemvigh, 2021;). Obstetric complications such as low birth weight (LBW) are one of the most widely studied environmental risk factors (Costas-Carrera, 2020; Sormunen, 2019). LBW is a well-documented risk factor for schizophrenia (Stilo, 2019). Psychotic experiences (PE) are more prevalent in young than in adults, most are non-pathological, typically transient, not associated with functional impairment and do not develop in psychotic disorder. However, the presence of PEs in childhood non-help-seeking community samples is associated with a 4-fold risk of a psychotic disorder (Tyson, 2019).

The present study aimed to examine the occurrence of PE in adolescents ages 14-15 and investigated whether environmental factors of early stress such as LBW would increase the presence of psychotic experiences and cognitive biases. We also explored if the relationship is moderated by gender.

Methods: Our sample was composed of 240 adolescents (147 girls; 93 boys, 1 transgender) born in 2004 (aged between 14 and 15 years) who were studying in high schools from Sabadell (Spain). A psychoeducation session on psychosis and risk for psychosis was conducted for each recruited high school followed by the anonymous self-applied online questionnaires on google forms to obtain sociodemographic and clinical information on psychotic experiences and cognitive biases of participants. The following questionnaires were administered: The 15-item Community Assessment of Psychic Experiences – Positive Scale [CAPE-P15]) (Capra, 2013); The Cognitive Biases Questionnaire for Psychosis [CBQp], with some items adapted for adolescents) (Peters, 2014); birthweight was obtained from childhood booklet. Multiple linear regression analyses were used for exploring the association between birthweight and psychometric scales while adjusting for gender, previous mental health history. The interaction between gender and birthweight was tested in all analyses, and only significant interactions were kept in the final model. We conducted a multiple linear regression analysis for each psychometric scale, which was considered the dependent variable. Therefore 6 regressions were tested for cognitive biases (CBQ total score plus 5 CBQ subscores) and 4 regressions were tested for positive psychotic-like experiences

(CAPE total score and 3 CAPE subscores). Significance was set as $p < 0.05$ (two-sided).

Results: There were significant differences between boys and girls in birth weight, as girls had a lower birth weight. The proportion of LBW was 4.3% in boys and 15.4% in girls ($p = 0.022$). Regarding the association between birth weight and psychometric scales, no associations were found for CAPE scores. However, for cognitive biases, the multiple linear regression analyses indicated significant gender by birth weight interactions in two CBQ domains: dichotomous thinking and jumping to conclusions. In girls, lower birth weight was associated with more cognitive biases in these two CBQ domains, whereas in boys an inverse association was found.

Discussion: PE and cognitive biases in adolescent general population are important predictors of transition to psychosis. Our study suggests that birth weight can be a risk factor for cognitive biases with sex differences. If our Results: are replicated in other adolescent populations, the assessment of birth weight might be useful for identifying adolescents at risk of presenting cognitive biases, a known risk factor of developing psychotic experiences and symptoms.

T25. HIPPOCAMPAL FUNCTIONAL CONNECTIVITY-BASED NEUROCOGNITIVE PREDICTION IN PATIENTS WITH CLINICAL HIGH RISK FOR PSYCHOSIS

Guanfu Wu^{*1}, Xiaochen Tang¹, LiHua Xu¹, HuiRu Cui¹, Zhenying Qian¹, Yanyan Wei¹, TianHong Zhang¹, Jijun Wang¹, Yingying Tang¹

¹*Shanghai Mental Health Center, Shanghai Jiaotong University School of Medicine, Shanghai Key Laboratory of Psychotic Disorders, Shanghai*

Background: Neurocognitive impairments have occurred in patients with clinical high risk for psychosis (CHR) and are candidates to predict the risk of transition to schizophrenia. The hippocampus is highly related to the pathophysiology of schizophrenia and its functional connectivity (FC) with other brain regions might underpin distinct neurocognitive domains. Therefore, it is important to identify the hippocampal FC-neurocognition associative patterns and whether/how these patterns are different between CHR and healthy control (HC) populations.

Methods: We recruited 226 CHR patients and 215 HC at the Shanghai Mental Health Center (part of the second phase of the Shanghai At-Risk for Psychosis Program). All CHR patients completed neurocognitive assessments using the MATRICS Consensus Cognitive Battery. Structural and resting-state functional MRI (fMRI) scans were acquired using a 3T Siemens Verio MRI scanner. The individual resting-state fMRI images were parcellated into 300 cortical parcels and 84 subcortical parcels using the AICHA atlas. The hippocampus was segmented into anterior and posterior subfields in each hemisphere and the FC map was obtained from each hippocampal subfield with the whole brain regions (383 FC for each subfield). We used support vector regression and performed 10 repeats of 10-fold cross-validation to build the FC-based neurocognitive prediction model. The model performance was measured by the Pearson's correlation coefficient between the predicted score and the actual score in each task. To find out the most predictive model for each task, we iteratively included an increasing number of FC from 1 to 383. The order of the included FC was based on each FC's absolute Pearson's correlation coefficient with the actual task score. Permutation test was performed by repeating 10-fold cross-validation 500 times while

shuffling the real task score. The predictive model with the best performance and passed the permutation test ($p < 0.05$) was identified for the specific neurocognitive task.

Results: We found that the anterior hippocampal subfields FC played an important role in predicting the Brief Assessment of Cognition in Schizophrenia Symbol Coding Test (BACS) and Brief Visuospatial Memory Test-Revised (BVRT) performances.

For the BACS task, FC between the bilateral anterior hippocampus (antHippo) and the left superior prefrontal gyrus, left precentral sulcus, bilateral temporal pole, left caudate, and left thalamus could well predict the BACS scores in HC (left antHippo: $r = 0.363$, $p = 0.048$; right antHippo: $r = 0.361$, $p = 0.046$). However, the predictive model for BACS scores in CHR showed a right-hemisphere effect, consisting of FC between the right antHippo and the right precentral sulcus, bilateral paracentral lobule, left occipital lobe, and right temporal pole ($r = 0.372$, $p = 0.046$). The predictive model in CHR included hippocampal FC with more widespread regions (sensorimotor areas) compared with HC (executive control network).

Regarding the BVRT task, there was no stable predictive model for HC. In CHR, FC between the left antHippo and the left prefrontal gyrus, left precentral sulcus, bilateral anterior cingulate, bilateral temporal lobe, and bilateral lingual cortex could predict their BVRT scores ($r = 0.357$, $p = 0.046$).

Discussion: We identified hippocampal FC-based predictive models for BACS and BVRT tasks, which were changed in CHR compared to HC. More importantly, the anterior hippocampal FC patterns may provide new insights into the underlying mechanism for impaired visuospatial learning and processing speed functions in CHR.

T26. THE ASSOCIATION BETWEEN ANTIPSYCHOTIC MEDICATION AND MORTALITY RISK IN PATIENTS WITH SCHIZOPHRENIA: EVIDENCE FROM THE 20-YEAR FOLLOW-UP

Chao Li^{*1}, Huiquan ZHOU¹, Kit Wa Sherry Chan¹

¹*The University of Hong Kong*

Background: Schizophrenia is associated with a higher mortality risk than other psychiatric disorders. Previous studies reported many risk factors related to greater and earlier mortality among individuals with schizophrenia. Among these related factors, the effects of antipsychotic medication on premature mortality have not reached a unanimous conclusion yet, especially in long-term mortality risk. We aimed to explore the association of antipsychotic medication with all-cause, natural cause, and unnatural cause mortality risk from the 20-year follow-up.

Methods: This cohort study included 1400 participants with a diagnosis of schizophrenia-spectrum disorders between July 1, 2001, to June 30, 2003. All participants were followed up until death or the end of the study (September 30, 2021). Information about time, cause of death, and clinical symptoms was obtained from the Clinical Management System (CMS) in Hong Kong. Antipsychotic medication information was collected from the Hong Kong Clinical Data Analysis and Reporting System (CDARS).

Results: A total of 1149 participants were included in the final analysis, and 108 participants died during 20 years of follow-up. In the whole follow-up period, longer duration of having antipsychotics was reported to be a protective factor of all-cause (HR, 0.9994; 95%CI, 0.9993-0.9995) and unnatural cause mortality (HR, 0.9993; 95%CI, 0.9992-0.9994) among patients with schizophrenia, and larger number of antipsychotic drugs was a risk factor of all-

cause (HR, 1.2143; 95%CI, 1.0949-1.3467) and unnatural cause mortality (HR, 1.214; 95%CI, 1.071-1.377). In the last year before death, longer duration of having antipsychotics (all-cause: HR, 1.0160; 95%CI, 1.0124-1.020; unnatural cause: HR, 1.0110; 95%CI, 1.0090-1.0140; natural cause: HR, 1.0330; 95%CI, 1.0240-1.0430) or the more significant number of discontinuous doses (all-cause: HR, 1.489; 95%CI, 1.208-1.834; unnatural cause: HR, 1.578; 95%CI, 1.405-1.771; natural cause: HR, 2.186; 95%CI, 1.428-3.346) were all reported to be the risk factors of all-cause, natural cause, and unnatural cause mortality among patients with schizophrenia.

Discussion: These findings suggested that longer antipsychotic medication duration could have long-term protective effects on mortality. In contrast, larger number of antipsychotic drug counts for a long period could increase long-term mortality risk among participants with schizophrenia. The antipsychotic medication over a long period has a different effect than that of the year before death, highlighting the importance of future research on antipsychotic medication in psychiatric patients both over a long period and over different periods.

T27. CLIMATE CHANGE, A MAJOR DETERMINANT OF MENTAL HEALTH AND A TARGET FOR EARLY INTERVENTION

Philippe Conus^{*1}, Yaëlle Fouvy¹, Philippe Golay¹, Céline Bourquin¹

¹*Lausanne University Hospital*

Background: Many elements in the scientific literature suggest that climate change has a negative influence on mental health. Considering this impact, we wanted to explore this link which may support the idea that acting against climate change may become a valid early intervention strategy in mental health.

Methods: We conducted an extensive literature review on the subject and conducted a large survey among 15'000 students at Lausanne university in order to explore various potential impact of climate change issues on the mental health of the young people aged 18 to 25.

Results: Many elements of the literature suggest there is a link between climate change and mental health which can be defined as direct (during major natural disasters), progressive (due to drought or rise in sea levels) and indirect (through mechanisms such as solastalgia and ecoanxiety). Amongst university students, 86% are worried to extremely worried about climate change, 55% exclude having children due to this problem and 26% consider themselves as suffering from ecoanxiety.

Discussion: Climate change has an important impact on mental health and may drive our societies to an important increase in the prevalence of many disorders such as PTSD, anxiety and depressive disorders and suicide. In addition, students are at high risk of mental health issues due to this phenomenon. Considering these elements, acting on climate change is a valid strategy for early intervention in mental health.

T28. EFFORT-BASED DECISION MAKING IN SUBCLINICAL PSYCHOTIC SYMPTOMS AND ITS RELATIONSHIP WITH AMOTIVATION

Sai Ting Chu^{*1}, CoCo Ho Yi Tong¹, Corine Sau Man Wong², Wesley Chor Yin Tang¹, Charlotte Cheuk Lok Chan¹, Christy Lai Ming Hui¹, Kit Wa Sherry Chan¹, Edwin Ho Ming Lee¹, Simon Sai Yu Lui¹, Yi Nam Suen¹, Eric YH Chen¹, Wing Chung Chang¹

¹The University of Hong Kong, ²School of Public Health, LKS Faculty of Medicine, The University of Hong Kong

Background: Research suggests that people with subclinical psychotic symptoms (PS) exhibit similar abnormalities in various cognitive functions with, albeit in a milder degree than, schizophrenia patients. Suboptimal effort-based decision-making with reduced willingness to exert effort for high-probability/high-value reward is observed in schizophrenia patients and is related to diminished motivation, but is understudied in PS. This study aimed to examine effort-allocation in PS individuals and its association with amotivation.

Methods: We recruited 100 individuals with PS and 100 demographically-matched healthy controls based on Psychosis Module of Composite International Diagnostic Interview (CIDI), from Hong Kong Youth Epidemiology Study of Mental Health (HK-YES), a population-based mental health study examining over 3500 youths in Hong Kong. Participants with lifetime diagnosis or family history of psychotic or bipolar disorder, or history of antipsychotic treatment were excluded. A well-validated computerized Effort-Expenditure for Reward Task (EEfRT) was administered to quantify physical effort allocation (hard vs easy task based on button pressing) for monetary reward (small, medium, high and highest) of varying magnitude and probability levels (12%, 50% and 88%). In addition, negative/amotivation symptoms were assessed by the Brief Negative Symptom Scale (BNSS). Individuals with PS were categorized into high-amotivation and low-amotivation groups based on a median-split of BNSS amotivation domain score.

Results: Our results showed marginally significant group by probability interaction effect (in two-group comparison) ($p=0.064$) on effort task performance. Selected EEfRT performance indices revealed that people with PS displayed marginally smaller increase in effortful options from low- to high-probability (probability-difference score) than controls ($p=0.063$). When median-splitting BNSS amotivation score, we observed a significant group by probability interaction ($F_{3,79,373.06}=2.80$, $p=0.028$). Post-hoc contrast tests on probability by group interaction were all non-significant (all p GREATER THAN 0.05). Three-group comparison analyses on selected EEfRT performance indices revealed that high-amotivation individuals with PS displayed significantly less increase in effortful options from low- to high- probability (probability-difference score) than controls ($p=0.022$), and a significant and marginally significant between-group effects from low-probability/low-value to high-probability/high-value reward (probability/reward-difference score) than low-amotivation individuals ($p=0.049$) and controls ($p=0.095$) respectively.

Discussion: Our findings indicated subtle effort-allocation abnormalities in PS individuals with high levels of diminished motivation. Our results in general aligned with subtle findings in studies in schizotypy and PS.

T29. PROGNOSTIC MODELS PREDICTING TRANSITION TO PSYCHOTIC DISORDER USING BLOOD-BASED BIOMARKERS: A SYSTEMATIC REVIEW AND CRITICAL APPRAISAL

Jonah Byrne^{*1}, David Mongan², Jennifer Murphy³, Colm Healy³, Melanie Föcking³, Mary Cannon³, David Cotter³

¹Royal College of Surgeons in Ireland, ²Queen's University Belfast, ³RCSI University of Medicine and Health Sciences

Background: Accumulating evidence suggests individuals with psychotic disorder show abnormalities in metabolic and inflammatory processes. Recently, several studies have employed blood-based predictors in models predicting transition to psychotic disorder in risk-enriched populations. A systematic review of the performance and methodology of prognostic models using blood-based biomarkers in the prediction of psychotic disorder from risk-enriched populations is warranted.

Methods: Databases (PubMed, EMBASE and PsycINFO) were searched for eligible texts from 1998 to 15/05/2023 which detailed model development or validation studies. The checklist for Critical Appraisal and Data Extraction for Systematic Reviews of Prediction Modelling Studies (CHARMS) was used to guide data extraction from eligible texts and the Prediction Model Risk of Bias Assessment Tool (PROBAST) was used to assess risk of bias and applicability of the studies. A narrative synthesis of included studies was performed.

Results: 17 eligible studies were identified: 16 eligible model development studies and one eligible model validation study. Several biomarkers were assessed including nucleic acids, proteins, metabolites and lipids. The range of C-index (area under the curve) estimates reported for the models was 0.67-1.00. No studies assessed model calibration. According to PROBAST criteria, all studies were at high risk of bias in the analysis domain.

Discussion: While a range of potentially predictive biomarkers were identified in the included studies, most studies did not account for overfitting in model performance estimates and all models were at high risk of bias according to PROBAST criteria. External validation of the models is needed to provide more accurate estimates of their performance. Future studies which follow the latest available methodological and reporting guidelines and adopt strategies to accommodate required sample sizes for model development or validation will clarify the value of including blood-based biomarkers in models predicting psychosis.

T30. COURSE OF NEUROCOGNITIVE DEVELOPMENT IN CHILDREN AT FAMILIAL HIGH RISK OF SCHIZOPHRENIA OR BIPOLAR DISORDER: A PROSPECTIVE COHORT STUDY FROM 7 TO 15 YEARS OF AGE. THE DANISH HIGH RISK AND RESILIENCE STUDY – VIA 15

Andreas Færgemand Laursen^{*1}, Anette Faurskov Bundgaard², Nanna Lawaetz Steffensen², Merete Birk³, Sinnika Rohd⁴, Martin Wilms⁵, Marta Schiavon⁶, Doris-Helena Feodora Bjarnadóttir Olsen⁶, Jens Richardt Møllegaard Jepsen⁷, Torill Ueland⁸, Merete Nordentoft⁹, Ole Mors¹⁰, Anne A.E. Thorup¹¹, Aja Neergaard Greve², Nicoline Hemager¹²

Jebsen, Psychosis Research Unit/TOP; University of Oslo, Norway,

⁹*Copenhagen University Hospital, Mental Health Center Copenhagen, Copenhagen Research Center for Mental Health - CORE,* ¹⁰*The Lundbeck Foundation Initiative for Integrative Psychiatric Research, Psychosis Research Unit, Aarhus University Hospital,* ¹¹*Mental Health Services – Capital Region of Denmark, Child and Adolescent Mental Health Centre, The Lundbeck Foundation Initiative for Integrative Psychiatric Research,* ¹²*Research Unit at Mental Health Center, Capital Region of Denmark and The Lundbeck Foundation Initiative for Integrative Psychiatric Research (iPSYCH)*

Background: Schizophrenia (SZ) and bipolar disorder (BP) are severe mental disorders with shared and distinct clinical, cognitive, and genetic risk factors. These risk markers are also present in the offspring, who have an increased risk of developing severe mental disorders. SZ is a neurodevelopmental disorder and neurocognitive impairments are presenting years before the manifestation of overt clinical symptoms. Findings regarding premorbid neurocognitive impairments in BP are less conclusive. Investigating the course of neurocognitive development before illness offers insights into both shared and disorder-specific vulnerability markers.

The neurocognitive results from previous assessments of the presented cohort showed stable neurocognitive deficits in children at familial high risk (FHR) of SZ and stable neurocognitive functioning in children at FHR-BP that were comparable to population-based controls (PBC).

The aim of the current study is to characterize the neurocognitive development in children at FHR-SZ and FHR-BP compared with PBC from age 7 to 15 and to identify potential subgroups of children across high-risk groups, with distinct neurocognitive profiles and developmental patterns.

We hypothesize that children at FHR-SZ will display either stable deficits or neurocognitive lags compared with PBC at age 15, and that children at FHR-BP will display stable comparable neurocognitive development or incipient lags at age 15 compared with PBC.

Methods: The Danish High Risk and Resilience Study is a population-based cohort of 522 children (202 FHR-SZ, 120 FHR-BP, and 200 PBC). They were assessed at baseline at age 7 (the VIA 7 study) and at first follow-up at age 11 (the VIA 11 study) with a retention rate of 89%. The VIA 15 study is the third wave of assessments at 15 years of age and started May 2021. Neurocognitive functioning is assessed with a comprehensive neurocognitive test battery of validated tasks covering a wide range of neurocognitive functions. The tests were selected to target neurocognitive functions known to be impaired in SZ and BP, including intelligence, processing speed, attention, verbal and visuospatial memory, verbal fluency, working memory, and executive functions.

Results: Data collection is ongoing and will be finalized in the spring of 2024.

Discussion: Examining the development of neurocognitive deficits in children at FHR-SZ and FHR-BP will elucidate shared and distinct endophenotypes and help differentiate the pathophysiology of these severe mental disorders. The long-term perspective is the ability to use the knowledge about the developmental trajectories to guide intervention studies and inform preventive interventions to improve functioning, quality of life, and potentially even prevent transition to mental disorders.

T31. THE LONGITUDINAL RELATIONSHIP BETWEEN PSYCHOTIC EXPERIENCES AND DISORDERED EATING IN HIGH SCHOOL ADOLESCENTS: BODY IMAGE AS A MEDIATOR

Feten Fekih-Romdhane*¹, Lilia Houissa¹, Souheil Hallit², Alexandre Andrade Loch³, Majda Cheour¹

¹Tunis El Manar University, Faculty of Medicine of Tunis, ²Holy Spirit university of Kasik, Lebanon, ³Universidade de Sao Paulo

Background: Despite all the evidence on the highly prevalent co-occurrence of psychosis and disordered eating (DE), the relationship between these psychopathological entities remains a challenging area of research to which little interest has been paid. As the vast majority of previous studies were hindered by a cross-sectional design and an inability to establish temporal associations or their corresponding underlying mechanisms, it is still unclear whether DE precedes or follows the onset of psychosis. In addition, previous evidence was mainly based on clinical samples at advanced stages of the diseases, which precludes investigation of the relationship psychosis-DE along the continuum, particularly in early stages where confounders such as chronicity of the disease and treatment effects are excluded. Using longitudinal data, we aimed to explore the hypothesis that the pathways from psychotic experiences (PEs) to DE and body-mass index (BMI) are mediated by body-image disturbances.

Methods: A prospective longitudinal study was performed. High-school students (N=510, 61.2% females, mean age of 16.05±1.01 years) were asked to complete three scheduled assessments (Baseline, 6 months, and 12 months).

Results: Two body image components, i.e. Overweight Preoccupation and Body Area Satisfaction, mediated the prospective association between baseline PEs and DE 12 months later. Direct effects were significant. After accounting for indirect effects through more severe body image concerns at 6 months, higher baseline PEs were significantly associated with greater DE at 12 months. Baseline PEs and 6-month body image explained a significant proportion of variance in 12-month DE. However, we did not find evidence of a direct prospective association between PEs and BMI.

Discussion: To the best of our knowledge, the present study provides, for the first time in literature, empirical evidence of direct and indirect longitudinal associations between PEs and DE through body image in non-clinical adolescents from an Arab North-African country. The first key finding that emerged from this study is that two body image components, i.e. Overweight Preoccupation and Body Area Satisfaction, mediated the prospective association between baseline PEs and DE 12 months later. Second, direct effects were significant. After accounting for indirect effects through more severe body image concerns at 6 months, higher baseline PEs were significantly associated with greater DE at 12 months. Together, baseline PEs and 6-month body image explained a significant proportion of variance in 12-month DE. However, we did not find evidence of a direct prospective association between PEs and BMI. These findings suggest that the identification of PEs as valid and reliable early markers of DE can further enhance our ability to detect its emergence in adolescents from the general population before it progresses to more severe stages. In addition, body image disturbances may be the key to reducing the impact of PEs on the emergence of later DE and are thus recommended to be the focus of prevention and individualized early intervention strategies.

T32. RISK OF HOMELESSNESS AFTER PRISON RELEASE AND RECIDIVISM IN DENMARK: A NATIONWIDE, REGISTER-BASED COHORT STUDY

Sandra Nilsson^{*1}, Merete Nordentoft², Seena Fazel³, Thomas Munk Laursen⁴

¹*Copenhagen Research Center for Mental Health - CORE*, ²*Mental Health Centre Copenhagen*, ³*University of Oxford*, ⁴*Aarhus University*

Background: Transitional periods between and across services have been linked to homelessness. We aimed to study the prior homelessness and psychiatric disorders according to the risk of post-release homelessness and the post-release homelessness and the risk of recidivism.

Methods: We did a register-based nationwide cohort study of 37,382 people aged at least 15 years released for the first time from prison in Denmark from 1 Jan, 2001, until 31 Dec, 2021, born 1980-2007. Information on release date, homeless shelter contact, psychiatric disorders (severe mental illness defined as any schizophrenia spectrum disorder or any bipolar disorder), and new convictions were obtained from the linked population-based registers. We estimated incidence rate (IR) and incidence rate ratio (IRR) using Poisson regression analysis adjusting for confounders and calculated cumulative incidences of post-release homelessness and recidivism.

Results: The study cohort included 37,382 individuals (34,792 males (93.1%) and 2590 females (6.9%)) aged 15-41 years of age who were released from prison during 2001-2021, accounting for 202,197 person-years (mean follow-up: 5.4 person-years) at risk. Overall, 1843 (4.9%) individuals became homeless. One year after release from prison, 2.1% had at least one homeless shelter contact, and it was 20.7% in those with homelessness prior to the index-imprisonment. The IR of post-release homelessness was 102.5 per 1000 person-years for individuals with prior homelessness and 6.7/1000 person-years in individuals without (IRR 16.4, 95% CI 14.8-18.2 adjusted for sex, age, and calendar year). Individuals who additionally had a severe mental illness had a similar IRR (16.2, 95% CI 12.8-20.7) compared with those without either, but higher for those with prior homelessness and drug use disorder (IRR 25.0, 21.6-28.9). Within two years post-release, the cumulative probability of recidivism was 73.2% (95% CI 72.8-73.7). People experiencing post-release homelessness had an IRR for recidivism of 1.5 (95% CI 1.3-1.7) compared with no homelessness. Individuals who experienced homelessness after prison release who also had a severe mental illness had 1.9-times increased rate of recidivism (95% CI 1.3-2.9) compared with no homeless shelter contact after release and no severe mental illness. Higher risk was found for homelessness in combination with drug use disorder or substance misuse comorbidity.

Discussion: Particularly attention to mental health and pre-prison homelessness and unstable housing is warranted for individuals incarcerated, to reduce the risk of further homelessness and other negative outcomes post-release.

T33. ABNORMAL GESTATIONAL AGE PREDICTS PSYCHOSIS RISK SYNDROME IN CHILDREN AND ADOLESCENTS: RESULTS FROM THE CAPRIS STUDY

Inmaculada Baeza^{*1}, Elena De la Serna², Olga Puig-Navarro³, Daniel Ilzarbe⁴, Gisela Sugranyes⁵, Adriana Fortea⁶, Andrea Juez-Gali⁷, Jordina Tor⁸, Daniel Muñoz-Samons⁸, Marta Rodriguez-Pascual⁸, Xavier Álvarez-Subiela⁸, Montse Dolz Abadia⁹

¹*Hospital Clinic de Barcelona*, ²*Centro De Investigación Biomédica En Red De Salud Mental, CIBERSAM*, ³*Child and Adolescent Psychiatry and Clinical Psychology Dept. H Clínic Barcelona*, ⁴*Institute of Neuroscience, Hospital Clinic de Barcelona*, ⁵*Instituto de*

Investigaciones Biomedicas de Barcelona, CSIC-IDIBAPS-CIBERSAM, ⁶Department of Child and Adolescent Psychiatry, Hospital Clinic / Fundació Clinic per la la Recerca Biomèdica (FCRB) / Universitat de Barcelona, ⁷Hospital Clínic de Barcelona, Spain; Universidad Internacional de la Rioja, ⁸Hospital Sant Joan de Déu, Barcelona, ⁹Hospital Sant Joan de Deu Barcelona

Background: Obstetric complications (OCS) are risk factors for a first episode of psychosis (Davies et al, 2020), but in clinical high risk states or psychosis risk syndrome (PRS) the results are controversial (Mittal et al, 2009; Yun et al, 2005). However, in children and adolescents with PRS no studies have addressed this issue.

The objective was to study the differences in OCS in children and adolescents with PRS for psychosis and healthy controls (HC).

Methods: An 18-month prospective longitudinal study (CAPRIS) in which help-seeking minors meeting PRS criteria were recruited from two hospitals in Barcelona, Spain. A sample of HCs were also included. At baseline, the Semistructured Interview for Prodromal Syndromes and Scale (SIPS/SOPS) were administered, as well as a clinical scale battery. To measure OCS, the Obstetric Complications Scale (Lewis and Murray, 1988) was used. Either definite or equivocal ratings were considered an indication of OCS.

Results: 198 PRS subjects and 153 HC were included. No differences were found in age between the samples (15.1 ± 1.7 v 15 ± 2) but 69.5% of PRS subjects were girls, significantly different than the 57.5% in HC ($\chi^2 = 5.425$, $p = 0.024$).

Subjects with PRS presented more OCS than HC (56.6 vs. 42.5%, $\chi^2 = 6.847$, $p = 0.010$). Moreover, 12.4% of PRS subjects had their birth at a definite abnormal gestational age vs. 3.6% of HC ($\chi^2 = 7.769$, $p = 0.005$). No other significant differences were found in the other OCS nor birth weight.

Logistic regression showed an association of abnormal gestational age with PRS (OR=1.68 95%CI:1.00-2.82, $p = 0.048$).

Discussion: OCS were more frequent in CHR subjects, specifically, abnormal gestational age, in line with previous studies of risk factors of psychosis (Fusar-Poli et al, 2017; Davies et al, 2020). The role in transition to psychosis and other psychopathological outcomes in this at risk young population deserves further study.

This study has been funded by Instituto de Salud Carlos III (ISCIII) through the projects PI21/00391 and PI21/0009, and co-funded by the European Union.

T34. AN EXAMINATION OF THE EARLY AND LATE STARTER TYPOLOGY OF CRIMINOGENIC BEHAVIOUR AND ITS RELATION TO IMPULSIVITY, PSYCHOTIC SYMPTOMS, AND AGGRESSION IN A SAMPLE OF INDIVIDUALS EXPERIENCING A FIRST EPISODE OF PSYCHOSIS

Shreya Jagtap^{*1}, Marco Kilada², Cory Gerritsen¹

¹Centre for Addiction and Mental Health, University of Toronto, ²Centre for Addiction and Mental Health

Background: Individuals with psychosis are at an increased risk, relative to the general population, of committing an aggression-related criminal offence, with up to one third of individuals experiencing their first episode of psychosis (FEP) engaging violence. Thus, early intervention of factors predicting aggression in this population is crucial. Past research has

identified two groups of offenders with major mental illnesses: early starters and late starters. These groups can be differentiated based on a range of factors which co-occur with criminogenic activity. One of these factors includes impulsivity, with greater impulsivity and lower behavioural control being characteristic of early starters (those who have committed criminal acts prior to the age of 18). Both psychotic symptoms and cognitive and behavioural impulsivity are shown to be predictive of aggression, however, little research has examined the relationship between these variables and aggressive behaviour in a FEP sample. The primary aim of this study was to determine whether individuals experiencing a FEP who are differentiated based on the early and late starter typology exhibit significant differences in levels of psychotic symptoms and cognitive and behavioural impulsivity.

Methods: This study recruited a sample of 24 individuals with a diagnosis of FEP syndrome who entered the mental healthcare system through both forensic (incarceration) and non-forensic (hospitalization) pathways. Cognitive impulsivity was assessed using contrast scaled scores of the interference trial of the Delis Kaplan Colour-Word Interference Test, and behavioural impulsivity was assessed using the Barrett Impulsiveness Scale. Current psychotic symptoms were assessed using factor dimensions from the Brief Psychiatric Rating Scale (BPRS). Aggressive incidents over childhood, adolescence, and adulthood were assessed using the Brown-Goodwin Aggression Scale. Three multiple linear regression models were conducted to examine if psychotic symptoms and cognitive and behavioural impulsivity predicted aggression in adolescence/childhood as well as during adulthood.

Results: Results of the first linear regression model indicated that model was statistically significant, $F(7,16) = 2.74$, $p = .045$, and the BPRS factors of negative ($\beta = -.48$, $p = .046$) and positive symptoms ($\beta = .65$, $p = .010$) significant predicted childhood and adolescent aggression, when controlling for adult aggression. Results from the second linear regression indicated that the model was statistically significant, $F(6,17) = 3.26$, $p = .026$, with the BPRS factor of anxiety/depression ($\beta = .55$, $p = .021$), as well as positive ($\beta = .62$, $p = .009$) and negative symptoms ($\beta = -.53$, $p = .017$) found to significantly predict childhood and adolescent aggression. Our third model was not found to be significant, $F(6,17) = 1.40$, $p = .270$, however, the BPRS factor of anxiety/depression was found to significantly predict adult aggression ($\beta = .60$, $p = .033$).

Discussion: Our findings highlight that current psychotic symptoms were demonstrated to be significantly linked to aggression in childhood and adolescence. These findings converge with existing literature supporting the existence of a predisposing factor related to aggression that is present prior to adulthood (e.g., conduct disorder), representing a possible distinct subtype of psychosis, which the current research suggests may be related to symptom severity during FEP. Of note, neither behavioural nor cognitive impulsivity predicted aggression in either childhood/adolescence or adulthood, suggesting that current symptoms are more related to past aggression than impulsivity in FEP, even when controlling for current aggression.

T35. THE ASSOCIATION OF AUTISTIC TRAITS AND PSYCHOSIS PRONENESS WITH ALLOCENTRIC AND EGOCENTRIC INTERPERSONAL DISTANCE

Ahmad Abu-Akel*¹, Mais Kanaan¹

¹University of Haifa

Background: People with autism and psychosis spectrum disorders (ASD and PSD, respectively) present more social isolation than any other diagnostic group and have smaller social networks than people from the general population. Interpersonal distance is a key

component of social behavior, which when violated may cause significant discomfort or distress and might help explain social isolation and functioning in both ASD and PSD. However, despite these similarities, the relationship between ASD and PSD and their extended phenotypic continua in the general population on how they might impact interpersonal distance within the same individual is yet to be examined. To address this gap, this study examines how variations in co-occurring autistic traits and psychosis proneness, and their specific phenotypes are similarly or differently associated with preference for interpersonal distance.

Methods: Data were obtained from 87 neurotypical adults from the general population (M/F = 27/61; Mean Age = 27.7; SD = 10.44) in whom both autistic traits and psychosis proneness were assessed in tandem. Autistic traits were assessed using the Abridged Version of the Autism-Spectrum Quotient (AQ-28) and psychosis proneness was assessed with the positive subscale of the Community Assessment of Psychic experiences. Analyzing subclinical expressions of ASD and PSD confers several advantages such as eliminating the confounding effects of medication, active symptomatology or illness chronicity. Participants were asked to indicate their preferred interpersonal distance from another person in a social setting under two conditions: when approaching a person (the egocentric condition) and when being approached (the allocentric condition). For each of the experimental conditions, regression analyses estimated the association of autistic traits, psychosis proneness and their interaction with preferred interpersonal distance. In a separate analysis, we also estimated for both conditions the association of autistic (social skills ,routine ,focus of attention, imagination ,and numbers and patterns) and psychosis proneness subscales (bizarre experiences, perceptual abnormalities, persecutory ideation, and magical thinking) with preferred interpersonal distance.

Results: The regression analyses showed that increased overall autistic traits were significantly associated with preference for greater interpersonal distance in both the egocentric and allocentric conditions. Overall psychosis proneness or its interaction with overall autistic traits were nonsignificant predictors. The regression analyses estimating the association of autistic and psychosis proneness phenotypes with preferred interpersonal distance revealed a more nuanced picture. In the egocentric condition, higher levels of autistic focus of attention traits were associated with greater distance, whilst higher levels of bizarre experiences were associated with shorter distance. In the allocentric conditions, higher levels of autistic focus of attention traits and higher levels of persecutory ideation were associated with greater distance, whilst higher levels of bizarre experiences were associated with shorter distance.

Discussion: Co-occurring psychosis proneness and autistic traits are associated with preferred interpersonal distance through both overlapping and diametric pathways. Increased focused of attention and bizarre experiences may respectively contrast in terms of rigid versus flexible self-boundaries. Persecutory ideation in the allocentric condition may relate to perceived threat and thus may be associated with a different mechanism pertaining to social isolation and self-protection. This study highlights the benefit of adopting a transdiagnostic, multidimensional approach in examining the impact of psychiatric and mental health conditions on the individual's social functioning and practices.

T36. TIME EXPECTATION AND SENSE OF SELF: THE ROLE OF MOTOR PREPARATION

Anne Giersch^{*1}, François Foerster², Brice Martin³, Ellen Joos¹, Jennifer Coull⁴

¹INSERM (French Medical Research Institute), ²INSERM U1114, ³Centre Hospitalier Drôme Vivarais, Montéleger-Valence, ⁴UMR 7291, Aix-Marseille Université, and Service Universitaire de Psychiatrie. Hôpital Ste Marguerite. Marseille

Background: It has long been proposed that individuals with schizophrenia (SZ) experience a breakdown of the experience of time continuity, and that this relates to disorders of the minimal self. This proposal relies on the patients' self-reports and the phenomenological analysis of their verbal descriptions. Recent experimental evidence supported this proposal by exploring time expectation in parallel with phenomenological evaluations (the EASE, Martin et al. 2017, Sci Rep), and by showing a link between disorders of the minimal self and of time expectation. Time expectation is indexed by the ability to benefit from the passage of time. This is observed when individuals react to a visual target appearing at various delays after a cue: expectation increases with time, leading to shorter reaction times when the target occurs after a long than after a short delay. Such expectation is implicit, as it does not require to explicitly think about time. It is close to conditions in everyday life. However, our former study required the target to be processed before giving a response (the subjects had to press to the side of the target), meaning that participants could not prepare their motor response in advance. This is a limitation because time accumulation is associated with SMA activation (Coull and Giersch, Nat Rev Psychol 2022) and involves motor aspects. Here we explored the benefit of the passage of time associated with motor preparation. To make sure the preparation was not altered by a 'surprise' effect (e.g. a target appearing earlier than on the previous trial), we considered only consecutive trials with identical delays.

Methods: Twenty four outpatients with SZ and 22 neurotypicals were recruited in a first study, and eighteen outpatients with SZ and 18 neurotypicals in a second study (in a different centre). In the first study, the target was shown 400 or 1000 ms after a neutral cue. Targets were shown on the left or on the right but participants could choose the side of their response. The second task took place in virtual reality, the target was always displayed in the centre, and delays were 900 and 1500 ms. There was no interaction with the task, and for the sake of simplicity here we display the results over the two tasks put together. We extracted a common factor reflecting the benefit of the passage of time by calculating the difference in RT between the short and long delays. We normalized the data by dividing this difference by the sum of RTs for short and long delays. The minimal self was evaluated with the EASE scale in the first study.

Results: The benefit of the passage of time was observed only in neurotypicals; it was not present in patients with SZ. Moreover, in study 1, we observed a correlation between the calculated benefit and the subscale 'presence'. Sub-group analyses confirmed that patients who feel as not being immersed in the world (EASE) do not benefit from the passage of time, consistent with previous results.

Discussion: The results confirm a fragility in time expectation in individuals with SZ, and generalize the results to motor preparation. They also confirm a link between this vulnerability and minimal self disorders, consistent with the idea that individuals with minimal self disorders (altered immersion in the world) display a breakdown of time continuity. The generalization of the effect to motor preparation means a disruption close to bodily self disorders, and is consistent with prior work suggesting altered motor planning.

T37. COGNITIVE CONTROL OVER SOCIAL THREAT: A TRUST VARIANT OF THE AX TASK PREDICTS PERSECUTORY IDEATION IN PSYCHOSIS PATIENTS AND HEALTHY ADULTS

Angus MacDonald*¹, Rebecca Kazinka²

¹University of Minnesota, ²University of Minnesota Medical School

Background: Failures of dorsolateral prefrontal cortex (DLPFC) on non-social cognitive control tasks have been replicably associated with the disorganization symptoms of psychosis patients (Chun, et al., 2018). In contrast, positive symptoms such as persecutory ideation have been modeled as the result of predictive coding errors which are largely unrelated to DLPFC (Sheffield, et al., 2022). However, recent imaging work suggests dysconnectivity between DLPFC and emotional and salience networks predicts suspicious decision making on a modified trust game (Wisner, et al., 2021; Kazinka, et al., in press). The current study used a social variant of a DLPFC-related task, the expectancy AX task, to scrutinize how cognitive control related to the expression of persecutory ideation.

Methods: In two studies (Study 1 n=117 undergraduate students; Study 2 = 46 psychosis patients and n=44 persecution-matched controls) participants responded as to whether or not to accept a “deal” from an individual identified by their face to obtain a favorite snack that they had picked. On most trials, participants were presented with a partner’s face (hereafter A) that was commonly followed by the preferred snack the partner would never actually give (hereafter X). Other faces (B’s) presenting that preferred snack would give it. Similarly, partner A would also be willing to give lesser snacks (Y’s) The task had 144 trials, with 72% AX, 11% AY, 11% BX, 6% BY trials. Participants were rewarded with a snack based on a random deal at the end of the experiment. Participants were psychometrically assessed for persecutory ideation, and patients were additionally interviewed.

Results: In both Studies 1 and 2, participants made relatively few errors when rejecting the untrustworthy A partner when offered the X snack, and made the most errors when attempting to trust that partner for other Y snacks. However, participants with the highest levels of persecution also failed to trust the B partners when they were offered their preferred X snack. Furthermore, patients showed more impairment on these trials than healthy adults.

Discussion: This social cognitive control task suggests an important role for the breakdown of the representation and maintenance of a trustworthy partner. This failure seems to occur in individuals expressing persecutory ideation and even more moderate levels of suspiciousness. This has important implications for understanding how common network and connectivity failures may manifest in different symptom factors and adds cautions to our interpretation of persecution as being simply a function of early reward-learning based predictions.

T38. INTRAUTERINE POSITION EFFECTS SHAPE RISK AND RESILIENCE IN A MOUSE MODEL OF MATERNAL IMMUNE ACTIVATION

Ron Schär*¹, Flavia Müller², Ulrike Weber-Stadlbauer³, Urs Meyer⁴

¹University of Zürich, ²Institute of Pharmacology and Toxicology, University of Zurich - Vetsuisse, Zurich, ³Institute for Veterinary Pharmacology and Toxicology, University of Zurich – Vetsuisse, ⁴Institute of Pharmacology and Toxicology, University of Zurich-Vetsuisse, Zurich

Background: Rodent models of maternal immune activation (MIA) are widely used as experimental tools to study the neuronal and behavioral dysfunctions in relation to immune-mediated mental illnesses, including psychotic disorders. Using a viral-like MIA model that is based on prenatal poly(I:C) exposure in mice, we have recently identified the existence of subgroups of MIA-exposed offspring that show dissociable behavioral, transcriptional, brain network and inflammatory profiles even under conditions of genetic homogeneity and

identical MIA. Interestingly, this variability in the effects of MIA was found to be largely driven by within-litter rather than between-litter variation. Here, we tested the hypothesis that intrauterine position, which are known to shape individual variability in litter-bearing mammals through variations in fetal hormone exposure, contribute to the variable outcomes of MIA in mouse models.

Methods: MIA was induced by maternal administration of poly(I:C) (5 mg/kg, i.v.) on gestation day 12 in C57BL/6N mice. In a first cohort, MIA-exposed and control offspring were delivered by Cesarean section (C-section) in order to determine possible intrauterine position effects on behavioral outcomes in adulthood. Offspring delivered by C-section were raised by foster mothers with identical treatment histories, whereby each foster mother kept 2 of its own (vaginally born) pups and received 6 C-sectioned pups. In a second cohort of offspring, MIA-treated and control dams were killed to collect fetal brains 3 hrs or 5 days after poly(I:C) or vehicle treatment. Fetal brain specimens were then used to measure pro- and anti-inflammatory cytokines (IL-1 α , IL-6, IL-10, and TNF- α) and testosterone.

Results: Adult offspring of MIA-exposed mothers displayed deficits in social approach behavior and prepulse inhibition (PPI) of the acoustic startle reflex, but only under conditions when fetuses were not neighbored by males in utero (0M-MIA offspring). In contrast, MIA-exposed offspring developing between 1 or 2 males in utero (1/2M-MIA offspring) did not show significant deficits in social approach behavior or PPI at adult age. These intrauterine position effects similarly emerged in male and female offspring. At 3 hrs after poly(I:C) administration, MIA elevated fetal brain levels of pro- and anti-inflammatory cytokines independent of the precise intrauterine position and sex of adjacent fetuses. At the later sampling interval (i.e., 5 days after treatment), however, fetal brain levels of TNF- α remained elevated specifically in 0M-MIA offspring, whereas all cytokine levels normalized in 1/2M-MIA offspring to levels measured in control fetuses. As expected, 1/2M offspring generally showed higher testosterone levels in the fetal brain as compared to 0M offspring, confirming the transfer of testosterone from male fetuses to adjacent male or female fetuses.

Discussion: The present study provides the first direct evidence suggesting that intrauterine position effects contribute to variable outcomes in schizophrenia-related behaviors and inflammatory responses in a widely used mouse model of MIA. In broader context, our findings highlight that individual differences in fetal testosterone exposure may be a perinatal factor that shapes risk and resilience to MIA.

T39. TEMPORAL ORDER AND CAUSALITY JUDGMENTS IN SCHIZOPHRENIA

Cristina Rusu¹, Brice Martin², Anne Giersch¹, Cristina Rusu*³

¹INSERM (French Medical Research Institute), ²Centre Hospitalier Drôme Vivarais, Montéleger-Valence, ³INSERM

Background: Ordering events in time is involved in the understanding of causal relationships between successive events. Faulty causal interpretations can lead to false beliefs, which might eventually result in an altered perception of reality. We repeatedly showed that individuals with schizophrenia (SZ) have difficulties to judge the temporal order of two events (Capa et al., 2014, Schiz Res; Arrouet et al., 2022, Timing and Time Perception). Here we explored how temporal difficulties affect causality. We adapted a paradigm typically used to explore causality (the Michotte paradigm) in order to evaluate causality and order judgements on the same material, i.e. to explore the relation between those two judgements in individuals with SZ vs. neurotypicals.

Methods: Twenty eight outpatients with SZ and 21 neurotypicals were recruited for this study. The two groups were matched on age, sex and education level. All participants ran three successive tasks entailing exactly the same trials. However, each task required different judgements. On each trial a square moved at 2°/second on a horizontal axis, starting from 1.7° in the periphery (left or right) and moving in the direction of the center of the screen. It stopped when it reached the position of a second square, which was displayed on the opposite side of the screen (1.7° left or right from the screen center). This second square remained static, and was displayed at various time delays (17, 32, 64, 128, 256 or 512 ms) before or after the stop of the moving square. In one task the participant evaluated to which amount the static square stopped the moving square, and answered by giving a number between 0 and 100. On the other causality task, the participant evaluated to which amount the moving square caused the appearance of the static square, and again answered with a number between 0 and 100. The order of the two causality tasks was randomized. In the third task participants had to emit a temporal order judgement, by pressing to the side of the first event, i.e. the stop of the moving square (event M) or the onset of the static square (event S).

Results: In controls causality judgement dropped when the delay between events M and S was more than 200 ms. Judgements of causality in individuals with SZ were similar to neurotypicals for short delays between events M and S (LESS THAN 200 ms), but remained high, and significantly higher than controls for large delays between events M and S (GREATER THAN 200 ms). In the temporal order judgement task, patients gave less correct responses than neurotypicals for delays larger than 200 ms, despite the fact that these are the easiest conditions. In addition at short delays, neurotypicals, but not individuals with SZ, were biased to answer that event S was the first one.

Discussion: This study brings further evidence for a difficulty in temporal order processing in SZ. Importantly it shows that difficulty at correctly detecting temporal order is accompanied by increased perceived causality when two successive events are temporally separate. Such a difficulty may contribute to aberrant causality. The bias at short delay appears to be due to an attentional bias following causality judgements. Motion is believed to play an important role in causality judgements. Conversely having to judge whether the static square stopped the moving one may have biased the participants' attention towards the S event. The lack of bias in individuals with SZ shows that causality judgements do not impact their temporal order perception. Their judgement of causality may be of a different nature if they have difficulty to determine order, and may be more noisy. In turn if their causality judgements are noisy, they may not influence temporal judgements as strongly as in controls.

T40. COGNITIVE REMEDIATION THERAPY FOR EXECUTIVE FUNCTION AND AGGRESSIVE BEHAVIOURS IN FORENSIC PSYCHOSIS

Cecelia Shvetz*¹, Patrizia Pezzoli², Jasmin Yee¹, Yuvika Dandiwal³, Katie Bush¹, Nicole Rodrigues⁴, Sanjiv Gulati⁴, Michael Seto³, Synthia Guimond³

¹Carleton University, ²University College London, ³University of Ottawa Institute of Mental Health Research, ⁴Brockville Mental Health Centre

Background: Executive function deficits are a core feature of psychosis, encompassing difficulties in planning, strategic thinking, problem-solving, and appropriate behavioural responses^{1,2}. In forensic patients with psychosis, executive function deficits can interfere with rehabilitation outcomes and may relate to displays of verbal and physical aggression³. Cognitive remediation therapy (CRT) can be used to improve executive function⁴ and relevant outcomes, including aggressive behaviours^{5,6} in schizophrenia. Despite chronic and

persistent executive function deficits in forensic patients with psychosis, CRT is not a standard component in forensic rehabilitation programs⁷. Therefore, further testing of CRT with forensic patients is required.

Methods: Thus far, 16 forensic psychiatry patients with psychosis (target N = 30) participated in a randomized, double-blinded randomized controlled trial using CRT. Groups are referred to as A and B for blinding purposes. Training visits occurred twice per week for 5 weeks. Executive function was assessed using a subset of tests from the Cambridge Neuropsychological Test Automated Battery⁸, psychiatric symptoms were assessed using the Clinical Outcomes in Routine Evaluation-Outcome Measure⁹, incidents of aggressive behaviours were assessed through the Aggression Questionnaire¹⁰, and functional capacity was assessed using the Generalized Self-Efficacy Scale¹¹. All variables were assessed at three timepoints one-week pre-training (T1), one-week post-training (T2), and 3-months post-training (T3). Paired-sample t-tests were used for the preliminary analyses, and Cohen's d was used to measure effect sizes.

Results: All participants had a primary diagnosis of schizophrenia, schizoaffective disorder, or bipolar I disorder with psychotic features, except one participant with a diagnosis of major depressive disorder. Executive function: Group A showed a significant decline from T1 to T2 ($t(4) = 2.90$, $p = 0.04$), and T1 to T3 ($t(3) = 3.61$, $p = 0.04$), but not T2 to T3 ($p > 0.05$). Group B showed no significant changes across timepoints (all $p > 0.05$), but moderate improvements were found from T1 to T2 (Cohen's $d = 0.69$) and T1 to T3 (Cohen's $d = 0.77$), and small improvements from T2 to T3 (Cohen's $d = 0.69$). Mental health symptoms: No significant differences were found across timepoints in either Group A or B (all $p > 0.05$), but small improvements were found from T2 to T3 (Cohen's $d = 0.32$) and T1 to T3 (Cohen's $d = 0.45$) in Group A and from T1 to T2 (Cohen's $d = 0.24$), and large improvements from T2 to T3 (Cohen's $d = 0.95$) and T1 to T3 (Cohen's $d = 1.27$) in Group B. Aggressive behaviours: Group A showed significant improvements from T2 to T3 ($t(3) = 4.38$, $p = 0.02$), and small, but statistically insignificant improvements (all $p > 0.05$) from T1 to T2 (Cohen's $d = 0.24$) and T1 to T3 (Cohen's $d = 0.47$). Group B showed significant improvements in self-reported aggressive behaviours between T1 and T2 ($t(2) = 5.47$, $p = 0.03$), and statistically insignificant but a small improvement was seen from T2 to T3 (Cohen's $d = 0.23$).

Discussion: Group A showed significant reductions in executive function from T1 to T2 and T2 to T3 and significant improvements in aggressive behaviours from T2 to T3. No other comparisons were significant. Group B showed no significant change; however, we observed moderate improvements in executive function from T1 to T2 and T1 to T3, and large improvements in mental health symptoms from T2 to T3 and T1 to T3. While our results are still blinded, we cannot draw direct conclusions on the efficacy of CRT in forensic patients. After achieving our target sample size of 30 participants, we intend to use mixed-effect models to compare outcomes in the two groups, thus more conclusively evaluating the efficacy of CRT in improving cognitive, behavioral, and clinical outcomes in forensic psychiatry patients.

T41. DEFICITS IN VISUAL AND AUDITORY EMOTION RECOGNITION AND AMYGDALAR VOLUME ABNORMALITIES IN AT-RISK MENTAL STATES AND SCHIZOPHRENIA

Francesca Serio^{*1}, Matthew Cotter², Alessia McGowan², Cheryl Corcoran², Shalaila Haas³

¹*Icahn School of Medicine at Mount Sinai; University of Milan*, ²*Icahn School of Medicine at Mount Sinai*, ³*Icahn School of Medicine at Mount Sinai Tri-institutional Center for Translational Research in Neuroimaging and Data Science (TReNDS)*

Background: Schizophrenia is characterized by profound deficits in visual and auditory emotion recognition. These deficits are related to poor disease outcome, with lack of efficacy of pharmacological treatments. Different studies demonstrated links between reduced amygdalar volumes and ability to recognize emotions, specifically of threats, in schizophrenia (SZ). Evidence suggests that these alterations might be present years before the onset of the disease, still, little is known about individuals at clinical high risk (CHR) for psychosis. In this study, we investigated visual and auditory emotion recognition in CHR and SZ individuals and its association with amygdala volumes in structural MRI.

Methods: The Penn Emotion Recognition and Discrimination Task for face emotion recognition (FER) and the Brief Swedish Task for auditory emotion recognition (AER), were administered to 38 healthy controls (HC; age[SD]=25.88 [4.44]; 17 [49%] females), 72 CHR subjects (age=23.03 [4.99]; 33 [51%] females), and 21 schizophrenia patients (SZ; age=26.92 [5.27], 6 [38%] females). Additionally, all participants included in the study underwent T1w brain structural neuroimaging, and Freesurfer v7.1.0 was used to extract left and right amygdala volumes. ANOVA and Bonferroni post-hoc t-tests were used to evaluate group differences, and Spearman's correlations were performed to identify associations between AER and FER, and their links with bilateral amygdala across the three cohorts.

Results: There was no significant difference in sex between the groups ($\chi^2=0.48$, $P = 0.79$), however there was a significant difference in age ($F = 7.70$, $P = 6.97E-4$) with CHR younger than both the HC and SZ groups. One-way ANOVA revealed significant differences in FER ($F = 3.88$, $P = 0.02$), with post-hoc t-tests revealing significant pairwise group differences between HC-CHR ($P = 0.05$) and HC-SZ ($P = 0.04$). Across all subjects, there were significant positive correlations between FER and AER total scores ($\rho = 0.35$, $P = 9.26E-5$), and between threats emotions of anger ($\rho = 0.27$, $P = 3.51E-3$) and fear ($\rho = 0.26$, $P = 4.03E-3$). Within CHRs, there were significant correlations between anger FER and left ($\rho = 0.36$, $P = 0.03$) and right ($\rho = 0.33$, $p 0.05$) amygdala volumes. In SZ, there were significant

correlations between anger AER and left ($\rho = 0.68$, $P = 0.03$) and right ($\rho = 0.68$, $P = 0.03$) amygdala was found. No other associations were significant.

Discussion: In this study, we identified group differences in emotion recognition across the psychosis spectrum, and links between auditory and visual emotion recognition. Although we did not identify associations between overall auditory and emotion recognition with amygdala volume in CHR and SZ, differential modalities were linked with amygdala volume for anger across the psychosis spectrum, with bilateral amygdalar volumes associated with the recognition of anger in visual and auditory expressions within CHR and SZ, respectively. This study supports findings indicating amygdala dysfunction may contribute to alterations in emotion recognition in at various stages of schizophrenia.

T42. SOCIAL WITHDRAWAL IN PSYCHOSIS PHENOTYPE IN THE GENERAL POPULATION: NOVEL INSIGHTS FROM THE NETWORK ANALYSIS PERSPECTIVE

Michal Hajdúk^{*1}, Hana Kutlikova¹, Alexandra Straková¹, Vladimír Ivančík¹, Jakub Januška¹, Adam Kurilla¹, Natália Čavojská¹, Anton Heretik¹

¹*Comenius University in Bratislava*

Background: Psychosis symptoms are also observable in the non-clinical population and have been shown to be linked to the same risk factors as those found in individuals with psychotic disorders. More specifically, the severity of positive and negative symptoms is linked to the indicators of social withdrawal, such as loneliness, a smaller number of social contacts, or perceived rejection. These associations are present even in the general population. The aim of this study is to examine unique associations of symptoms with indicators of social withdrawal in the general population using a network analysis approach.

Methods: The sample was representative of the general adult Slovak population. The final sample consisted of 1200 participants, of whom 51,5% were female. Data were collected via a professional survey agency. The psychotic phenotype was measured by the Community Assessment of Psychic Experiences - CAPE-42. The UCLA loneliness scale, Social Functioning Scale, NIMH Perceived Rejection, and WHO-DAS-2 were utilized to assess social withdrawal. In addition, we administered self-report measures of social motivation and mentalizing. A Gaussian Graphical Model with EBIC Lasso regularization was used for network estimation. The centrality of nodes in the network was evaluated using Strength centrality. The stability of the network was evaluated with the Bootstrap approach.

Results: Bizarre experiences were strongly connected to other positive psychotic-like experiences. Paranoia was a link between positive psychotic-like symptoms and negative symptoms. Social approach motivation was connected to other social functioning domains, as well as to social withdrawal measured by CAPE-42. Out of all negative symptoms, paranoia was primarily connected to perceived rejection. The most central nodes in the estimated network were delusion-like experiences, social withdrawal (from CAPE-42), approach social motivation, avolition, and paranoia. The nodes with the lowest importance, showing few or weak connections within the networks, were perceived rejection, participation activities, social engagement measured by SFS, mentalizing, and grandiosity. Based on the Bootstrap analysis, the estimated network was very stable. The CS coefficient was very high ($CS=0.75$).

Discussion: The results reveal that positive and negative symptoms in the general population have specific links to particular domains of social withdrawal. More specifically, paranoia is linked to negative perception of others, while negative symptoms are linked to the aspects related to the approach motivation and social engagement. Supported by VEGA: 1/0493/23

T43. BREAKING DOWN PROCESSING SPEED: MOTOR AND COGNITIVE INSIGHTS IN FIRST-EPISODE PSYCHOSIS AND UNAFFECTED FIRST-DEGREE RELATIVES

Ángel Yorca-Ruiz*¹, Rebeca Magdaleno Herrero², Nancy Murillo-García³, García de la Foz Víctor⁴, Rosa Ayesa-Arriola⁵

¹Valdecilla Research Institute, ²Marqués de Valdecilla University Hospital, IDIVAL, ³Valdecilla Biomedical Research Institute. Research Group on Mental Illnesses., ⁴Marqués de Valdecilla University Hospital. IDIVAL, Instituto de Investigación Valdecilla. Santander, Spain. CIBERSAM, ⁵Valdecilla Biomedical Research Institute IDIVAL Research Group on Mental Illness, Marqués de Valdecilla University Hospital, University of Cantabria

Background: Processing Speed (PS) deficits represent a fundamental aspect of cognitive impairment, evident not only in schizophrenia but also in individuals undergoing their first episode of psychosis (FEP) and their unaffected first-degree relatives. This observation suggests a potential hereditary component within this cognitive domain. While the Digit-Symbol Coding Test (DSCT) is considered the gold standard for assessing PS in schizophrenia, the involvement of motor and cognitive subcomponents in task performance may not precisely indicate a specific measure of PS. In light of this, our study aims to comprehensively explore several tests related to PS, revealing the implications of motor and cognitive subcomponents across various PS tests in FEP patients, their parents and siblings, and a control group.

Methods: The study involved 579 participants, including 133 individuals with FEP, 146 parents, 98 siblings, and 202 healthy controls. Neuropsychological assessments covered verbal and visual memory, executive functions, working memory, PS, motor dexterity, attention, and premorbid IQ. Tasks were selected wherein execution time served as an indicator of PS and included the Trail Making Test part A and B, DSCT, Grooved Pegboard Test, and Stroop Word and Color subtests. From the selected PS tests, ANCOVA analysis of covariance was administered to observe differences between groups. Pearson correlation was applied to scrutinize the relationships between the tests across groups. Subsequently, a model was derived by applying Exploratory Factor Analysis (EFA) within the control group. Finally, Confirmatory Factor Analysis (CFA) was implemented across the FEP, sibling, and parent groups to determine whether individuals with FEP and their first-degree relatives shared a cognitive structure in PS.

Results: FEP obtained the lowest scores in all tests compared to the sibling, parent, and control groups. Post-hoc tests showed that first-degree relatives obtained intermediate scores between the controls and FEP, except for the Stroop color test, where the siblings group scored lower than the other groups. The data were suitable for factor analysis (KMO: 0.732). EFA reveals a two-factor structure; resolution accounted for 62.9% of the total variance, with Factor 1 explaining 45.09% of the variance and Factor 2 explaining 17.85%. CFA confirms the two-factor model across groups, with varying correlations between factors.

Discussion: The two-factor model, common to all the groups, shows a Factor 1 reflects the motor subcomponent, and Factor 2 is associated with the cognitive subcomponent. Patients exhibit higher motor factor loadings, while relatives show intermediary patterns showing heritability. Cognitive dedifferentiation, as indicated by correlations between Factor 1 and Factor 2, suggesting a loss of functional specialization, is observed in individuals experiencing their FEP and their relatives. The distinct patterns of involvement in various PS

subcomponents suggest the adoption of compensatory strategies to succeed in PS tasks. Motor subcomponent performance in PS is preserved in first-degree relatives, whereas deficits in response selection are shared with FEP, implying the involvement of hereditary factors. A profound understanding of the nuances of processing speed has the potential to guide precise diagnostic assessments and targeted interventions in schizophrenia spectrum disorders.

T44. SYNERGISTIC, LONG-TERM EFFECTS OF GLUTAMATE DEHYDROGENASE 1 DEFICIENCY AND MILD STRESS ON COGNITIVE FUNCTION AND MPFC GENE AND MIRNA EXPRESSION

Kfir Asraf*¹, Hiba Zaidan¹, Inna Gaisler-Salomon¹

¹*University of Haifa*

Background: To investigate gene x environment interactions in a mouse model of cognitive deficits, we examined the impact of mild stress in mice genetically modified to express deficient levels of glutamate dehydrogenase 1 (GDH). GDH (gene name: Glud1) plays a central role in glutamate metabolism and is downregulated in the hippocampus of patients with schizophrenia. Mice with a full deletion of Glud1 in CNS (C-Glud1^{-/-} mice) previously showed abnormally high glutamate levels and a wide range of behavioral deficits.

Methods: Here, we exposed heterozygous C-Glud1^{+/-} mice and their C-Cre⁺ controls to mild stress in early adulthood. Stress-naïve mice of both genotypes were used as controls. Seven days later, mice were tested in a battery of behavioral tests assessing locomotor activity, social behavior and cognitive function. Fourteen days following behavior, medial prefrontal cortex samples were removed and analyzed for expression changes in transcriptome and select microRNA molecules using RNA-seq and RT-PCR, respectively. In a second cohort, brains were extracted immediately after the stress.

Results: Stress-exposed C-Glud1^{+/-} mice showed novelty-induced hypo-locomotion and impaired spatial acquisition and reversal. Transcriptomic analyses revealed vast changes in glutamatergic, GABAergic and stress-related genes, which were unique to stress-exposed Glud1-deficient mice. These behavioral and molecular deficits were absent in stress-naïve CNS-Glud1^{+/-} mice and in stress-exposed CNS-Cre⁺ controls. MiR203-5p emerged as a potential mechanism for the effect of stress exposure.

Discussion: Our findings indicate that CNS-Glud1^{+/-} mice exposed to stress in early adulthood display cognitive deficits, as well as molecular abnormalities, which are also relevant to stress exposure and psychopathology.

T45. A REVIEW OF SPEECH MARKERS IN BIPOLAR DISORDER MENTAL STATES

Farida Zaher*¹, Jessica Ahrens², Alban Voppel³, Lena Palaniyappan⁴

¹*McGill University*, ²*Douglas Research Centre*, ³*McGill University, Department of Psychiatry*, ⁴*Douglas Mental Health University Institute*

Background: Bipolar disorder (BD) is a chronic, recurrent, and life-long disorder that is characterized by mild to severe fluctuations in mood and energy, lasting anywhere from days to months. Early intervention for BD is especially important because it is more responsive to

treatment in the early phases of the illness. The occurrence of psychotic symptoms in bipolar disorder further impacts illness severity, increasing the likelihood of comorbid disorders, rates, and duration of hospitalization. BD is commonly misdiagnosed, especially in the initial presentation, however, there is increasing evidence that an at-risk bipolar state could potentially be targeted through speech because it can capture various bipolar mental states, such as psychosis, mania, depression, and other mood fluctuations; manic and depressive episodes have been characterized by speech abnormalities, such as pressured speech and poverty of speech. Therefore, this review aims to summarize the current research on speech markers in bipolar mental states.

Methods: We searched MEDLINE, PubMed, and Google Scholar databases in July 2023. All published human studies written in English relating to speech markers during any bipolar mood state were included.

Results: We initially screened 636 studies and selected 40 studies investigating speech in patients with BD. Results demonstrated observable linguistic patterns across bipolar mood states. Manic states were associated with pressured speech, derailment, increased grammatical errors, word repetition, verb, and pronoun use, as well as decreased adjective and preposition use. Associations were found between depressive states and increased use of personal pronouns, modifying adverbs, and poorer verbal fluency. Pressured speech was found to be able to differentiate between bipolar-depressed and unipolar-depressed youth. Hypomania and depression were differentiated using speech-based classifiers. Voice quality parameters and features were also found to correlate with emotional states, with an increased accuracy in the classification of manic and mixed states compared to depressive states.

Discussion: Due to the nature of the mood swings that occur in BD, the risk of suicide is significantly higher than the rest of the population. Identifying speech markers that characterize a manic, psychotic, or depressive state may facilitate the development of prediction and prevention frameworks for early intervention and treatment. The ability to use speech to identify mental state fluctuations in BD could lessen the consequences associated with this mental illness, by providing patients and clinicians with a more reliable and objective method to predict an oncoming mood episode, for accurate diagnosis, early intervention, and treatment. Also, if we can use speech to distinguish between bipolar mental states, then we can also use these same speech markers to further our study of psychosis, schizophrenia, and depression.

T46. UNLOCKING COGNITIVE POTENTIAL: THE EFFICACY OF CO.DI.S INTERVENTION AND QUALITATIVE AND QUANTITATIVE ANALYSIS OF AUDIO-RECORDED SPEECH IN PSYCHOTIC SPECTRUM DISORDER

Valerio De Lorenzo^{*1}, Federico Fiori Nastro², Fabiola Ferrentino³, Francesca Russo³, Syria Dimonte², Valeria Gosti², Maria Chiara Scaramella², Alberto Siracusano², Cinzia Niolu², Giorgio Di Lorenzo²

¹*University of Rome Tor Vergata*, ²*University of Rome Tor Vergata, Rome, Lazio*, ³*Institute of Neuroscienze NEOMESIA, KOS Group*

Background: Psychosis spectrum disorders are complex and lifelong conditions marked by atypical cognitive, linguistic, and social functioning. Recently, cognitive dysfunctions have been identified as a predictor of unfavorable functional outcomes in the psychosis prodrome.

Language domain has been demonstrated to be impaired in various aspects, including syntax, semantics, and pragmatics. Studies have consistently shown disruptions in the coherence and organization of speech and challenges in expressing thoughts cohesively.

Psychosocial interventions consistently demonstrate advantages in restoring cognitive abilities.

This study aims to validate the effectiveness of specific cognitive exercises for semantic differentiation (*esercizi Cognitivi di Differenziazione Semantica, Co.Di.S*) as reinforcement of standard cognitive remediation rehabilitation treatment. Additionally, it seeks to conduct a qualitative and quantitative analysis of audio-recorded voice samples from a group of patients suffering from psychotic spectrum disorder.

Methods: Preliminary data were collected from a longitudinal research investigation. A cohort of 19 participants (79% males; age mean: 29.4 years) was recruited from the psychiatric outpatient program of Policlinico Tor Vergata in Rome. Inclusion criteria encompassed individuals with psychotic spectrum disorder, clinically stabilized for a minimum of 3 months, without a history of head trauma, comorbid neurological diseases, or IQ deficiency.

Global cognitive and functional assessments were administered, including the MATRICS Consensus Cognitive Battery (MCCB), Rey Auditory Verbal Learning test (RAVLT), Babcock, Verbal Fluency-Semantic Category, and the Life Skills Profile (LSP). Furthermore, the Faux Pas assessment and the screening of the video Monsterbox were employed for all subjects to delve into social cognition skills, with vocal audiological samples recorded during these evaluations.

All participants engaged in a conventional cognitive remediation treatment (Cogpack®) enhanced by the Co.Di.S.

Results: A paired-sample t-test was employed to assess the efficacy of the treatment across various cognitive domains. Notably, statistically significant improvements were identified in verbal learning (HVL) ($p < .001$) and working memory (LNS) ($p = .003$). Additionally, RAVLT and Verbal Fluency-Semantic Category, which investigated verbal learning, also exhibited statistically significant enhancements ($p = .003$ and $p = .010$, respectively). Finally, the LSP demonstrated a statistically significant improvement ($p = .003$).

The audiological speech analysis indicates improvement in social cognition and perception. Additionally, evidence of extended pauses and increased specificity and quality of words and sentences suggest reduced response impulsivity. Finally, the increased density of expressions with affective content implies a broader range of emotional features in patients' speech.

Discussion: The study is a preliminary validation of the efficacy of Co.Di.S intervention in improving cognitive and social functioning among individuals with psychotic spectrum disorders. Considering the restricted effectiveness observed in pharmacological treatments for cognitive and language impairments in psychosis, the integration of psychosocial and rehabilitation interventions becomes imperative. Subsequent investigations will be conducted to assess the impact of semantic fluency improvement on both positive and negative symptomatology. Future research endeavors should expand the study's sample size and compare treatment effectiveness with a control group.

T47. PRELIMINARY STUDIES ON THE GRAMMATICAL PROSODY OF SCHIZOPHRENIA PATIENTS

Leonardo Lopes¹, Daniela Coelho², Marcelo Sousa³, Igor Oliveira³, Lucas Mantovani², João Salgado⁴, Tommaso Raso³, Bruno Rocha³, Joao Salgado*⁵

¹other, ²Instituto Raul Soares/ FHEMIG, ³Universidade Federal de Minas Gerais (UFMG), ⁴Instituto de Ciências Biológicas da Universidade Federal de Minas Gerais (UFMG), Instituto Raul Soares/ FHEMIG, ⁵Federal University of Minas Gerais

Background: Schizophrenia is a disorder that encompasses, with high interindividual variability, anomalies in different language domains, such as prosody. Successful interpersonal communication requires individuals capable of expressing and receiving varied information through verbal and non-verbal stimuli. Moreover, they must possess the necessary skills for language comprehension, with prosody being one of the most important pragmatic tools. According to evidence in the medical literature, affective prosody seems compromised in its production and recognition in schizophrenia patients, while studies involving the subdomain of grammatical prosody in these patients still appear scarce. Through acoustic recordings obtained from the C ORAL-ESQ corpus, we obtained preliminary linguistic data (words per speech turn, per terminal prosodic sequences, and per tonal units) that facilitated attempts to verify correlations with clinical parameters.

Methods: The C-ORAL-ESQ, a corpus of schizophrenic patients speaking Brazilian Portuguese, records audio from psychiatric consultations with schizophrenic patients. After recordings, alignments, transcriptions, and segmentations are performed based on criteria proposed by the Language in Action Theory (L-Act), a theory focused on understanding the informational structure of speech. The technical treatment of acoustic recordings provides prosodic data that can be compared with data obtained from C ORAL-BRASIL, a reference corpus composed of healthy controls. The corpus includes stable schizophrenia patients aged 18 to 65, assessed for the PANSS positive domain, among other parameters. Exclusions are based on nosological criteria, clinical instability, or neurological comorbidities. Once selected, patients undergo various tests to evaluate clinical parameters.

Results: Two groups of speakers were compared (not balanced in gender, age, and schooling): 38 from C-ORAL-BRASIL (27,932 words) and 29 from C-ORAL-ESQ (42,222 words). We extracted measurements and observed a higher standard deviation in C-ORAL-ESQ for the following metrics: number of words per turn (mean 14.1 vs. 11.7; median 11.1 vs. 9.8; s.d. 9.8 vs. 5.8); words per utterance (mean 8.5 vs. 6.8; median 8.4 vs. 6.2; s.d. 4.2 vs. 2.6), words per prosodic units (mean 3.8 vs. 2.9; median 3.0 vs. 2.8; s.d. 2.0 vs. 0.4). This is notable, given that C-ORAL-BRASIL speakers engage in different yet similar communicative situations, while patients are not affected by this variable.

For us, this finding points to an important factor of interindividual variability in the group of schizophrenia patients, which may be related to various specificities such as the pattern of negative symptoms in these patients or their prescription profiles. After appropriate and reviewed statistical tests, however, we did not find correlations between the severity of negative symptoms and the dose of antipsychotics in chlorpromazine equivalents with the number of words per turn, per tonal unit, and per terminal prosodic ending.

Discussion: It is possible that the parameters studied, albeit preliminary, may indicate a significant sensitivity of prosodic aspects to the specificities of schizophrenia, such as symptom profiles and pharmacological prescription. Although our initial analyses were not successful, a more in-depth evaluation of the prosodic informational structure of speech may provide valuable insights that point to potential correlations with clinical parameters.

T48. THE C-ORAL-ESQ AND THE STUDY OF GRAMMATICAL PROSODY IN PATIENTS WITH SCHIZOPHRENIA

Leonardo Lopes¹, João Salgado², Lucas Mantovani³, Daniela Coelho³, Marcelo Sousa⁴, Igor Oliveira⁴, Lucas Attoni³, Bruno Rocha⁴, Tommaso Raso⁴, Joao Salgado*⁵

¹other, ²Universidade Federal de Minas Gerais, Instituto Raul Soares/ FHEMIG, ³Instituto Raul Soares/ FHEMIG, ⁴Universidade Federal de Minas Gerais, ⁵Federal University of Minas Gerais

Background: Schizophrenia is a disorder that encompasses highly variable language anomalies among individuals, such as prosody - a fundamental pragmatic tool for interpersonal communication. According to evidence in the medical literature, this tool appears compromised in production and recognition in schizophrenia patients, making it a significant subject of study. The C-ORAL-ESQ is a corpus aiming to document the speech of schizophrenia patients, enabling linguistic and medical studies. This corpus will be available for free consultation after analysis of prosodic and pragmatic parameters, facilitating the development of new medical and linguistic research.

Methods: C-ORAL-ESQ records audio from everyday psychiatric consultations with schizophrenia patients. After recordings, alignments, transcriptions, and segmentations are performed based on criteria proposed by the Language Into-Act Theory (L-ActT), a theory focused on understanding the informational structure of speech. Technical treatment of acoustic recordings provides quantitative and qualitative prosodic-grammatical data, such as words per turn, per prosodic terminal unit, and per tonal unit, along with the ratio of dialogical and non-dialogical informational units. Linguistic findings can be compared with C-ORAL-BRASIL, a corpus of healthy Brazilian Portuguese speakers. The corpus includes stable schizophrenia patients aged 18 to 65, assessed for positive PANSS domain, among other parameters. Exclusions are based on nosological criteria, clinical instability, or neurological comorbidities.

Results: Currently, C-ORAL-ESQ has 40 audio recordings, totaling about 48,000 words spoken by patients and 659 minutes of conversations between doctors, patients, and their companions. Recordings are in various stages of processing, so parameters of interest are not fully accessible. We extracted measurements and observed a higher standard deviation in C-ORAL-ESQ in comparison with C-ORAL-BRASIL for the following metrics: number of words per turn (mean 14.1 vs. 11.7; median 11.1 vs. 9.8; s.d. 9.8 vs. 5.8); words per utterance (mean 8.5 vs. 6.8; median 8.4 vs. 6.2; s.d. 4.2 vs. 2.6), words per prosodic units (mean 3.8 vs. 2.9; median 3.0 vs. 2.8; s.d. 2.0 vs. 0.4). This is notable, given that C-ORAL-BRASIL speakers engage in different yet similar communicative situations, while patients are not affected by this variable.

Discussion: Prosody plays a crucial role in interpersonal discourse, emotional rapport, and understanding intentions and feelings of interlocutors. Its compromise may be linked to observed social performance issues in schizophrenia patients. Access to various prosodic parameters through C-ORAL-ESQ allows for studying the topic and establishing potential correlations with clinical variables, such as negative symptoms and pharmacological prescription profiles. Schizophrenia is a disorder that involves highly variable anomalies in various language domains among individuals, such as prosody - a fundamental pragmatic tool for establishing interpersonal communication. Evidence from medical literature suggests that this tool appears compromised in production and recognition among schizophrenia patients, making it a significant subject of study. The C-ORAL-ESQ is a corpus aiming to

document the speech of schizophrenia patients, enabling linguistic and medical studies. This corpus will be available for free consultations after analyzing prosodic and pragmatic parameters, facilitating the development of new medical and linguistic research.

T49. SLEEP ON IT: DOES SLEEP QUALITY AFFECT COGNITION AND METABOLIC SYNDROME IN SCHIZOPHRENIA?

Marta Bosia^{*1}, Michele Francesco D'Incalci², Jacopo Sapienza³, Carolina Passani³, Andrea Fortunato³, Salvatore Novello⁴, Giulia Agostoni⁵, Margherita Bechi³, Mariachiara Buonocore², Francesca Martini³, Marco Spangaro⁵, Guglielmino Carmelo³, Cocchi Federica³, Roberto Cavallaro⁶, Stefano Comai⁷

¹*Faculty of Medicine and Surgery, Vita-Salute San Raffaele University, Milan, Italy,* ²*IRCCS San Raffaele Scientific Institute, Milan, Italy,* ³*IRCCS San Raffaele University Scientific Institute,* ⁴*Vita-Salute San Raffaele University,* ⁵*IRCCS San Raffaele University Scientific Institute,* ⁶*Vita Salute San Raffaele University,* ⁷*University of Padua*

Background: Cognitive impairment still represents one the the main cause of poor outcome in patients with schizophrenia and current pharmacological treatment does not satisfactorily address it. Additionally, individuals suffering from schizophrenia are intrinsically at higher risk to develop metabolic syndrome (MetS), also because of the side effects of antipsychotic medications. MetS aggravates the prognosis of patients with schizophrenia, as it leads to higher mortality and cardiovascular diseases.

Up to 80% of patients with schizophrenia suffer from sleep disturbances, which have been associated with worsening of both cognition and metabolic profile.

Despite converging evidence, to date few studies have investigated the relationship between poor sleep and either metabolic alterations or cognition in schizophrenia, and their interplay has not yet been explored.

Based on these premises, this study aims to better characterize the impact of sleep disturbances on cognition, MetS and psychopathology in schizophrenia, as well as to elucidate the possible interplay between sleep and metabolic syndrome on cognitive functions.

Methods: Seventy-seven patients with a diagnosis of psychotic disorder were enrolled and assessed for: sleep quality and habits with the Pittsburgh Sleep Quality Index (PSQI) questionnaire and the Mornigness Eveningness Questionnaire (MEQ); cognition with the Brief Assessment of Cognition in Schizophrenia (BACS); psychopathology with the Positive And Negative Syndrome Scale (PANSS).

Pearson's correlation analysis was used to explore the relationship between sleep quality and habits and psychopathology, cognition and MetS. The effects of sleep quality on cognitive abilities and MetS parameters were then analyzed by means of forward stepwise regressions, taking into account confounding factors. Finally, to disentangle the interplay between sleep quality and MetS on cognitive abilities, we performed separate slope models.

Results: The analysis showed significant correlations between general and overall psychopathology as evaluated by PANSS and short sleep duration. Concerning cognition, significant correlation emerged between working memory, verbal memory, processing speed and planning and sleep efficiency, sleep disturbances and sleep habits. Regarding MetS, positive correlations were found between sleep disturbances, higher triglycerides and lower

HDL, and between MetS severity and both daytime dysfunction because of sleepiness and global sleep quality.

The regressions highlighted a main role of sleep disturbances on core cognitive domains of verbal memory, processing speed and planning, as well as specific effects of sleep parameters on fasting glucose, triglycerides and overall MetS severity. Finally, the separate slope model showed a significant interaction between sleep disturbances and MetS on planning ability, with a stronger negative impact of sleep disturbances in patients with MetS.

Discussion: Our data confirm the impact of sleep quality and habits on clinical and cognitive outcome, as well as on physical health in patients with schizophrenia. In particular, results suggest that cognitive abilities are mainly affected by sleep disturbances, while metabolic parameters are differentially influenced by sleep latency and use of hypnotic drugs. Innovatively with respect to previous literature, our study also shows an interactive effect between sleep and MetS on cognition, contributing to better clarify the relation between sleep alterations, cognitive deficits and MetS.

Our findings further highlight the importance of monitoring and managing sleep in patients with schizophrenia to possibly ameliorate cognitive deficits and metabolic syndrome, which, due to the limitations of antipsychotic treatments, are among the biggest challenges that patients with schizophrenia have to face.

T50. ROLE OF ASTROCYTES IN THE DEVELOPMENT OF ADULT BRAIN PATHOLOGY AFTER TRANSIENT PREFRONTAL MICROGLIA DEFICIENCY IN ADOLESCENCE

Sina-Maria Schalbetter^{*1}, Ron Rabin¹, Anja Krütli¹, Anina Sara von Arx¹, Olga Krzyzaniak¹, Han-Yu Lin¹, Johanna Furrer¹, Tina Notter¹, Urs Meyer¹

¹*University of Zurich*

Background: Microglia, the innate immune cells of the central nervous system, play a crucial role in synaptic pruning during adolescence. Using a mouse model of cell-specific, transient and local depletion of microglia, we recently showed that deficiency of prefrontal microglia during adolescence is sufficient to induce an adult emergence of impairments in cognitive functions, dendritic complexity, and synaptic structures and functions. Based on previous findings suggesting that astrocytes may functionally compensate microglia deficiencies, we explored the role of astrocytes in development of adult brain pathology after transient prefrontal microglia deficiency in adolescence. A special emphasis was placed on inositol trisphosphate (IP3)-dependent Ca²⁺ signaling in astrocytes, given that this pathway is upregulated in reactive astrogliosis.

Methods: Brain region-specific and transient depletion of prefrontal microglia during adolescence was induced by a single, bilateral stereotaxic injection of clodronate disodium salt (CDS) into the medial portion of the PFC in 6-week-old C57BL/6 mice. Control mice received a bilateral stereotaxic injection of phosphate-buffered saline (PBS). Immunohistochemistry and confocal microscopy were used to ascertain the density of microglia and astrocytes at 1, 5, 10, and 40 days post-injection (dpi), whereas the expression of genes involved in astrocyte-mediated synaptic pruning (Mefl0, Mertk) and the astrocytic activity marker glial fibrillary acidic protein (Gfap) was assessed via quantitative real-time PCR (qRT-PCR) at the same dpi intervals. Astrocytic IP3 signaling was blocked using recombinant adeno-associated virus (rAAV) expressing an inhibitory peptide from β -

adrenergic receptor kinase 1 (i β ARK) under the GFAP promoter. To ensure brain region specificity, stereotaxic bilateral injections, of rAAVs expressing i β ARK or a corresponding control rAAV, in the medial PFC were conducted 10 days before microglia depletion. A battery of PFC-dependent cognitive tests, including social recognition memory and temporal order memory, was used to explore the functional role of astrocytes in mediating the adult emergence of cognitive dysfunctions after prefrontal microglia deficiency in adolescence.

Results: A single intra-PFC injection of CDS led to a robust (~ 80% depletion) but temporary (~ 1 week) depletion of microglia in the adolescent PFC. Even though the density of S100 β -immunoreactive astrocytes was not altered, the CDS-induced prefrontal microglia depletion led to a marked (2-3 fold) upregulation of Gfap expression in the PFC at 1 and 5 dpi. These changes were, however, not associated with alterations in the expression of genes involved in astrocyte-mediated synaptic pruning (Megf10, Mertk). Furthermore, blocking astrocytic IP3 signaling through GFAP-driven i β ARK expression did not prevent the adult emergence of social recognition memory and temporal order memory deficits after prefrontal microglia depletion in adolescence

Discussion: The present study provides novel insights into the intricate interactions between microglia and astrocytes. Our findings suggest that prefrontal astrocytes become transiently reactive during temporary microglia depletion, but astrocytic IP3 signaling does not seem to play a major role in mediating the adult emergence of cognitive dysfunctions after transient prefrontal microglia deficiency in adolescence. Hence, the astrocytic contribution to brain pathology after prefrontal microglia deficiency likely involves mechanisms beyond astrocytic IP3 signaling.

T51. OLFACTORY BIOMARKER FOR SOCIAL ANHEDONIA IDENTIFIES ANTERIOR CINGULATE ABNORMALITIES IN PATIENTS WITH SCHIZOPHRENIA

Julie Walsh-Messinger*¹, Eugene Ruby², Oded Gonen³, Dolores Malaspina⁴

¹University of Dayton, ²University of California, Los Angeles, ³NYU Langone School of Medicine, NY USA, ⁴Icahn School of Medicine at Mount Sinai

Background: Anhedonia, or the diminished capacity to experience pleasure, is a common feature of depression and schizophrenia and is widely considered to reflect reward circuitry dysfunction. However, the processing of information on “self” vs “other” for social motivation and pleasure is associated with activity in the anterior cingulate cortex (ACC). Olfaction, which is associated with emotion function along with social and emotional impairments in schizophrenia, shares close neural connections to the ACC. The present study investigated associations between biomarkers for cellular processes in the anterior cingulate, psychiatric symptoms, social anhedonia, and olfaction in schizophrenia patients.

Methods: Nineteen individuals diagnosed with a DSM-IV schizophrenia spectrum disorder (11 male, 8 female) underwent three-dimensional 3-T voxel proton magnetic resonance spectroscopy (MRSI) to measure biomarkers for cellular processes, including neuronal integrity (N-acetylaspartate- NAA), energetics (creatine-Cr), myelin (choline -Cho) and glia (myo-inositol -mI) concentrations in the ACC. Spearman correlations were computed to examine associations between these metabolites, PANSS five factor scores, chapman physical and social anhedonia scales, along with olfaction based on Sniffin’ Sticks odor threshold, identification and discrimination.

Results: The combination of reduced cellular energy usage (Cr) and hypomyelination (Cho) in the ACC, respectively, predicted more severe positive ($r=-.555$, $p=.014$; $r=-.522$, $p=.022$),

negative ($r=-.499$, $p=.030$; $r=-.564$, $p=.012$), autistic preoccupation ($r=-.607$, $p=.006$; $r=-.677$, $p=.001$) and social anhedonia ($r=-.503$, $p=.034$; $r=-.524$, $p=.026$) symptoms. Reduced glia predicted autistic symptoms ($r=-.481$, $p=.037$) and social anhedonia ($r=-.540$, $p=.021$). By contrast, impaired odor identification and discrimination, was robustly associated with blunted affect ($r=-.523$, $p=.021$; $r=-.523$, $p=.021$), physical anhedonia ($r=-.628$, $p=.005$), and the myelin reduction ($r=.582$, $p=.001$; $r=.504$, $p=.028$) that likewise predicted social anhedonia.

Discussion: The association between olfactory dysfunction and social anhedonia is sensitive to hypomyelination in the ACC. Despite apparently preserved neuronal integrity, schizophrenia symptoms were associated with reduced myelin and glia and associated reductions in cellular energetics. The strong associations of olfactory function with negative symptoms and anhedonia were specifically indicative of reduced ACC myelin.

T52. REVISITING THE OBVIOUS: A META-ANALYTIC UPDATE ON THE PROCESSING SPEED IMPAIRMENT IN SCHIZOPHRENIA

Danielle Pratt^{*1}, Vijay Mittal¹

¹*Northwestern University*

Background: A global cognitive impairment is well established for people with schizophrenia. Dickinson et al. (2007) meta-analyzed cognitive studies and found that the digit symbol coding test, a measure of processing speed, was the most impaired test across studies and asserted that this task taps into an information processing inefficiency that is a central feature of the cognitive impairment in schizophrenia. As an answer to this meta-analysis, Knowles et al. (2010) reexamined these results (with the addition of 11 new studies up through January 2009) and found that the processing speed impairment is substantially affected by several moderating factors, including publication year, IQ difference from controls, and chlorpromazine dose equivalents. As nearly 15 years have passed since this last analysis of the processing speed impairment, in which time measurement of cognition has changed substantially, this study aims to revisit the evidence for a specific processing speed impairment and the potential moderating factors.

Methods: Articles were identified through a series of searches of the PubMed and PsycINFO electronic databases with combinations of the key words *schizophreni**, *cogniti**, *neuropsychologi**, *digit symbol*, *symbol coding*, *processing speed*, *perceptual speed*, and *psychomotor speed* from February 1, 2009 to November 2, 2023. Inclusion criteria require studies to report results for a symbol coding task and two other cognitive domains, contrast people with schizophrenia to healthy controls, and include sufficient detail to calculate effect sizes. New articles will be assessed alongside and with the previously identified articles. Effect sizes for each cognitive variable from each study will be calculated as the mean difference between schizophrenia and healthy control performance divided by the pooled standard deviation and adjusted for small sample bias (Hedges g). We will also calculate 95% confidence intervals, chi-square statistics, Q (homogeneity of effect sizes), and Orwin's fail-safe N (publication bias).

Results: 4530 articles were identified through the initial search and 2876 of those were removed due to being duplicates. The final number of articles for inclusion is still being finalized and results for this study are impending.

Discussion: There has been extensive focus on cognition in people with schizophrenia in the last 15 years and methods have evolved over time. This study provides the opportunity to

directly test whether the previous findings of a specific processing speed impairment, as well as the impact of moderating factors, are still present.

T53. PSYCHOMETRIC PROPERTIES OF THE FRENCH VERSIONS OF THE COMBINED STORIES TEST (COST) AND THE SOCIAL KNOWLEDGE TEST (SKT) IN PEOPLE WITH SCHIZOPHRENIA

Audrey Cayouette*¹, Élisabeth Thibaut², Frédéric Haesebaert³, Caroline Cellard⁴, Amélie M Achim⁵

¹Université Laval, ²McGill University, Douglas Mental Health University Institute, ³CH le Vinatier, Lyon, France, ⁴Centre De Recherche Université Laval Robert-Giffar, ⁵Département de psychiatrie et de neurosciences Université Laval; VITAM - Centre de recherche en santé durable; Centre de recherche CERVO

Background: Individuals with schizophrenia often present with social cognition deficits, including theory of mind (ToM) and social knowledge deficits. Among the measures available to assess these abilities, the Combined stories test (COST) and the Social knowledge test (SKT), that respectively target ToM and social knowledge, have shown promising psychometric properties in prior studies. However, test-retest reliability was only examined in healthy participants, and participant's subjective appreciation of these tasks has never been examined. The objective of this study was thus to further document the psychometric properties of the COST and the SKT and to document the participant's appreciation for both tests, in people with schizophrenia (SZ) and in healthy controls (HC).

Methods: Thirty-four (34) participants (33 men) with SZ (mean age = 39.8 (11.9); duration of illness = 13.5 (10.3) years) and 46 HC (mean age = 35.7 (14.0)) were assessed twice with the French versions of the COST and SKT, about 4 weeks apart (T1 and T2), and were also asked to rate their appreciation of the tests on a 10-point scale. The COST is a story-based ToM test in which participants must answer 26 second-order ToM questions (COST-QToM) and includes a control condition with 6 non-social reasoning questions (COST-QR). The SKT includes 14 situations for which participants are asked to report the emotions that most people would typically experience in that situation. For all three scores (COST-QToM, COST-QR and SKT), the following properties were examined: inter-rater reliability, test-retest reliability, practice effects, and ceiling effects.

Results: The inter-rater reliability was excellent in the SZ group, for the COST-QToM ($\alpha = .883$), the COST-QR ($\alpha = .858$) and the SKT ($\alpha = .941$) and in the HC group for the COST-QToM ($\alpha = .892$), the COST-QR ($\alpha = .898$) and the SKT ($\alpha = .976$).

For the test-retest reliability, the correlations between T1 and T2 for the SZ group were good ($r = .814$) for the COST-QToM, and for the SKT ($r = .673$), though the COST-QR (control condition) showed poorer test-retest reliability ($r = .296$). In the HC group, the correlations between T1 and T2 were acceptable ($r = .59$) for the COST-QToM, for the COST-QR ($r = .468$) and for the SKT ($r = .596$).

Some practice effects were observed. In the SZ group, the analyses revealed a significant practice effect only for the COST-QToM ($t(33) = -2.29$, $p = .029$, Effect size d (ESd) = 0.39), whereas no significant practice effect was observed for the COST-QR ($t(33) = 1.10$, $p = .281$) or for the SKT ($t(36) = -1.18$, $p = .246$). In the HC group, significant practice effects emerged for both the COST-QToM ($t(45) = -4.72$, $p < .001$ ESd = 0.70) and the

SKT ($t(45) = -2.46$, $p = .018$, $ESd = 0.36$), whereas no significant practice effect emerged for the COST-QR ($t(45) = -0.11$, $p = .914$).

The only evidence for a ceiling effect emerged for the COST-QR for both SZ and HC groups. Finally, the average appreciation scores for the COST and the SKT were of 6.8/10 and 8.3/10 in the SZ group and of 7.7/10 and 8.2/10 for the HC group.

Discussion: These results add to the previously reported psychometric properties and that show globally adequate psychometric properties for these tests. While the observed practice effects were surprising given the previous results in healthy participants, practice effects are common for social cognition measures. The ceiling effects observed for the COST-QR, particularly in the HC group, may be explain by the number of participants that obtained a perfect score at T1. The appreciation ratings by participants from both groups were generally positive. Therefore, these two measures prove to be valuable options for clinicians to use in their practice, especially given the few options in French.

T54. COMPUTERIZED ADAPTIVE TESTING IMPROVES PRECISION AND EFFECT SIZE IN EXPERIMENTAL PSYCHOPATHOLOGY RESEARCH

Michael Thomas^{*1}, Anastasia Sares¹, Emily Sturm¹, John Duffy¹, Maiele Mignard¹, Tessa Mitchell², Max Henneke¹, Haley Pyscher², Jazmin Diaz¹, Donald Rojas¹, Jason Tregellas¹, Jared Young³

¹Colorado State University, ²University of Colorado Anschutz Medical Campus, ³UC San Diego School of Medicine

Background: Cognitive testing plays a pivotal role in studies of psychosis and other forms of serious mental illness. Unfortunately, many of these tests lack psychometric refinement, leading to weakened effect size and poor statistical power. At the same time, psychometric refinement is a slow, iterative process that requires large amounts of data, and is therefore not feasible in many settings. However, newer statistical approaches based on item response theory make it possible to improve measurement precision with novel tasks, even with limited data, using methods like computerized adaptive testing. This study demonstrates this technology by administering an adaptive version of a cross-species cognitive control task: the multi-choice continuous performance test (MC-CPT). We hypothesized that adaptive testing would produce more precise estimates of ability and larger effect size than non-adaptive testing.

Methods: Participants included 37 healthy controls (HCs) and 35 individuals diagnosed with schizophrenia or schizoaffective disorder (SZs) who were administered the MC-CPT using the free and open-source stimulus presentation package PsychoPy. During the task, participants pressed a key corresponding to a circle that appeared briefly on a screen in one of four positions or withheld their response if circles appeared in all four positions. Task difficulty was manipulated using a backward visual mask, in this case, a set of squares that covered the possible circle locations after the circle was presented. For the fixed version of the task, the backward mask onset times were predetermined. For the adaptive version of the task, an algorithm chose the backward mask onset time in a manner that optimized precision (minimized standard error) for each participant on a block-trial basis. Fixed and adaptive versions of the task were administered on separate days in a counterbalanced order.

Results: As hypothesized, the adaptive MC-CPT produced more precise estimates of ability than the non-adaptive version, and the effect size comparing ability estimates between HCs

and SZs was larger for the adaptive versus fixed version of the test. Participants' tolerability ratings of each test version did not significantly differ.

Discussion: Our findings underscore the potential of adaptive testing and advanced psychometric tools to enhance novel and previously unrefined measures of cognition in experimental psychopathology research. Adaptive technology not only enhances precision but also improves effect size and statistical power, which will benefit numerous studies, especially those evaluating neurocognitive theories of psychosis. Our group has developed CogIRT, a free and user-friendly R package that facilitates the development and implementation of adaptive neurocognitive tests, including the MC-CPT.

T55. RELATIONSHIP BETWEEN COGNITIVE PERFORMANCE AND PLASMA RATIO OF CLOZAPINE TO N-DESMETHYLCLOZAPINE IN PATIENTS WITH TREATMENT-RESISTANT SCHIZOPHRENIA

Bomin Kim^{*1}, Hyejin Sim¹, Seoyoung Kim², Euitae Kim²

¹Seoul National University, ²Seoul National University Bundang Hospital

Background: Cognitive deficits and poor prognosis are commonly observed in patients with treatment-resistant schizophrenia (TRS) due to their inadequate therapeutic responses to first-line antipsychotic treatments. However, the effect of clozapine (CLZ), the most efficacious antipsychotic for TRS, on cognition remains inconclusive. According to previous studies, clozapine and its main metabolite, N-desmethylclozapine (NDMC), have opposing pharmacological profiles at the muscarinic receptor, known for its association with cognition. While clozapine acts as an antagonist at M1 receptors, leading to anticholinergic burden, NDMC operates as a partial agonist, enhancing cognitive functions. Considering these opposing mechanisms, this study focused not only on the two individual concentration levels but also on the CLZ/NDMC ratio to investigate their associations with cognitive performance.

Methods: Forty-four patients with TRS completed baseline and follow-up assessments before and 18 weeks after initiating clozapine treatment, respectively. The assessments included Positive and Negative Syndrome Scale (PANSS), MATRICS Consensus Cognitive Battery (MCCB), and blood trough levels of CLZ and NDMC.

Results: Multiple regression found significant negative associations between CLZ/NDMC ratio and MCCB scores after controlling for age, gender, duration of illness, antipsychotics equivalent dose, baseline MCCB score, and PANSS score. In path analysis, higher clozapine dose and clozapine concentration were associated with lower MCCB scores, whereas the effect of NDMC concentration did not reach statistical significance.

Discussion: With the association between CLZ/NDMC ratio and MCCB scores, our finding implies that careful observation of the CLZ/NDMC ratio is important to monitor cognitive treatment outcomes. Furthermore, elevated clozapine plasma levels seem to hinder the improvement of cognitive functions in patients with TRS. However, the expected pro-cognitive effect of NDMC remains unclear. This suggests that further investigation is required to fully understand the relationship between cognition and clozapine-related pharmacological factors.

T56. PRIMALS AND PSYCHOSIS: A NOVEL APPROACH TO UNDERSTANDING THE ROLE OF WORLD BELIEFS IN DELUSIONS AND HALLUCINATIONS

Emma Palmer-Cooper*¹, Jeremy Clifton²

¹*University of Southampton*, ²*University of Pennsylvania*

Background: Primal world beliefs ('primals') are simple observations about the world's overarching qualities, and can be conceptualised as schemas. Whilst beliefs about the world, and their role in psychopathology, are not a new concept, novel methods of assessment have supported empirical study of these beliefs. Primals also allow mapping of beliefs to different dimensions, fitting to a hierarchical structure. The belief that the world is Good (vs. bad) is considered the Primary primal, and secondary primals include beliefs the world is Safe (vs. dangerous), Enticing (vs. dull) and Alive (vs. mechanistic). Primals can be assessed with self-report questionnaire measures, with options to measure different dimensions of interest. Primals appear stable over time, similar to Big Five personality traits, and demonstrate considerable variation across individuals. Interestingly, primals appear to poorly describe the objective conditions people are experiencing, and notable changes in global circumstances. For example, belief the world is dangerous did not appear to be more prevalent during the Covid-19 pandemic. Recent work has demonstrated that primals are associated with different aspects of psychopathology, including depression, anxiety, suicide history, life satisfaction, and positive affect.

There is currently no research investigating primals in psychosis-spectrum disorders. We aimed to investigate possible differences in primary (Good) and secondary primals (Safe, Enticing and Alive) between people experiencing psychosis-spectrum disorders and controls with no experience of psychosis. We also aimed to understand associations between primals and psychosis-related experiences of hallucinations, delusions, and interpretations of these experiences.

Methods: This online, cross-sectional, self-report study included 99 participants. Participants were individuals with a psychosis-spectrum disorder (n=47; mean age = 34.89, SD = 12.23), and control participants with no experience of psychosis (n=52; mean age = 38.87; SD = 13.12). In the psychosis-spectrum group, 48.9% had a primary diagnosis of psychotic disorder, with the remaining participants having another serious mental health problem with psychotic features.

All participants were screened for psychosis using the Prodromal Questionnaire-16 (PQ-16) and were assessed for hallucination-proneness with the Multi-Modality Unusual Sensory Experiences Questionnaire (MUSEQ) and delusion-proneness using the Peters' Delusion Inventory-21 (PDI). Primals were measured using the Primals Inventory (PI-18). The PI-18 measures primal beliefs the world is Good (vs bad), as well as Safe (vs. dangerous), Enticing (vs. dull) and Alive (vs. mechanistic). Participants are asked to indicate how much they agree with 18 statements, such as 'On the whole, the world is a dangerous place'.

Results: Individuals with a psychosis-spectrum disorder reported more negative primals than controls, relating to fewer beliefs that the world is Good, Safe and Enticing. Beliefs the world is less Safe were associated with more psychotic symptoms, subjective distress about symptoms, and preoccupation with delusions. Positive delusions of inflated self-worth were associated with belief that the world is Good, and delusions of magical thinking were positively associated with beliefs that the world is more Enticing and Alive.

Discussion: Our findings indicate that experience of psychosis leads to more negative views about the world as being a Bad, Dangerous and Dull place. Relatedly, the world is considered more dangerous as severity and distressing experiences increase. As people experiencing psychosis have often experienced adversity, we suggest there is a cumulative impact of

biopsychosocial factors that result in development of negative schemas about the world and aberrant processing of stimuli as threatening and pervasive.

The number of positive symptoms was not related to primals. However, breaking down delusional ideation into different factors revealed that positive delusions of inflated self-worth and magical thinking were related to a more positive world view. We suggest that it is therefore more likely the case that biased cognitive schemas that influence a person's interpretations of their experiences and views about the world, rather than the number or frequency of symptoms themselves.

Primals may be a useful construct to address in psychotherapies to shift world views, and thus life experiences, to be less distressing. Future work should consider if changes in primals over time are related to changes in individual interpretations and content of symptoms, in order to better understand clinical implications and applications.

T57. REINFORCEMENT LEARNING IN PEOPLE WITH SCHIZOPHRENIA: A META-ANALYSIS OF 16 EXPERIMENTS CONDUCTED AT THE MARYLAND PSYCHIATRIC RESEARCH CENTER

Adam Culbreth*¹, James Gold², James Waltz³, Shuo Chen³

¹*Maryland Psychiatric Research Center, University of Maryland School of Medicine,*

²*MPRC,* ³*Maryland Psychiatric Research Center*

Background: Alterations in aspects of reinforcement learning have been widely reported in people with schizophrenia. In many studies, these deficits are also associated with core clinical characteristics of schizophrenia, including severity of negative symptoms and cognitive impairment. In the current analysis, we aimed to quantify the consistency of group differences in reinforcement learning between people with schizophrenia and healthy controls, as well as associations with negative symptoms and global measures of cognition.

Methods: We aggregated 15 separate datasets (total sample size: HC = 530, SZ = 709) collected by our group at the Maryland Psychiatric Research Center, which included a reinforcement-learning task, negative symptom interview (the Scale for the Assessment of Negative Symptoms (SANS)), and neuropsychological measure of premorbid intellectual function (Wechsler Test of Adult Reading (WTAR)). We hypothesized that across these studies individuals with schizophrenia would show lower reinforcement learning task performance (overall task accuracy) compared to healthy controls, and that negative symptom severity and premorbid intellectual function would be significantly associated with reinforcement-learning task performance.

Results: Consistent with our hypothesis, across our 15 experiments, people with schizophrenia showed reduced reinforcement learning (percent correct) compared to healthy controls (Cohen's $d = -0.48$, 95%-CI [-0.60 to -0.37], z -value = -8.03, p -value LESS THAN 0.001). Further, reinforcement learning was significantly associated with measures of premorbid intellectual function (r -value = 0.28, 95%-CI [0.21 to 0.35], z -value = 7.10, p -value LESS THAN 0.001) such that participants with schizophrenia with lower premorbid IQ showed lower performance on reinforcement learning tasks. When examined continuously, associations between negative symptom severity and reinforcement learning were in the hypothesized direction but were not statistically significant (r -value = -0.06, 95%-CI [-0.15 to 0.03], z -value = -1.36, p -value = 0.17). When examined categorically, patients with severe avolition showed significantly weaker reinforcement learning compared to

patients without severe avolition (Cohen's $d = -0.17$, 95%-CI [0.0063; 0.3484], z -value = -2.03, p -value = 0.042)

Discussion: Taken together, these results demonstrate robustness of RL impairment in people with schizophrenia, as well as associations to particular aspects of the disorder. In analyses presented at the SIRS meeting we will further contextualize these findings through supplemental analyses examining interactions of the above effects with reinforcement-learning task features including valence and probability contingencies, as well as more nuanced measures of symptoms (e.g., separating expressive vs. experiential negative symptoms).

T58. PREPAREDNESS FOR CLIMATE-DRIVEN HURRICANES IN SEVERE MENTAL ILLNESS

Mary Gorora^{*1}, Gabrielle Wong-Parodi², Zelde Espinel³, James Shultz⁴, Philip D. Harvey⁵

¹University of Miami Miller School of Medicine, ²Stanford University, Department of Earth System Science, ³University of Miami Miller School of Medicine, Department of Psychiatry and Behavioral Sciences, ⁴University of Miami Miller School of Medicine, Department of Public Health Sciences, ⁵University of Miami Miller School of Medicine, Department of Psychiatry and Behavioral Sciences / Miami VA Healthcare System

Background: Individuals with severe mental illness (SMI), such as schizophrenia and bipolar disorder, face distinct challenges in preparing for climate-related disasters, particularly hurricanes. This study aims to explore how cognitive impairments, specifically in prospective memory (PM) and introspective accuracy (IA; the ability to self-assess various cognitive and functional abilities), affect their preparedness. Understanding these impairments is crucial for developing more effective hurricane preparedness guidelines tailored to the unique needs of the SMI population.

Methods: We conducted a comprehensive survey with 40 SMI patients (20 with schizophrenia, 20 with bipolar disorder) and their respective informants. The survey assessed participants' PM, hurricane risk perception, and adaptation appraisal using a modified disaster behavioral health model. A shortened Prospective Memory Concerns Questionnaire was employed to evaluate PM, and introspective accuracy was gauged by comparing patient self-reports with informant observations.

Results: In the schizophrenia group, self-reported PM scores exhibited a significant negative correlation with IA scores (-0.686 , $p=0.005$), while informant reports on the patients' PM displayed a positive correlation (0.577 , $p=0.024$). This pattern of impaired IA was similarly observed in the bipolar group, with patient self-reports and informant assessments showing correlations of -0.710 ($p < 0.001$) and 0.869 ($p < 0.001$), respectively. Both groups reported a higher need for assistance in executing the most helpful preparedness tasks (SCZ: 0.702 , $p < 0.001$; BP: 0.526 , $p=0.017$). Moreover, there was a notable discrepancy between the patients' perceived self-efficacy and the informants' assessment of the patient's abilities, with negative correlations observed in self-efficacy scores and IA for both schizophrenia (-0.668 , $p=0.002$) and bipolar groups (-0.589 , $p=0.008$), and positive correlations in informant reports (SCZ: 0.818 , $p < 0.001$; BP: 0.712 , $p < 0.001$).

Discussion: Our findings highlight significant deficits in introspective accuracy among SMI patients, impacting not only their prospective memory but also their adaptation appraisal abilities. These IA deficits are likely a key factor in being underprepared for hurricanes. The

pronounced contrast between self-assessment and informant evaluation suggests a notable gap in self-awareness about their own preparedness capabilities. Tailoring hurricane preparedness guidelines to accommodate these cognitive challenges is critical. Developing specialized support and strategies, considering these cognitive impairments, could significantly enhance the safety and preparedness of this vulnerable group in the face of impending disasters.

T59. TRANSDIAGNOSTIC COGNITIVE BIASES IN PSYCHIATRIC DISORDERS: A SYSTEMATIC REVIEW AND NETWORK META-ANALYSIS

Katie Lavigne^{*1}, Jiaxuan Deng², Delphine Raucher-Chéné¹, Adèle Hotte-Meunier², Chloe Voyer², Lisa Sarraf³, Martin Lepage¹, Genevieve Sauve⁴

¹McGill University, Douglas Mental Health University Institute, ²Douglas Mental Health University Institute, ³Douglas Mental Health University Institute, Carleton University, ⁴Douglas Mental Health University Institute, Université du Québec à Montréal

Background: Psychiatric disorders, including schizophrenia, bipolar disorder, and depression, are characterized by cognitive deficits, which have been proposed as a transdiagnostic feature of psychopathology (“C” factor). Similarly, cognitive biases (e.g., in attention, memory, and interpretation) represent common tendencies in information processing that are often associated with psychiatric symptoms, such as delusions and hallucinations in schizophrenia-spectrum disorders, and emotion regulation in mood disorders. However, the question remains whether cognitive biases are also transdiagnostic or are specific to certain psychiatric disorders or symptoms. We sought to address whether the proposed “C” factor of transdiagnostic cognitive dysfunction in psychopathology can be extended to cognitive biases and transdiagnostic symptom dimensions of psychopathology.

Methods: We performed a systematic review of the literature on cognitive biases in psychiatric disorders reporting group differences or associations with symptoms and including two or more diagnostic categories from the Diagnostic and Statistical Manual of Mental Disorders (DSM) or International Classification of Diseases (ICD). Title and abstract screening was performed by at least 2 reviewers, who showed good agreement (83%, AC1 = 0.671, SE = 0.013, CI = [0.645, 0.698], $p < 0.001$). Biases were categorized as either attention, memory, or interpretation biases and were reverse coded when necessary (e.g., reaction times, difference scores) to ensure that higher values equated to greater bias severity. Symptoms were categorized into transdiagnostic super-spectra based on the Hierarchical Taxonomy of Psychopathology (HiTOP): general psychopathology (p factor) emotional dysfunction, psychosis, and externalizing. Traditional random-effects meta-analyses were conducted by bias category to examine (1) group differences between patients and non-clinical controls (Hedge’s g) and (2) associations between biases and transdiagnostic symptom categories (Fisher’s r -to- z). Network meta-analyses were then conducted by bias category to compare direct and indirect effects between diagnoses with non-clinical controls as a reference group.

Results: Overall, 31 studies comprising 4401 participants (2536 patients, 1865 non-clinical controls) across 21 diagnostic categories met inclusion criteria, assessing 19 cognitive biases with most studies focusing on interpretation ($k = 22$) and attention ($k = 11$) biases, with only 2 assessing memory biases. Traditional meta-analyses found a moderate effect size ($g = 0.32$) for more severe cognitive biases in all patients relative to non-clinical controls, as well as small but significant associations between interpretation biases and transdiagnostic symptom categories (general psychopathology: $r = .20$, emotion dysfunction: $r = 0.17$, psychotic

symptoms: $r = 0.25$). Network meta-analyses revealed significant patient versus control differences on attention and interpretation biases across diagnoses, as well as significant differences between diagnoses, with highest severity for attention biases in panic and other anxiety disorders and for interpretation biases in obsessive-compulsive and other anxiety disorders as well as schizophrenia-spectrum disorders.

Discussion: The current findings support a big “C” interpretation of transdiagnostic cognitive dysfunction in psychiatric disorders, extending the concept to cognitive biases and transdiagnostic symptom dimensions, particularly emotion dysfunction and psychosis symptoms. They also suggest that while the presence of cognitive biases is transdiagnostic, bias severity differs across diagnoses, as is the case for traditional neurocognitive deficits.

T60. PUTTING A LABEL ON SOMEONE: IMPACT OF SCHIZOPHRENIA STIGMA ON EMOTIONAL MIMICRY, LIKING, AND INTERPERSONAL CLOSENESS

Mathilde Parisi*¹, Stéphane Raffard², Pierre Slangen³, Till Kastendieck⁴, Ursula Hess⁴, Heidi Mauersberger⁴, Tifenn Fauviaux³, Ludovic Marin³

¹*EuroMov Digital Health in Motion*, ²*Epsilon Laboratory Dynamic of Human Abilities and Health Behaviors, University of Montpellier 3, Montpellier, France.*, ³*EuroMov Digital Health in Motion, Univ Montpellier, IMT Mines Ales, Montpellier, France.*, ⁴*Department of Psychology, Social and Organizational Psychology, Humboldt-Universität zu Berlin, Berlin, Germany*

Background: Affiliation has been shown to be both an antecedent and a consequence of emotional mimicry (i.e., the imitation of a counterpart’s emotional expression). For instance, interacting with an unlikeable partner can decrease emotional mimicry, leading to diminished liking. This perpetuating circle has not been investigated in the context of mental health stigma yet. Schizophrenia is a mental disorder associated with social interaction deficits and heavy public stigma. Consequently, this study aimed to test the influence of the label “schizophrenia” on emotional mimicry, liking, and interpersonal closeness.

Methods: We conducted an online experiment ($n=200$). Participants recruited from the general population were shown several videos of actors displaying emotional expressions. Actors were described with one of four labels (“schizophrenia”, “healthy”, “diabetes”, and a negative adjective) to discern whether stigma, a specific diagnosis, or a negative label influenced participants' response to the schizophrenia label. While watching the videos, participants were filmed with their computer’s webcams. We assessed emotional mimicry using OpenFace 2.2, which is an automated coding software for facial expressions. Liking and interpersonal closeness were measured using questionnaires.

Results: Results demonstrated decreased liking and interpersonal closeness of the actors with the schizophrenia label compared to all other labels. However, no effect on emotional mimicry was found. We also found that decreased liking of the schizophrenia actors was explained by lack of knowledge of schizophrenia. In addition, decreased liking, and interpersonal closeness of the actors with the schizophrenia labels were associated with increased willingness to socially distance from individuals with schizophrenia.

Discussion: Our study contributes to the literature on schizophrenia stigma by demonstrating implicit stigmatized reactions through decreased liking and interpersonal closeness. However, in contrast to other studies that demonstrated that liking and interpersonal closeness predict emotional mimicry, we could not find any influence of the schizophrenia label on emotional

mimicry. These results could be explained by the fact that despite being a validated tool, OpenFace 2.2 was shown to be less sensitive than other emotional mimicry measurement tools (e.g., electromyography). Consequently, small effects might not have been detected. Our work encourages future studies to reconduct this experiment using other methodologies. Implications and recommendations for future studies are discussed.

T61. SOCIAL MOTIVATION TENDENCIES IN PATIENTS WITH SCHIZOPHRENIA SPECTRUM DISORDERS: RELATIONSHIP WITH SYMPTOMS AND ROLE FUNCTIONING

Background: Social disconnection is common in schizophrenia spectrum disorders (SSD). Based on research on anxiety disorders, it has been postulated that, compared to healthy individuals, patients with SSD may show biases in social motivation characterised by a stronger tendency to avoid aversive social stimuli and a milder tendency to approach pleasant social stimuli. However, empirical evidence has been inconsistent possibly due to how social motivation is assessed.

Methods: This study examined social motivation tendencies in SSD using an enhanced version of the Approach Avoidance Task (AAT; Heuer et al, 2007). In this task, participants were asked to respond to pictures of faces by pushing or pulling the joystick according to the colour of the pictures (push upon grey pictures and pull upon sepia pictures). This is an implicit measurement of social motivation because the reaction time (RT) difference of pushing and pulling for each emotion embedded in the faces was of interest.

Three methodological improvements were built into this task. Firstly, on top of happy and angry faces (i.e. pleasant and aversive social stimuli respectively), neutral faces were included as control. This allowed for calculations of both the 'difference score' (RT difference (push-pull) within each target emotion, with a positive score indicating approach and a negative score indicating avoidance) and the 'double-difference D-score' (the discrepancy between the difference score for emotionally-valenced faces and the difference score for emotionally-neutral faces divided by the standard deviation of the participant's RTs). Secondly, faces carrying both straight and averted gazes were included, allowing for more nuanced differences in social motivation to emerge. Thirdly, to increase sense of familiarity and salience, faces of Chinese models were pilot-tested and used in our Chinese sample. Patients were assessed on social motivation (192 trials of AAT presented in 4 blocks), clinical symptoms (Positive And Negative Syndrome Scale and Calgary Depression Scale for Schizophrenia), and role functioning (Role Functioning Scale).

Results: The sample consisted of 95 patients with SSD (mean age = 34.34; 54.7% female), among whom 93 participants completed the AAT and had an error rate LESS THAN 20%. Trials with extreme RTs (LESS THAN 300ms, GREATER THAN 2000ms, and GREATER THAN 3 SDs from the participant's mean) were excluded. In both straight- and averted-gaze conditions, there was an approach tendency towards angry faces (ps LESS THAN .050), which was stronger than neutral faces (ps LESS THAN .050). There was no

significant approach/avoidance tendency towards happy faces (p GREATER THAN .050). The double-difference D-score was greater for angry faces than happy faces on the averted-gaze condition (p LESS THAN .001), indicating a stronger tendency to approach angry faces than happy faces.

Level of approach towards angry faces was negatively correlated with severity of PANSS positive and general psychopathology scores and depressive symptoms (p s = -0.21 to -0.24; p s LESS THAN .050). Level of approach towards happy faces was negatively correlated (p = -0.26) with depressive symptoms and positively correlated (p = 0.22) with role functioning (p s LESS THAN .050).

Discussion: The modified AAT provided a sensitive assessment for social motivation tendencies for patients with SSD, revealing meaningful relationships with symptoms and role functioning. Contrary to the hypothesis, patients tended to approach rather than avoid angry faces. Unlike in anxiety disorders, an approach tendency towards angry faces correlated with less severe symptomatology in our sample. Our results add to the accumulating evidence of social motivation tendencies across psychiatric disorders.

T62. NEURAL CORRELATES OF SOCIAL-PERCEPTUAL COMPONENT OF THEORY OF MIND IN SCHIZOPHRENIA

Cemal Demirlek^{*1}, Nabi Zorlu², Merve Karakılıç², Ecenaz Sarıkaya², Adem Bayrakçı², Burcu Verim³, Funda Gülyüksel², Berna Yalınçetin³, Elif Oral², Fazıl Gelal⁴, Emre Bora³

¹*Institute of Health Sciences, Dokuz Eylul University,* ²*Department of Psychiatry, Katip Celebi University, Ataturk Education and Research Hospital, Izmir, Turkey,* ³*Department of Neurosciences, Institute of Health Sciences, Dokuz Eylul University, Izmir, Turkey,* ⁴*Department of Radiodiagnostics, Katip Celebi University, Ataturk Education and Research Hospital, Izmir, Turkey*

Background: Theory of mind skills are disrupted in schizophrenia. This multimodal neuroimaging study aimed to identify the neural correlates of social-perceptual (mental state decoding) component of theory of mind in schizophrenia and healthy controls (HCs) using structural (T1-weighted) and diffusion-weighted (DTI) magnetic resonance imaging (MRI).

Methods: Sixty-two patients with schizophrenia and 34 HCs were included. The Reading the Mind in the Eyes (RMET) test were used to evaluate social-perceptual component of theory of mind. Correlations between theory of mind and cortical parameters (thickness, volume, surface area), or DTI scalars (fractional anisotropy, axial diffusivity, radial diffusivity) were cluster-based corrected for multiple comparisons.

Results: RMET scores showed positive correlations in 3 clusters, including left insula thickness, right superior-temporal thickness, left superior-temporal-sulcus volume in schizophrenia. DTI analysis revealed that fractional anisotropy showed positive correlations in 3 clusters, including right inferior-fronto-occipital fasciculus, left forceps-major, left inferior-fronto-occipital fasciculus in schizophrenia.

Discussion: In conclusion, this study provided evidence for the involvement of particular cortical regions and white matter tracts in social-perceptual (mental state decoding) component of theory of mind in schizophrenia. These findings have implications for targeted interventions development and treatments aimed at improving social functionality in patients with schizophrenia.

T63. RETINAL MICROVASCULATURE AND COGNITIVE FUNCTIONS IN FIRST-EPISODE PSYCHOSIS

Cemal Demirlek*¹, Merve S. Gurbuz², Ferdane Atas³, Berna Yalincetin², Burcu Verim², Ezgi Cesim², Muhammed Demir², Simge Uzman-Ozbek⁴, Ekin Sut⁵, Burak Baykara⁵, Berna B. Akdede⁴, Mahmut Kaya⁶, Emre Bora⁴

¹*Institute of Health Sciences, Dokuz Eylul University,* ²*Department of Neurosciences, Institute of Health Sciences, Dokuz Eylul University, Izmir, Turkey,* ³*Department of Ophthalmology, Cerkezkoy State Hospital, Tekirdag, Turkey,* ⁴*Department of Psychiatry, Dokuz Eylul University Medical School, Izmir, Turkey,* ⁵*Department of Child and Adolescent Psychiatry, Dokuz Eylul University Medical School, Izmir, Turkey,* ⁶*Private Practice, Izmir, Turkey*

Background: Both schizophrenia and its associated neurocognitive impairments, along with retinal abnormalities, constitute significant aspects of the condition. Impairments in neurocognitive functions are evident in both chronic and first-episode psychosis, with notable deficits observed in processing speed, memory, and executive functions. During embryogenesis, the eye originates from the diencephalon, making it part of the central nervous system (CNS) and often regarded as a window into the brain. Its vascular development is closely tied to neural development through neurovascular coupling. Studies employing fundus photography have revealed abnormalities in retinal microvasculature in psychotic disorders, encompassing variations in vascular caliber, fractal dimension, branching, and tortuosity. Additionally, despite some conflicting results in OCT-angiography (OCT-A) studies, individuals with schizophrenia exhibit reduced vessel densities and perfusion. Notably, retinal microvasculature abnormalities have been linked to the cognitive functions in patients with chronic schizophrenia. In this present study, our objective is to explore the connection between cognitive functions and retinal microvasculature in first-episode patients, utilizing OCT-A as a diagnostic tool.

Methods: Before OCT-A imaging, each participant underwent assessment of premorbid ability using the Wechsler Intelligence Scale for Children-R (WISC-R) or the Wechsler Adult Intelligence Scale-R (WAIS-R) information subtests. Processing speed was evaluated through the Digit Symbol Substitution Test (DSST), while visual memory (both immediate and delayed recall) was measured using the Visual Reproduction Test. Executive functions were assessed using the Wisconsin Card Sorting Test (WCST) and the Stroop Color and Word Test. Outcome variables included the number of categories completed and perseverative errors from the WCST, as well as the Stroop interference score and Stroop error score. Swept-source OCT-A images of the macular region (3 x 3 mm) for both the right and left eyes were acquired using the DRI Topcon Triton to visualize the retinal superficial capillary plexus. While OCT-A images were obtained for both eyes of all participants, only the right eye was utilized to ensure accurate and unbiased results. Vessel area density, fractal dimension, and mean tortuosity in the superficial capillary plexus were quantified using MATLAB and ImageJ software.

Results: Thirty patients with first-episode psychosis included in this study. Stroop interference score was positively correlated with retinal vessel area density ($p = 0.008$, $r = 0.477$) and fractal dimension ($p = 0.009$, $r = 0.468$), but not with mean tortuosity ($p = 0.199$) in patients with first-episode psychosis. Additionally, the other cognitive domains were not significantly associated with any retinal microvasculature measures in first-episode patients ($p > 0.05$).

Discussion: The findings of this study offer intriguing insights into the relationship between retinal microvasculature and cognitive functions in first-episode psychosis patients. Notably, a positive correlation was observed between the Stroop interference score and both retinal vessel area density and fractal dimension. This association implies that changes in retinal microvascular structure may reflect alterations in cognitive processing, particularly in the domain of attention and executive functioning as measured by the Stroop test. Considering the embryological link between the eye and the central nervous system, these findings support the hypothesis that retinal abnormalities could serve as a non-invasive biomarker for neurocognitive impairments in psychotic disorders. This is particularly relevant given the challenges associated with direct assessments of CNS abnormalities in these patients. However, the study's limitation to the small sample size should be noted, as these factors might limit the generalizability of the results. Future research could expand upon these findings by including a larger and more diverse sample, examining longitudinal changes in retinal microvasculature and their correlation with cognitive trajectories in psychosis, and exploring potential mechanisms underlying these associations.

T64. OCULOMICS AND CONNECTOMICS IN EARLY PSYCHOSIS

Cemal Demirek*¹, Burcu Verim², Muhammed Demir², Ferdane Atas³, Berna Yalincetin², Berna B. Akdede⁴, Mahmut Kaya⁵, Nabi Zorlu⁶, Emre Bora⁷

¹*Institute of Health Sciences, Dokuz Eylul University,* ²*Department of Neurosciences, Institute of Health Sciences, Dokuz Eylul University, Izmir, Turkey,* ³*Department of Ophthalmology, Cerkezoy State Hospital, Tekirdag, Turkey,* ⁴*Department of Psychiatry, Dokuz Eylul University Medical School, Izmir, Turkey,* ⁵*Private Practice, Balçova, Izmir, Turkey,* ⁶*Department of Psychiatry, Katip Celebi University, Ataturk Education and Research Hospital, Izmir, Turkey,* ⁷*Dokuz Eylul University, School of Medicine, Department of Psychiatry, Balçova, Izmir*

Background: Recent studies reported parallel changes in anatomy and function in the eye and the brain in neuropsychiatric diseases. In addition to the eye's role as an easily and non-invasively accessible research target to develop biomarkers and to investigate the pathophysiology of neuropsychiatric diseases, the eye also may have significant pathophysiological relationships with the brain. Therefore, this study aimed to investigate; i) ocular differences between first-episode psychosis (FEP) and healthy controls (HC), ii) structural occipital cortex differences between FEP and HCs, iii) relationship between the ocular measures and cortical structure and global functional brain networks in FEP.

Methods: Nine-teen patients with FEP and 13 HCs included in this study. All participants underwent psychiatric evaluation, ocular imaging with optical coherence tomography, brain imaging with 3 Tesla T1-weighted magnetic resonance imaging (MRI), and resting-state functional MRI (fMRI). FEP patients were from the Early Intervention Unit, while HCs had no personal/family history of mood/psychotic disorders. Imaging the eyes was performed using a spectral-domain OCT. Ocular imaging measured retinal layers, and T1-weighted MRI analyzed cortical regions in the occipital cortex. The retinal layers include: the nerve fiber layer (NFL), ganglion cell layer (GCL), inner plexiform layer (IPL), inner nuclear layer (INL), outer plexiform layer (OPL), outer nuclear layer (ONL). fMRI analysis involved preprocessing steps, and graph theory analyses were conducted on resting-state fMRI data. Freesurfer was used for analysis of T1-weighted structural MRI. fMRIPrep software was used for the resting state fMRI analysis. Graph-based network analysis were performed using

Brain Connectivity Toolbox as implemented in MATLAB. Statistical analyses were performed using SPSS to compare FEP and HC differences and relationships between ocular and graph-theory based connectome parameters.

Results: There were no significant differences in gender and age between the FEP and HC groups ($p > 0.05$). All participants with FEP were clinically stable. Regarding demographic and clinical parameters, the age of patients with FEP was 21.6 ± 3.93 , and the age of patients with HCs was 24.3 ± 3.54 . The Scales for the Assessment of Positive Symptoms score was 18.18 ± 11.8 , and the Brief Negative Symptom Scale score was 30.7 ± 15.44 in patients with FEP. For structural MRI analysis, occipital cortex regions were not significantly different between FEP and HCs. Furthermore, functional brain networks also were not significantly different between FEP and HCs. For the right eye, retina total thickness ($p = 0.01$), GCL volume ($p = 0.01$), IPL volume ($p = 0.029$), INL volume ($p = 0.005$) were increased in patients with FEP compared to HCs. For the left eye, GCL volume ($p = 0.005$), IPL volume ($p = 0.026$), INL volume ($p = 0.003$) were increased in patients with FEP compared to HCs. The thicknesses of retinal layers of both the right and left eyes were not significantly different between groups. In patients with FEP, characteristic path length was significantly associated with NFL volume ($p = 0.41$, $r = 0.687$), GCL volume ($p = 0.007$, $r = 0.685$), OPL volume ($p = 0.034$, $r = 0.567$). Cluster coefficient was significantly associated with the total retina central thickness ($p = 0.003$, $r = 0.686$), GCL thickness ($p = 0.018$, $r = 0.622$), IPL thickness ($p = 0.019$, $r = 0.576$), OPL thickness ($p = 0.003$, $r = 0.686$). The small-worldness was associated with the total retina central thickness ($p = 0.022$, $r = 0.567$), IPL thickness ($p = 0.009$, $r = 0.626$), OPL thickness ($p = 0.023$, $r = 0.564$). Modularity was significantly associated with the total retina central thickness ($p = 0.02$, $r = 0.574$), GCL thickness ($p = 0.015$, $r = 0.636$), OPL volume ($p = 0.027$, $r = 0.587$) and thickness ($p = 0.04$, $r = 0.517$). Global efficiency was associated with NFL thickness ($p = 0.045$, $r = 0.676$), GCL thickness ($p = 0.42$, $r = 0.550$), OPL thickness ($p = 0.022$, $r = 0.567$). In patients with FEP, the total retina thickness was significantly associated with lateral occipital cortex thickness ($p = 0.006$, $r = 0.605$), and showed non-significant trend with lingual thickness ($p = 0.059$, $r = 0.441$). The total retina volume was not significantly associated with any occipital cortex region volumes.

Discussion: To the best of our knowledge, this is the first study identifying the relationship between ocular parameters and brain structure and function in patients with FEP. These findings contribute to the growing body of research in oculomics and connectomics aspects of early psychosis. Intriguingly, while there were no significant differences in occipital cortex structures and functional brain networks between FEP and HCs, ocular imaging with OCT revealed notable differences. Patients with FEP exhibited increased volumes in certain retinal layers, particularly GCL, IPL, and INL. These correlations could reflect underlying systemic changes affecting both the eye and the brain, possibly mediated by common neurobiological pathways such as aberrant neurodevelopment. In summary, our study contributes to the growing body of evidence suggesting that oculomics could be a valuable tool in understanding and potentially detecting early psychosis.

T65. PSYCHOSIS AND TRAUMA – MEASUREMENTS OF BLOOD-BASED EXOSOMAL BIOMARKERS FROM BRAIN ORIGINS

Charles Desmeules^{*1}, Olivier Corbeil², Laurent Béchard³, Maxime Huot-Lavoie¹, Colombe Claveau⁴, Chantale Thériault⁵, Coraline Canivet⁶, Anne-Marie Essiambre⁵, Élisabeth Anderson⁷, Marie-France Demers⁸, Marc-André Roy¹, Jessica Deslauriers⁸

¹Universite Laval Faculty of Medicine, ²Faculty of Pharmacy, Universite Laval, ³Faculty of Pharmacy, Laval University, ⁴CERVO Brain Research Center, ⁵CERVO Brain Research Centre, ⁶CHU de Québec Research Center, ⁷School of Psychology, Laval University, ⁸Pharmacy Faculty, Laval University

Background: Due to its reliance on heterogeneous symptomatology, accurate diagnosis of first-episode psychosis (FEP) remains challenging for clinicians. As early intervention has substantial benefits for long-term outcomes, early diagnosis of FEP is imperative to improve recovery for affected individuals. However, the lack of specific biomarkers poses a significant limitation for early diagnosis of FEP. It is therefore urgent to identify specific diagnosis biomarkers of FEP.

History of past psychotrauma is an important risk factor for developing psychosis. As chronic inflammation is observed in both FEP and trauma history pathogeneses, this suggests a sub-category of psychosis characterized by the history of a psychotrauma with an inflammatory component. To date, the mechanisms underlying the development of psychosis after a traumatic experience and the contribution of inflammation to this association are still unknown.

Another limitation in biomarker discovery studies is that circulating biomarkers are not reflecting neurological changes. Brain-derived exosomes have aroused increasing interest in recent years as they are produced by brain cells and cross the blood-brain barrier to release inflammatory cargo once they reach the bloodstream. Brain-derived exosomes are therefore a powerful and non-invasive tool to examine inflammatory marker specific to their brain origin. The present study aims to: (1) examine inflammatory content of several brain-derived exosomes in the FEP vs healthy populations; and (2) determine the effect of past psychotrauma on the brain-derived exosomal content in FEP individuals vs those without history of past trauma.

Methods: 50 healthy controls, 25 FEP individuals without psychotrauma and 25 FEP with psychotrauma were recruited. Psychopathological measures were collected with the Positive and Negative Syndrome Scale, as well as Childhood Trauma Questionnaire and Life Events Checklist scales for trauma history. Exosomes from astrocytes, microglia and neurons were isolated and enriched from collected plasma samples by immunocapture with anti-GLAST, anti-TMEM119 and anti-CD171 antibodies, respectively. Characterization of inflammatory content of brain-derived exosomes was conducted using high-sensitivity multiplex essays. Kruskal-Wallis analyses were performed to compare the biological parameters in healthy, FEP without trauma, and FEP with trauma groups.

Results: Preliminary results from a subgroup of participants (n=4-6/group) have been generated for several immune markers (IL-10, IL-12p70, IL-17, IL-1 β , IL-2, IL-4, IL-6, TNF- α and IFN- γ) from astrocyte-, neuron-, and microglia-derived exosomes. Individuals with history of trauma tends to exhibit higher levels of neuron-derived IL-12p70 (p LESS THAN 0.10 vs healthy group) and elevated levels of microglia-derived IFN- γ (p LESS THAN 0.09 and p LESS THAN 0.11 vs healthy and FEP without trauma groups, respectively). Complete analyses, namely analysis of covariables with sex as covariable, and including all participants will be presented at the meeting.

Discussion: As the history of past trauma in the FEP population tends to be associated with specific immune content from neuron- and microglia-derived exosomes, our findings highlight that: (1) that trauma history modulates psychotic risk via specific neuroimmune signaling pathways; and (2) that past trauma induces a distinct FEP biosignature. Importantly, our study: (1) strengthens the potential of brain-derived exosomes as accessible and non-invasive biomarkers that reflect neurological changes in humans; and (2) is a crucial step in

our understanding of the role of neuroinflammation in FEP and the association with traumatic history in a brain cell-specific manner.

T66. A MULTIMODAL ARCHITECTURE FOR DISTINGUISHING SCHIZOPHRENIA SPECTRUM DISORDER FROM BIPOLAR DISORDER USING LEXICAL FEATURES FROM TRANSCRIBED SPEECH

Omar Alqahtani¹, Julianna Olah^{*2}

¹UCL, ²King's College London

Background: Speech abnormalities, represented in the form of quantifiable deviations from normal language use, are characteristic of psychotic disorders and present even in the prodromal stage. Different methodologies have been proposed to automatically measure such differences. These methods root in an exponentially growing field, Natural Language Processing (NLP). However, the application of one of the most disruptive and successful technological developments of NLP, Large Language Models (LLM's) have not been explored in psychosis research.

Methods: In this project, we explored the potential of Large Language Models (LLMs) for classifying psychiatric disorders, with a focus on distinguishing between Bipolar Disorder (BD) (N = 189) and Schizophrenia Spectrum Disorder (SSD) (N = 83). We also considered representations of the general population, categorised as Healthy Control (N = 318) and Prodromal Psychosis (PP) (N = 332). To this end, we employed DistilRoBERTa as the core of a Multimodal model, integrating both lexical and non-lexical features.

Results: This unified approach achieved moderate performance to predict BD, SSD, PP demonstrating the potential of fine-tuned LLMs as reliable diagnostic tools in clinical settings. Moreover, the model's design and training addressed challenges commonly associated with mental health data, such as limited sample sizes and class imbalances.

Discussion: We discuss general considerations and challenges related to the technical applications and suggestions for target LLMs for deployment. We present technical solutions to overcome difficulties in health care applications (e.g. data scarcity, limited computational power, feeding in non-lexical information, multimodal assessment) and use our experiment data to present a know-how of fine-tuning LLM's for psychosis-related applications.

T67. THE ROLE OF ENDOCANNABINOID IN LIPID METABOLISM IN PATIENTS AT HIGH RISK OF PSYCHOSIS

Background: Recently we identified a set of lipid biomarkers which associated which could stratify patients at clinically high risk of psychosis and could their clinical progression. This was developed in the EU-GEI cohort. However, the reasons for these lipid changes remain unclear. Therefore, we sought to identify potential lipid mediators that could start to identify why the lipids change in these individuals. Our recent study demonstrated that upon first episode psychosis there is a clear breakdown in the association between the CB1 receptor availability in the CNS compared to the circulating endocannabinoids. The ECS comprises of a complex interaction between endogenous cannabinoids (endocannabinoids), the enzymes involved in the up and down stream metabolism of endocannabinoids and the cannabinoid receptors (CB1 and CB2). Current knowledge regarding the endogenous endocannabinoids (ECs) is mostly limited to the two major ECs, anandamide (AEA) and 2-arachidonoylglycerol (2-AG). These two ECs are known to act at both CB1 and CB2 receptors. In addition to these two molecules there is a chemically diverse set of related compounds more broadly known as long chain N-acylethanolamines (NAE)s and 2-monoacylglycerols. To understand the role of the ECS in early psychosis we quantified endocannabinoids and related structures with mass spectrometry in the serum taken from the EU-GEI cohort. We then combined this data with the previously published lipidomic data to understand how the changes in circulating endocannabinoids impacted the lipid metabolism. Given the previous sex effects observed in CB1 receptor availability we also stratified the patients based on sex to observe if there were any differences between the interaction of the lipid metabolism and the endocannabinoid system.

Methods: The samples were obtained from the EU-GEI (European Network of National Schizophrenia Networks Studying Gene-Environment Interactions) High Risk study which is a multicenter longitudinal observational study of CHR individuals. 344 CHR individuals from 11 sites. Previous exposure to antipsychotic medication was not an exclusion criterion for CHR subjects, but it was for HC subjects. The lipidomic analysis was carried out using an untargeted high resolution mass spectrometry (MS) analysis. The circulating endocannabinoids were quantified with a targeted QqQ MS based assay.

Results: When comparing the HC to the CHR the PCR analysis showed a high degree of association between the circulating EC system and the lipids in the healthy controls. However, these associations were lost in the CHR group. This trend was especially observed in the n-linked ECs such as AEA, PEA, and OEA. The only exception to this was SEA which was close to the limit of detection of the mass spectrometer thus making quantification less reliable. The downstream metabolite AA also showed a similar pattern, however, AG which is an o-linked EC did not show such a dramatic reduction in R². Interestingly, the associations were different between males and females. AG, AEA and PEA showed a similar trend in both males and females but the R values in the females were larger in all lipids in the females. 2-AG were positively associated with all lipid classes except LPC. In AEA and PEA there was a similar pattern except for the TGs which were generally had a negative regression coefficient with the ECs. AA, OEA, and PEA the patterns of associations between male and

female were very different. In females these lipids showed a similar pattern to AEA and PEA. However, in males there was no clean pattern when the lipids were grouped according to class.

Discussion: This study demonstrates that there is a clear role of the ECS in early psychosis and it has an effect on the lipids that change early in disease. This could suggest that the ECS plays a key long range signalling role in brain to periphery communication. The non-classical NAEs clearly need further investigation in psychosis to fully understand their role in disease development.

T68. UNVEILING VOICES: A PREREGISTERED CLUSTER APPROACH TO IDENTIFY PROSODY PATTERNS IN SCHIZOPHRENIA

Carlos Martínez-Asensi¹, Victor Ortiz-García de la Foz², Rosa Ayesa-Arriola*³

¹UNED; Valdecilla Biomedical Research Institute IDIVAL, ²University Hospital Marques de Valdecilla -IDIVAL; University of Cantabria; CIBERSAM, ³Valdecilla Biomedical Research Institute IDIVAL Research Group on Mental Illness, Marqués de Valdecilla University Hospital, University of Cantabria

Background: The intrinsic relationship between language and cognition has led to the exploration of language and speech analysis as a gateway to a better understanding of the underlying mental processes. Thus, language also emerges as a means of assessing the processes underlying dysfunctions, such as SSD.

Automatic speech analysis has been used to identify acoustic features to provide greater reliability for the diagnosis of SSD. However, the absence of pre-registration in some studies, heterogeneity in data acquisition protocols among teams, and utilization of supervised learning models could lead to a lack of generalization of their results.

One facet of language, prosody, is responsible for conveying paralinguistic information that could play a pivotal role in the identification of the speaker's mental processes.

In this context, this study focuses on addressing some of the methodological challenges and current limitations of automatic language analysis. The working hypothesis is that language prosody exhibits characteristics that enable the differentiation of individuals with SSD diagnoses.

Methods: This is a preregistered (<https://osf.io/fq4u3>), cross-sectional, observational, retrospective and confirmatory study.

Prosody data will be computationally extracted from masked discourse audio recordings. Interviews with a non-probabilistic convenience sample, comprising 51 patients with SSD and 48 healthy controls (HC), were carried out following the DISCORSE consortium protocols.

The study comprises two steps: 1) a simulation study based on data from other works in the field and 2) clustering modelling with our sample masked data. The simulation study is used to estimate the effect size and power and to test which analysis choices and clustering model could yield better performance in terms of precision and generalization. We then perform clustering modelling with data from our sample, following the findings of the simulation. The grouping variable (SSD or HC) will serve as a criterion for cross-validating the quality of the model, once unmasked.

Results: From the simulation study, we aim to identify the analytical choices that could lead to better performance in the subsequent cluster analysis. These choices include the type and number of prosodic variables, reduction (or lack thereof) of dimensions, and type of clustering model. Additionally, we will estimate the effect size and power of the clustering technique. Based on previous results from our colleges, we expect sufficient effect size and power to be able to cluster SSD patients separately from other individuals.

After obtaining the simulation results and pre-registering them, we will apply these findings to analyze our sample data. Our expectation is to develop a model that achieves more than 90% sensitivity, specificity, and precision in detecting SSD patients, as measured in model cross-validation tests, in comparison to clinical assessments.

Discussion: In this study, we use a pre-registry of analytical procedures, following precise standardized protocols in the acquisition of data, and use unsupervised learning modelling as a tool to overcome the lack of generalization and precision that some previous studies had suffered when trying to detect language features to diagnose SSD.

T69. A COGNITIVELY INFORMED BIOMARKER AND ASSESSMENT TOOL OF POSITIVE THOUGHT DISORDER: THE STRATEGIC USE OF LARGE LANGUAGE MODELS

Lin Wang¹, Anthony Yacovone², Victoria Sharpe², Sabrina Ford³, Lena Palaniyappan³, Gina Kuperberg*¹

¹Tufts University and Mass. General Hospital, ²Tufts University, ³McGill University

Background: Positive thought disorder (PTD) is prominent in schizophrenia and characterized by patients' over-reliance on local associations and under-reliance on the global discourse during language processing. Traditional clinical assessments of PTD (e.g. diagnostics of loosening of associations, derailment, and tangentiality) are subjective and time-consuming. We argue that Large Language Models (LLMs) can be used as objective, automatic assessment tools for measuring PTD. In this study, we used two LLMs, BERTopic and Word2Vec, to characterize the nature of global and local representations present in naturally produced speech. We find that these measures successfully capture the linguistic consequences of PTD.

Methods: We analyzed 3 picture descriptions (~1 minute each) from 70 first-episode psychosis patients (all unmedicated and treatment-naïve) and 34 demographically matched controls. We used the Disorganization subscore from the Thought and Language Index (TLI) to measure PTD. Symptoms and domain-general cognitive function were assessed using the PANSS-8, Semantic Fluency, Digit-Symbol Substitution, and the Trail-Making Test.

Results: Model 1 (BERTopic): We used a pre-trained BERTopic model with 2376 common topics ascertained from the Wikipedia corpus to assess how "topics" shifted throughout each picture description. Specifically, for each participant, we ascertained the variability in their topic representation, and characterized that variability as entropy. We then regressed these values onto TLI (while controlling for description length, age, gender, and SES). We found that TLI significantly predicted topic entropy such that participants with greater TLI scores produced more topics in their descriptions ($b = 0.06$, $SE = 0.03$, $t = 2.17$, $p = 0.03$).

Model 2 (Word2Vec): We used a pre-trained Word2Vec model with 300-dimensional word embeddings to calculate the pairwise cosine similarity for a given content word with each of its five preceding content words. For our analyses, we averaged similarity values across all content words for each pairing. We then regressed similarity values onto TLI, word pairing,

their interaction, and the control variables above. We found that larger TLI scores resulted in greater similarities between words and their local contexts ($b = 0.01$, $SE = 0.003$, $t = 2.88$, $p = 0.005$), and this similarity begins to weaken at 4 words back.

Model 3 (Classification): We also asked if entropy and cosine similarity values can jointly discriminate between patients and controls. To do this, we divided the data into training and testing sets (80-20), and trained a model to predict patients and controls using their entropy and similarity values. The model can effectively distinguish between patients and controls: overall accuracy = 0.86, sensitivity = 1.0, precision = 0.83, and AUC = 0.91.

Discussion: This work has clinical, neurocognitive, and computational implications: LLMs can provide linguistic biomarkers for fast, automated, and objective quantification of language disorganization, as PTD predicts the entropy and local similarity in patients' speech. LLM biomarkers can be used for illness detection, symptom monitoring, and outcome predictions. These results bridge the clinical characterizations of PTD with neurocognitive evidence for selective atypicalities in patients' language processing. Our work supports hierarchical generative models of psychosis, and future work will situate these findings within the biologically plausible, Predictive Coding framework, to provide a mechanistic account for over-reliance on local associations and under-reliance on the global discourse during language processing.

T70. METALLOPROTEINASE-9 IN FIRST EPISODE PSYCHOSIS: INTERPLAY OF GENE-ENVIRONMENT INTERACTIONS

Joao Roberto Lisboa^{*1}, Camila Marcelino Loureiro², Fabiana Corsi-Zuelli², Olga da Costa², Shuhama Rosana³, Aline Esposito⁴, Menezes Paulo Rossi⁵, Paulo Louzada-Junior⁶, Riccardo Lacchini⁴, Del-Ben Cristina Marta³, Felipe Villela Gomes⁷

¹Ribeirão Preto Medical School, University of São Paulo,, ²Department of Neuroscience and Behavioral Sciences, Ribeirão Preto Medical School, University of São Paulo, Ribeirão Preto, Brazil., ³Department of Neuroscience and Behavioral Sciences, Ribeirão Preto Medical School, USP, Ribeirão Preto, Brazil., ⁴Department of Psychiatric Nursing and Human Sciences, Ribeirão Preto College of Nursing, University of São Paulo, Ribeirão Preto, Brazil., ⁵Department of Preventive Medicine, Faculty of Medicine, University of São Paulo, São Paulo, Brazil., ⁶Department of Internal Medicine, Ribeirão Preto Medical School, University of São Paulo, Ribeirão Preto Brazil., ⁷Department of Pharmacology, Ribeirão Preto Medical School, University of São Paulo, Ribeirão Preto, Brazil.

Background:

Metalloproteinase-9 (MMP9), a broadly expressed metalloproteinase in the central nervous system, has wide ranging effects on extracellular matrix (ECM) structure and function. Disruptions in MMP9 may be caused by psychosocial trauma during critical periods of development, such as childhood and adolescence, and are proposed to underlie abnormalities in the ECM with detrimental downstream effects implicated in schizophrenia (SCZ), including an altered excitatory/inhibitory balance. Thus, early adverse events may modulate MMP9 expression, influencing the risk of developing psychosis. Recent studies indicate elevated MMP9 in peripheral blood of SCZ patients. Here, we investigated interactions between MMP9 gene polymorphisms and MMP9 protein blood levels with childhood trauma in first episode psychosis (FEP).

Methods:

Subjects were enrolled from a case-control study, including FEP (n=143) (60.1% male, 46.9% non-white) and community controls (n=286) (48.3% male, 31.5% non-white). Sociodemographic and clinical assessments were conducted for all participants along with the Childhood Trauma Questionnaire (CTQ). Blood samples were drawn at the nearest feasible time to psychosis onset. MMP9, pro-MMP9, and TIMP-1 levels were measured by gel zymography. Genetic testing characterized four MMP9 gene polymorphisms (rs3918242, rs17576, rs17577, rs20544). We investigated the impact of childhood trauma, genetic polymorphisms of the MMP9 gene, and their interaction in FEP individuals. These variables were also analyzed regarding their relation to expressed plasma levels of MMP9, pro-MMP9 and TIMP-1. Statistical analysis included chi-square and logistic regression analysis for CTQ-FEP and Generalized linear models (GLMs) to examine relationships between CTQ, FEP, MMP9 gene polymorphisms, and MMP9 protein levels.

Results:

A positive history of childhood trauma conferred an increased risk for FEP (OR=3.443; p LESS THAN 0.001). No associations between genetic polymorphisms and FEP or MMP9 plasma levels were found. In a GLM including both FEP and community controls, a positive association emerged between childhood trauma and increased pro-MMP9/TIMP-1 ratio (B=0.602; p=0.001). Another GLM indicated that the FEP group exhibited elevated pro-MMP9 levels compared to controls (B=0.256, p=0.041). Additionally, within this model, a robust interaction emerged between a history of trauma and FEP, revealing higher levels of both pro-MMP9 (B=0.428; p LESS THAN 0.013) and pro-MMP9/TIMP1 ratio (B=0.901; p LESS THAN 0.001) in participants with a positive trauma history within the FEP group. Another GLM revealed an interaction between a positive trauma history and the dominant model of the rs20544 polymorphism, resulting in increased pro-MMP9 (B=0.517; p=0.003) and pro-MMP9/TIMP1(B=0.917; p LESS THAN 0.001) ratio in participants with a trauma history and TT or CT genotypes.

Discussion:

Our findings confirmed a robust direct association between childhood trauma and FEP and revealed that trauma is associated with increased pro-MMP9/TIMP1 ratio. FEP patients exhibited heightened pro-MMP9, particularly in those with trauma history. Furthermore, we observed a gene-environment interaction involving an MMP9 gene polymorphisms and childhood trauma, influencing pro-MMP9 protein expression. No findings were observed for the active MMP9 molecule. These findings highlight the complex interplay of gene-environment interactions in SCZ, and how specifically trauma may modulate protein expression of MMP9, which may lead to neurodevelopmental abnormalities that increase risk for FEP.

T71. ENHANCING COGNITIVE RESERVE: HDL CHOLESTEROL AS A BIOLOGICAL PROXY

Rebeca Magdaleno Herrero^{*1}, Ángel Yorca Ruiz¹, Nancy Murillo-García¹, Jorge Crespo-Álvarez², Antonio Vita³, Rafael Penadés⁴, Benedicto Crespo Facorro⁵, Rosa Ayesa-Arriola⁶

¹Marqués de Valdecilla University Hospital, IDIVAL, ²Faculty of Health Sciences, Universidad Europea del Atlántico (Uneatlántico), ³University of Brescia, ⁴Hospital Clinic Barcelona, ⁵Hospital Universitario Virgen del Rocío. CIBERSAM. Universidad de Sevilla, IBiS, Sevilla, ⁶Department of Psychiatry. Marqués de Valdecilla University Hospital, IDIVAL, School of Medicine, University of Cantabria, Santander, Spain Centro Investigación Biomédica en Red de Salud Mental (CIBERSAM), Madrid, Spain

Background: Cognitive Reserve (CR) is the brain's capacity to enhance the efficiency of existing neural networks or employ alternative neural networks when conventional cognitive strategies failed to yield desired outcomes. In the case of schizophrenia spectrum disorders (SSD), CR has been observed to play a significant role in the onset and course of the disease. However, its estimation relies on heterogeneous proxies with limitations. The inclusion of biological measures, linked to cognitive performance, as CR proxies holds promise for refining its estimation. Attending the relationship between SSD and metabolism, and highlighting the role of lipids on the central nervous system, an association could be stabilised between high-density lipoprotein cholesterol (HDL) levels and alterations in various cognitive domains observed in SSD. The aim of this study is to validate a CR estimation composed by years of education and HDL levels.

Methods: A total of 378 first-episode psychotic disorder (FEP) patients and 149 healthy controls provided sociodemographic, clinical, HDL levels and neurocognitive data. The sample was classified into CR1 (years of education, occupation, and premorbid IQ) and CR2 (years of education and HDL levels). This classification enables comparative evaluations for both indices using machine learning models.

Results: The classification of FEP patients into CR1 and CR2 was very similar. In the CR1 group, 50.8% of FEP patients had low CR1, and 49.2% had high CR1. Similarly, in the CR2 group, 54.2% of FEP patients had low CR2, and 45.8% had high CR2. Neurocognitive comparisons reveal that, regardless of CR1 or CR2 classification, all cognitive domains assessed indicated that FEP patients with both low CR groups exhibit poorer performance compared to both high CR groups, as well as diminished global cognitive functioning (GCF). The Support Vector Machine (SVM) model was the best for predicting the Area Under the ROC Curve (AUC) of CR2 in FEP patients, it achieved an AUC of 0.725 ± 0.109 (95% CI: 0.616-0.834) for FEP patients. In comparison to CR1, CR2 achieved superior performance scores in metrics: accuracy (CR1: 62%; CR2: 66%), F-1 score (CR1: 59%; CR2: 69%), sensitivity (CR1: 54%; CR2: 70%), precision (CR1: 66%; CR2: 69%), and revealed an ROC curve characterized by higher discriminative capacity.

Discussion: The results of this study emphasize the significant predictive capacity of the combination of years of education and HDL levels in estimating CR in FEP patients. These findings are supported by previous evidence in the scientific literature, which has also highlighted the predictive ability of these two variables in relation to cognitive performance in FEP patients. The inclusion of years of education as an indicator is crucial due to its early in life establishment and its influence on lived experiences and cognitive enrichment during early life stages. Additionally, education stimulates neuroplasticity prior to the onset of the disease, which can provide cognitive protection against the negative effects of psychosis. Levels of HDL, on the other hand, provides specific information about metabolic functioning and cardiovascular health, which are essential for cognitive performance and mental well-being. Previous studies demonstrated a relationship between higher levels of HDL and better overall functioning and social relationships, as well as positive association lower levels of HDL and cognitive deficits in individuals with psychosis. The inclusion of HDL levels into CR index provides a more comprehensive understanding of cognitive performance in SSDs and enhances the predictive capacity of the model.

T72. DOPAMINE RELEASE FOLLOWING D-AMPHETAMINE IS PREDICTIVE FOR OUTCOME IN PATIENTS WITH FIRST EPISODE SCHIZOPHRENIA

Nicole Praschak-Rieder*¹, Ana Weidenauer¹, Ulrich Sauerzopf¹, Irena Dajic¹, Katharina Landesmann¹, Cornelia Diendorfer¹, Martin Bauer², Matthäus Willeit¹

¹Department of General Psychiatry, Medical University of Vienna, ²Social psychiatric outpatient clinic Donaustadt - SPA 22, PSD Vienna

Background: Three observations currently support the dopamine theory of schizophrenia: (i) untreated psychotic patients with schizophrenia show higher dopamine synthesis rates, (ii) they show greater behavioral and neurochemical sensitivity towards dopamine-releasing agents like amphetamines, (iii) antipsychotics relieve psychotic symptoms by blocking dopamine D2/3 receptors. However, up to one third of patients show no adequate response and poor overall clinical outcome. Aiming at its potential for predicting response, we measured D-amphetamine-induced dopamine release using the selective D2/3 dopamine receptor agonist radioligand [11C]-(+)-PHNO and positron emission tomography (PET) in untreated patients with first-episode psychosis. Thereafter, we assessed one-year clinical outcomes in these patients.

Methods: Twenty-one antipsychotic-naïve patients (6 female) underwent two [11C]-(+)-PHNO PET scans in a randomized balanced cross-over design. For estimating dopamine release, one scan was performed with, and another one without oral D-amphetamine pretreatment, as previously described by Weidenauer et al. (2020). The Positive and Negative Symptoms Scale (PANSS) was performed at baseline and at seven follow-up visits over one year. Patients received antipsychotic treatment in a naturalistic setting (Clinical Trial Registry: EUDRACT 2010-019586-29).

Results: Greater D-amphetamine-induced dopamine release in ventral striatum was associated with greater reductions in positive symptoms ($r=0.54$, $p=0.04$); greater dopamine release in globus pallidus was associated with reductions in PANSS negative ($r=0.58$, $p=0.02$), general ($r=0.53$, $p=0.04$), and total symptom scores ($r=0.063$, $p=0.01$). Greater dopamine release in substantia nigra/ventral tegmental area predicted larger reductions in general symptoms ($r=0.51$, $p=0.05$). Post-amphetamine radioligand binding in putamen correlated positively with negative symptom scores at baseline ($r=0.66$, $p=0.005$) and throughout all follow-up visits.

Discussion: Our data show a relationship between D-amphetamine-induced dopamine release and the expression, severity, and persistence of symptoms during the first year of illness in patients with first-episode schizophrenia. Higher [11C]-(+)-PHNO binding potentials in the putamen of patients with more pronounced negative symptoms indicate that the expression of negative symptoms of schizophrenia goes along with a relative deficiency in dopamine transmission. Thus, excess and deficiencies in dopamine signaling seem to coexist in subcortical brain regions of patients with schizophrenia, contributing to the expression of symptoms in their own way.

T73. THE BRIGHT SIDE OF SCHIZOTYPY: CHARACTERIZATION OF SCHIZOTYPY CLUSTERS IN NONCLINICAL YOUNG ADULTS

Valeria Lavín^{*1}, Pilar Torrecilla², David Gallardo³, Neus Barrantes-Vidal², Tom Richard Kwapił⁴

¹*Autonomous University of Barcelona*, ²*Department of Health and Clinical Psychology, Autonomous University of Barcelona*, ³*Department of Psychology, University of Barcelona*, ⁴*Department of Psychology University of Illinois at Urbana-Champaign*

Background: Schizotypy is defined as a multidimensional construct indexing liability for psychosis-spectrum psychopathology that is expressed across a broad range of traits, subclinical and clinical features. However, increasing evidence has shown that the impairment differs greatly for the distinct dimensions integrating the schizotypy construct (i.e., positive, negative and disorganized). Previous studies have reported that individuals with high positive schizotypy but with low negative and disorganized traits show preserved levels of functioning and well-being and may even present positive features such as creativity; in contrast, those who present overall high schizotypy scores usually report the poorest outcomes. The present study aimed to replicate previous findings by identifying schizotypy clusters in nonclinical young adults. We then compared the different clusters on depressive and anxiety symptoms, social functioning, and positive mental health outcomes.

Methods: A total sample of 1118 non-clinical young adults between the ages of 18 and 35 (mean=22.3; SD=3.4 ;76.2% female) completed a comprehensive battery of self-reported measures. Schizotypy dimensions were assessed using the Multidimensional Schizotypy Scale. Characterization of the clusters was performed with measures of anxiety (Beck Anxiety Inventory), depression symptoms (Beck Depression Inventory-II), social functioning (Social Functioning Questionnaire), well-being (Warwick-Edinburgh Mental Wellbeing Scale), resilience (Connor Davidson Resilience), self-reported creativity (Runco Ideational Behavior Scale), self-esteem (Rosenberg Self-Esteem Scale), and emotional clarity and attention to emotions (Trait Meta-Mood Scale). A K-means iterative cluster analysis was performed with the schizotypy dimension scores and then comparisons across variables were examined using one-way ANOVA.

Results: A forced four-cluster model yielded the following groups: 'Low schizotypy' (50%), characterized by overall low schizotypy; 'High Positive' (21.87%), presenting high positive but low negative schizotypy scores; 'High Negative' (10.44%) with the high scores in the negative dimension but low in the disorganized and positive ones; and 'High disorganized' (17.67%), presenting the highest scores in the disorganized dimension and medium scores in the negative and positive ones. The 'High Disorganized' group showed the poorest outcomes, including high anxiety and depression and low scores on functioning, well-being, resilience, self-esteem, emotional clarity, and attention to emotions. However, they surpassed the 'Low Schizotypy' group in creativity. The 'High Negative' cluster had lower scores in emotional clarity, attention to emotions, well-being, and social functioning compared to 'Low Schizotypy', whereas the 'High Positive' group showed slightly lower positive outcomes and higher anxiety and depression levels, and no notable differences in emotional clarity. Nevertheless, this group excelled in creativity and attention to emotions compared to the other clusters.

Discussion: This study replicates and expands previous work regarding the cluster structure underlying the multidimensional heterogeneity of schizotypy dimensions by using a larger sample of nonclinical adults and incorporating the disorganized dimension. The results underscore the importance of considering the specificities of these distinct yet associated dimensions when examining the relationship between schizotypy and various mental health variables. Furthermore, it adds support to previous studies reporting an association between positive schizotypy and creativity.

T74. RETINAL CYTOARCHITECTURE AS A BIOMARKER: A TRANS-DIAGNOSTIC META-ANALYSIS OF RETINAL MARKERS ACROSS PSYCHIATRIC DISORDERS

Nils Kallen*¹, Giacomo Cecere², Foivos Georgiadis³, Stephanie Homan⁴, Finn Rabe⁵, Erich Seifritz⁶, Philipp Homan⁷

¹Psychiatric University Hospital Zurich, ²Psychiatric Hospital, University of Zurich, Zurich, Switzerland, ³University Hospital of Psychiatry, University of Zurich, ⁴University Hospital of Psychiatry/University of Zurich, ⁵Department of Psychiatric Research, Psychiatric University Hospital Zurich, ⁶Department of Psychiatry, Psychotherapy and Psychosomatics, Psychiatric Hospital, University of Zurich, 8032 Zurich, Switzerland, ⁷Department of Psychiatry, Psychotherapy and Psychosomatics, Psychiatric Hospital of the University of Zurich, Zurich, Switzerland

Background: Psychiatric disorders involve a complex interplay of diverse genetic and environmental factors, often with shared mechanisms. In clinical settings, we often see an overlap of symptoms or syndromes between distinct diagnostic entities with different or opposite causes.

This diagnostic heterogeneity has proven problematic for both research and clinical practice. Different biomarkers have been investigated across the psychiatric spectrum, as endophenotypes could bridge the gap between observable symptoms and underlying disease mechanisms. In the last 20 years, many publications have explored the retina in different psychiatric and neuropsychiatric disorders.

In this meta-analysis, we review the current body of evidence and analyze whether and in what way retinal parameters could help to discriminate between diagnostic groups. Previous meta-analyses investigated changes in the retina in schizophrenia spectrum disorder (SSD) and, to a much lesser extent, affective disorders such as bipolar disorder (BD) and major depression (MD).

This is the first study to our knowledge with a trans-diagnostic approach across the psychiatric spectrum investigating SSD, affective disorders, obsessive-compulsive disorder (OCD), and attention-deficit/hyperactivity disorder (ADHD).

We hypothesize that differences in retinal cytoarchitecture, especially in retinal nerve fiber layer (RNFL) and ganglion cell layer (GCL), are more pronounced in or could be specific to disorders associated with psychotic symptoms such as SSD and BD.

Methods: We conducted a comprehensive search of MEDLINE and EMBASE databases for studies investigating retinal layers in psychiatric disorders. We included case-control studies in psychiatric disorders (diagnosed by DSM-V or ICD-10) reporting measurements of the thickness and volume of the RNFL, GCL, or the macula using optical coherence tomography (OCT).

We found 259 studies, of which we included 77 studies that fulfilled our inclusion criteria. We assessed study quality using the Newcastle-Ottawa-Scale. Statistical analysis and meta-regression were done in R Version 4.2.3. We investigated heterogeneity using the I² score and publication bias using Egger's Test.

Results: We included 77 studies in the final analysis across several psychiatric disorders. We found 36 studies investigating retinal markers in SSD, 20 studies investigating bipolar disorder (BD), 5 investigating MD, 5 investigating ADHD, and 3 for OCD.

Consistent with previous research, we found RNFL to be thinner in SCZ patients (SMD -0.42, $p < 0.01$) and BD patients (SMD -0.56, $p < 0.01$). In contrast, compared to controls, the RNFL thinning was less pronounced in major depression (SMD -0.23, $p = 0.01$) and OCD (SMD -0.27, $p = 0.03$). In ADHD, we found no significant differences between patients and controls (SMD -0.21, $p = 0.27$).

Discussion: Our meta-analysis revealed a significant reduction in RNFL thickness in SSD and BD, consistent with previous data. More research is needed, especially investigating additional disorders without psychotic symptoms, to further evaluate the specificity of these findings in a clinical context. In addition, longitudinal studies would provide further insight into the dynamics across disease states.

T75. FURTHER EVIDENCE OF THE LACK OF ASSOCIATION BETWEEN SCHIZOPHRENIA POLYGENIC RISK AND SCHIZOTYPY OR PSYCHOTIC-LIKE EXPERIENCES

Araceli Rosa^{*1}, Patricia Mas-Bermejo², Sergi Papiol³, Pilar Torrecilla⁴, Valeria Lavín⁵, Jackie Nonweiler⁶, Marc Via⁷, Irene Martínez-Alonso², Thomas R. Kwapił⁸, Neus Barrantes-Vidal⁴

¹Universitat de Barcelona, ²Secció de Zoologia i Antropologia Biològica, Departament de Biologia Evolutiva, Ecologia i Ciències Ambientals, Universitat de Barcelona, Barcelona, Spain. Institut de Biomedicina de la Universitat de Barcelona, Barcelona, Spain, ³IPPG / LMU, ⁴Departament de Psicologia Clínica i de la Salut, Universitat Autònoma de Barcelona, Spain, ⁵Department of Health and Clinical Psychology, Autonomous University of Barcelona, ⁶Universitat Autònoma de Barcelona, ⁷Department of Clinical Psychology and Psychobiology, Universitat de Barcelona, Barcelona, Spain. Institut de Neurociències, Universitat de Barcelona, Barcelona, Spain. Institut de Recerca Pediàtrica, Hospital Sant Joan de Déu, Barcelona, Spain, ⁸University of Illinois at Urbana-Champaign, United States of America

Background: According to the dimensional view of mental disorders, schizophrenia can be conceived as the extreme expression of a continuum of traits that are present in the general population. However, although many attempts have been made to identify the shared genetic background between these traits and the disorder itself, the general lack of significant findings has led to believe that this overlap might not be as robust as initially hypothesized. In a previous work, we tested the association between polygenic risk for schizophrenia and two of these disorder-related traits (i.e., schizotypy and psychotic-like experiences) in a sample of 253 nonclinical subjects and found no significant associations (Mas-Bermejo et al. 2023. Eur Arch Psychiatry Clin Neurosci). Here, we aim to replicate this study in a newly collected and larger sample of 941 nonclinical individuals, thereby overcoming the likely lack of statistical power of our previous analyses, to draw definitive conclusions.

Methods: Schizotypy and the positive dimension of psychotic-like experiences were assessed in these 941 subjects with the Multidimensional Schizotypy Scale and the Community Assessment of Psychic Experiences, respectively. Polygenic Risk Scores for schizophrenia (SZ-PRS) were computed for each participant with the PRS-CS method based on the latest schizophrenia genome-wide association study. Linear regressions were used to test the associations between the SZ-PRS and the psychometric variables.

Results: Our analyses did not reveal any significant association of the SZ-PRS with either the positive, negative or disorganized dimensions of schizotypy. Likewise, no association was found with the positive dimension of psychotic-like experiences.

Discussion: Our results seem to replicate once more, the lack of clear evidence that a genetic overlap between these disorder-related traits and schizophrenia truly exists regarding common genetic variation. One cannot rule out, however, that variants with larger penetrance (CNV, exonic variants, ultra-rare variation...) that are not included in the calculation of current SZ-PRS might contribute to such a shared genetic risk background between schizophrenia and disorder-related traits in the general population.

T76. THE BRAIN ENDOCANNABINOID SYSTEM IS DIFFERENTIALLY REGULATED IN MALES AND FEMALES WITH FIRST-EPISODE PSYCHOSIS

Heikki Laurikainen¹, Reetta-Liina Armio¹, Lauri Tuominen², Anna Kirjavainen³, Olof Solin³, Merja Haaparanta-Solin³, Raimo K R Salokangas¹, Jarmo Hietala¹

¹University of Turku, ²University of Ottawa, ³Turku PET Centre

Background: The endocannabinoid system (ECS) is a ubiquitous signaling system capable of modulating excitatory and inhibitory neurotransmission in the human brain. A sex difference of the endocannabinoid system has been documented in both human and animal studies. Further, the endocannabinoid system is dysregulated in male patients with first-episode psychosis (FEP). A difference in the ECS could potentially explain part of the demographic and clinical sex differences seen in psychotic disorders. We postulated that the ECS is differentially regulated in male and female patients with FEP.

Methods: In this cross-sectional case-control study brain endocannabinoid receptor type 1 (CB1R) availability was measured in medicated male (n=8) and female (n=10) patients with FEP, and age matched male (n=11) and female (n=10) healthy control (HC) subjects. CB1R availability was measured as distribution volumes (VT) of the selective CB1R radiotracer [18F]FMPEP-d2 using positron emission tomography (PET) and metabolite corrected arterial input. Assignment of group status was done according to the structured clinical interview for DSM-IV diagnoses. Female subjects using oral hormonal contraception were excluded.

Results: A total of 39 male and female subjects were included in the analyses. A rmANOVA model of CB1R availability in the anterior cingulate, hippocampus, thalamus and putamen revealed main effects of group ($F(1, 35) = 6.87, p = .013$), and sex*group interaction ($F(1, 35) = 4.30, p = .045$). Within-subjects analyses showed regionally differential effects of group ($F(1, 105) = 5.96, p = .0009$), and group*sex ($F(1, 105) = 4.31, p = .007$). There were no significant differences between female FEP and HC subjects ($F(3, 54) = 0.10, p = .96$). Female and male FEP patients showed a significant main effect of sex ($F(3, 48) = 3.429, p = .024$) in post-hoc pair-wise group analyses.

Discussion: The availability of CB1R is differentially altered in males and females with first-episode psychosis with most robust effect in the anterior cingulate. Further, our data suggest that CB1R dysregulation is seen preferentially in male patients with first-episode psychosis. The ECS sex difference increases our understanding of the pathophysiological processes in psychosis, and may further open new avenues for individualized treatment strategies.

T77. RELATIONSHIP OF ERYTHROCYTE OMEGA-3 FATTY ACIDS AND PLASMA BIOMARKERS IN ULTRA-HIGH-RISK PSYCHOSIS: A REPORT OF THE NEURAPRO CLINICAL TRIAL

Subash Raj Susai*¹, David Mongan², Colm Healy³, Jonah Byrne⁴, Rachel Davis¹, NEURAPRO Investigators⁵, Patrick D McGorry⁶, Melanie Föcking¹, G. Paul Amminger⁷, David Cotter¹

¹Royal College of Surgeons in Ireland, ²Queen's University Belfast, ³University College Dublin, ⁴RCSI University of Medicine and Health Sciences, ⁵International sites, ⁶Orygen - The National Centre of Excellence in Youth Mental Health, ⁷Orygen, National Centre of Excellence in Youth Mental Health, Melbourne, Australia

Background: Increasing evidence indicates the derangement of poly-unsaturated fatty acid (PUFA) mediated membrane function in the pathophysiology of schizophrenia. Various preclinical studies and clinical trials on non-psychiatric population have identified the anti-inflammatory properties of omega-3 fatty acids (FA). Even though early intervention with omega-3 supplementation is considered in various psychiatric disorders, their biologically role in psychosis is not clearly understood. In this study, we investigated the influence of omega-3 supplementation on peripheral immune markers in an ultra-high-risk (UHR) population.

Methods: Materials and methods: We quantified inflammatory cytokines and plasma proteins using immune assays and mass-spectrometry (MS) at baseline (n=293) and at follow-up (n=171) in plasma samples of UHR subjects. The relationship of erythrocyte membrane levels of total omega-3 FA with inflammatory markers was subsequently analysed using a linear regression model. Then using mediation analysis, we investigated whether immune-markers or plasma proteins mediated the relationship between change in omega-3 FAs and clinical outcomes.

Results: In linear regression models, the baseline plasma concentrations of Interleukin (IL)-15, Intercellular adhesion molecule (ICAM)-1 and Vascular cell adhesion molecule (VCAM)-1 were negatively associated with baseline omega-3 index. In addition, 6-month change in IL-12p40 and TNF- α showed a negative association with change in omega-3 index. In longitudinal analyses, the baseline and 6 month change in omega-3 index was negatively associated with VCAM-1 and TNF- α respectively at follow-up. Mediation analyses provided little evidence for mediating effects of plasma immune markers on the relationship between omega-3 FAs and clinical outcomes. On the other hand, 24 plasma proteins measured using MS showed association with omega-3 PUFAs. Pathway analysis revealed the complement and coagulation pathway as the main biological pathway to be associated with change in omega-3 PUFAs. However, The inflammatory protein complement C5 and protein S100A9 negatively mediated the relationship between change in omega-3 PUFAs and positive symptom severity, while C5 positively mediated the relationship between change in omega-3 and functional outcome. The relationship between change in omega-3 PUFAs and cognition was positively mediated through coagulation factor V and complement protein C1QB.

Discussion: Our results indicate a predominantly anti-inflammatory relationship of omega-3 FAs on plasma immune markers in CHR individuals, but this did not appear to convey clinical benefits at 6 month and 12 month follow-up. However, for the first time our findings provide evidence for a longitudinal association of omega-3 PUFAs with complement and coagulation protein changes in the blood. Further, the results suggest that an increase in omega-3 PUFAs decreases symptom severity and improves cognition in the CHR state through modulating effects of complement and coagulation proteins.

T78. EXAMINING PROTEIN MARKERS RELATED TO AGING AND PSYCHOSIS IN THE HUMAN CONNECTOME PROJECT FOR EARLY PSYCHOSIS

Johanna Seitz-Holland^{*1}, Moritz Haaf², Ana Paula Mendes-Silva³, Cornelius Berberich¹, Lauren Breithaupt⁴, Nora Penzel⁴, Sylvain Bouix⁵, Mike J. Coleman¹, Elana Bayla Kotle¹, Nicholas Kim¹, Omar John¹, Kathryn Eve Lewandowski⁶, Daphne Holt⁴, Matcheri S. Keshavan⁷, Dost Öngür⁶, Alan Breier⁸, Martha E. Shenton¹, Breno S. Diniz⁹, Steven E. Arnold⁴, Marek Kubicki¹

¹Brigham and Women's Hospital, Harvard Medical School, ²University Medical Center Hamburg, ³Department of Molecular Brain Science at the Centre for Addiction and Mental Health (CAMH), ⁴Massachusetts General Hospital, Harvard Medical School, ⁵École de technologie supérieure, ⁶McLean Hospital, Harvard Medical School, ⁷Beth Israel Deaconess Medical Center, Harvard Medical School, ⁸Indiana University School of Medicine, ⁹UConn Center on Aging

Background: Cumulative evidence suggests that the pathophysiology of psychosis involves an increased vulnerability to premature aging. However, this knowledge has not been translated into clinical practice due to the lack of understanding of the biological underpinnings and biomarkers. The present study addresses these challenges by examining aging-associated protein markers in the Human Connectome Project for Early Psychosis (HCP-EP). Specifically, we examined over 300 peripherally circulating plasma proteins associated with inflammation and cardiometabolic health. In addition, we calculated specific indices related to cell aging based on senescence-associated secretory phenotype (SASP) proteins.

Methods: The HCP-EP study was carried out across four recruiting and three scanning sites. It recruited individuals within five years of the onset of a DSM-5 diagnosis of psychosis (schizophrenia, schizophreniform disorder, schizoaffective disorder, psychosis not otherwise specified, delusional disorder, brief psychotic disorder, major depression with psychosis, or bipolar disorder with psychosis) as well as matched healthy individuals. Individuals underwent extensive testing, including NIH Toolbox, a structural and diffusion-weighted magnetic resonance imaging (MRI) scan, and a blood draw.

Protein expression levels from 380 proteins from 126 individuals were characterized by a commercial platform (O-link) for our primary analyses. Thirty-seven individuals were healthy individuals, 64 were diagnosed with non-affective psychosis, and 37 with affective psychosis. The groups were matched based on age and sex.

1. We ran data-driven analyses using all proteins to compare individuals with psychosis and healthy individuals while correcting for the effects of age and sex. In addition, we examined the main effects of sex and sex by diagnosis interactions. Last, we also split the psychosis group into individuals with non-affective psychosis versus affective psychosis.

2. We used principal component analyses to calculate a so-called SASP protein index based on a selected set of proteins that was used in previous studies performed in individuals with Alzheimer's disease and depression.

3. We used this SASP index to explore the association with clinical and cognitive variables.

Results: The data-driven analyses demonstrated differences between individuals with psychosis and healthy individuals in several proteins related to inflammation, cell communication, blood pressure, and cardio-metabolic regulation (e.g., Renin, Tumor necrosis

factor receptor superfamily member 9, Neuropilin 1, or Leptin; p LESS THAN 0.1 after FDR correction). In addition, we saw widespread sex effects but few sex-by-diagnoses interactions. The following steps will include the analyses of genetic pathways and networks to characterize these proteins further.

When calculating SASP indices, we found trend-level group differences between healthy individuals and individuals with psychosis (p LESS THAN .1). The effects were more pronounced in individuals with non-affective psychosis. As predicted, individuals with psychosis presented with higher SASP indices. Furthermore, the SASP indices in individuals with psychosis were significantly associated with age, sex, body mass index, and alcohol consumption (all p LESS THAN 0.05), but associations with cognition were only trend-level significant.

Discussion: The present study provides a first step toward developing novel protein-based biomarkers to identify individuals vulnerable to premature aging in psychosis. Aligning with previous studies on serious mental illness, we saw an increase in proteins related to inflammation and aging. The interaction of these variables with physical health parameters highlights the importance of studying schizophrenia as a whole-body disorder and might help in the understanding of comorbidity.

T79. SEX-DIFFERENCE IN THE EFFECT OF AN ADDITIONAL OXIDATIVE STRESS IN AN ANIMAL MODEL OF REDOX DYSREGULATION, RELEVANT FOR SCHIZOPHRENIA

Daphné Daphné Vorburger^{*1}, Basilio Giangreco², Enea Parietti², Pascal Steullet², Paul Klauser³, Daniella Dwir²

¹Center for Psychiatric Neuroscience, Lausanne University Hospital and the University of Lausanne, ²Center for Psychiatric Neuroscience, Department of Psychiatry, Lausanne University Hospital and the University of Lausanne, Lausanne, Switzerland, ³Center for Psychiatric Neuroscience and Service of Child and Adolescent Psychiatry, Department of Psychiatry, Lausanne University Hospital, Lausanne, Switzerland

Background: Schizophrenia (SZ) is a mental disorder with multifactorial origins including both genetic and environmental risk factors. Converging evidence points to impaired immune system and redox dysregulation as being central in the pathophysiology of SZ. More specifically, alterations in the glutathione (GSH) antioxidant system, the major antioxidant of the brain, has been associated with SZ. The alterations of these pathways, especially during early brain development affect the proper maturation of parvalbumin expressing interneurons (PVI) and their perineuronal net (PNN), producing a neuronal desynchronization, observed at the early stage of SZ. In this line of research, a transgenic mouse model of glutathione (GSH) deficiency (gclm-KO mice) displays increased oxidative stress (OxS) and a morphological phenotype relevant for SZ. The gclm-KO mice treated with GBR-12909 dihydrochloride (GBR), a dopamine reuptake inhibitor mimicking the increase in extracellular dopamine in the prefrontal cortex induced by a psychosocial stress, showed decreased PV/PNN, as well as increased microglia activation. Moreover, we have previously found that the matrix metalloproteinase 9 (MMP9) is involved in the PV/PNN alterations. This phenotype had been investigated in males only, but it may be different in females as the redox system is sensitive to sexual hormones. In this study, the effect of an additional OxS insult (GBR treatment) during early brain development was investigated on gclm-KO female mice.

Methods: To induce an additional oxidative stress, females gclm-KO and WT were subcutaneously injected with GBR for 10 days from postnatal day (PND) 10 to PND 20. Control animals were injected with PBS for the same duration. Then animals were sacrificed at PND 20 (N=4-5) or PND 90 (N=5-7) by intracardiac perfusion and coronal slices were performed. Immunohistochemistry was carried out to quantify PV-immunoreactive (IR) cell number and intensity, PNN-IR cell number and intensity, microglia number and morphology (intensity, area, number of branches) and MMP9-IR cell number. Images were acquired on a spinning disk microscope and analyzed on Imaris software. Two factors ANOVA tests were used to assess the statistical difference between genotype (gclm-KO vs WT) and treatment (GBR vs PBS).

Results: Firstly, PVI and PNN were not affected in female KO as compared to female WT mice, even after GBR injection, at both PND20 and PND90. However, a significant decrease of MMP9-IR was found in the KO mice compared to WT, without any effect of the GBR injection, at both time-points. In addition and irrespective of GBR treatment, an increase in number and activation of microglia was observed in KO compared to WT.

Discussion: We found no alterations in PV/PNN, a decrease in MMP9-IR and an increase in microglia activation in females gclm-KO at both PND20 and 90. Interestingly, no effect was observed for the GBR treatment on these outcomes. Thus, our results support a gender-specific effect of the genetic vulnerability to redox dysregulation in the gclm-KO, but also of the additional OxS induced by GBR. It is therefore essential to better understand the sex-specific mechanisms in order to optimize individualized treatments. Additional studies are needed to further explore the sex difference in gclm-KO mice, regarding sex-specificity in SZ.

T80. THE LINGUISTIC PROFILES OF PATIENTS DIAGNOSED WITH SCHIZOPHRENIA BASED ON NATURAL LANGUAGE PROCESSING.

Hironobu Nakamura*¹, Yoshinobu Kano², Genichi Sugihara³, Yusei Yamaguchi³, Masaaki Shimizu³, Mari Iizuka⁴, Saaya Tashiro⁵, Momoko Kitazawa⁴, Ayako Sento⁴, Hidehiko Takahashi³, Taishiro Kishimoto⁴

¹Tokyo Medical and Dental University, ²Faculty of Informatics, Shizuoka University, Shizuoka, Japan, ³Department of Psychiatry and Behavioral Sciences, Graduate School of Medical and Dental Sciences, Tokyo Medical and Dental University, Tokyo, Japan, ⁴Department of Neuropsychiatry, Keio University School of Medicine, Tokyo, Japan, ⁵Tokyo Medical and Dental University School of Medicine, Tokyo, Japan,

Background: Linguistic characteristics in the speech of schizophrenia patients, in relation to formal thought disorder (FTD), have been studied extensively. Recent studies have utilized natural language processing (NLP) to examine these features, yielding effective machine learning models. However, these studies are limited by small sample sizes, a narrow range of linguistic features and methods, and a lack of task variety. Therefore, we conducted a comprehensive analysis of Japanese speech data from schizophrenia patients and healthy controls, using three NLP tasks across extensive speech datasets, to identify disease-specific linguistic features. Our study included a large dataset of 102 schizophrenia patients and 91 healthy controls.

Methods: This study is a part of the Understanding psychiatric illness through natural language processing (UNDERPIN) project. Our sample included 102 schizophrenia patients and 91 healthy controls, derived from the UNDERPIN dataset. Participants were recruited

from seven Japanese hospitals and three outpatient clinics. Inclusion criteria included inpatients and outpatients aged 20 years or older, diagnosed with schizophrenia according to DSM-5 or ICD-11 criteria. Healthy subjects were individuals with no history of psychiatric disorders who volunteered to participate in the study and were at least 20 years old at the time of consent. Participants were required to attend two to five visits over the course of the study. The Positive and Negative Syndrome Scale (PANSS) was used as the clinical rating scale. Participants underwent 30-60 minute interviews, including free conversation, picture description, and storytelling tasks. Speech data were transcribed into text. Transcribed text was used to isolate patient speech and form the corpus for NLP analysis. NLP methods analyzed the corpus, identifying approximately eighty linguistic features at morphological, syntactic, and semantic levels, including word usage probabilities and named entities. GiNZA (spaCy Japanese-language model) was used for morphological and syntactic analysis and named entity recognition. Word2Vec and sentenceBERT were employed for semantic similarity, and N-gram analysis calculated word usage probability. Features were normalized by total morpheme count where necessary. Principal component analysis (PCA) was used to identify feature relationships and for dimension reduction. Generalized estimating equations (GEEs) were used for statistical analysis of the hierarchical data.

Results: Significant statistical differences were observed between the groups in the linguistic features such as total number of morphemes and content words, ratio of personal named entity, mean and variance of word similarity, variance of sentence similarity and so on. Features like total number of morphemes and variance of sentence similarity had a negative correlation with PANSS negative syndrome scales, whereas ratio of personal named entity had a positive correlation with PANSS positive symptom scales.

Discussion: This study features the largest sample size yet for the quantitative NLP-based analysis of linguistic abnormalities in schizophrenia. Covering crucial linguistic areas like morphology, syntax, semantics, and probability, it utilizes an extensive range of Japanese linguistic features. Features like sentence similarity variance were quantitatively identified only after analyzing patients' entire utterances, distinguishing this approach from traditional methods focused on local pathological findings.

T81. SYNTACTIC NETWORK ANALYSIS IN FIRST-EPISODE PSYCHOSIS: A GENERALIZABILITY STUDY

Silvia Ciampelli¹, Janna de Boer², Alban Voppel³, Hugo Corona-Hernández², Sanne Koops², Natalia Mota⁴, Iris Sommer²

¹University of Groningen, University Medical Center Groningen, ²Department of Biomedical Sciences of Cells and Systems, University of Groningen, University Medical Center Groningen, Groningen, The Netherlands, ³Douglas Mental Health Institute, McGill university, Montreal, QC, Canada, ⁴Institute of Psychiatry, Federal University of Rio de Janeiro, Rio de Janeiro, Brazil

Background: Natural Language Processing (NLP) provides tools for modelling and quantifying language deviations associated with psychosis. However, previous research has highlighted limitations in the generalizability of NLP measures, hindering their implementation in clinical settings. Here, we evaluated the generalizability of a previously developed NLP method to quantify syntactic relations in speech from patients with psychosis. Cross-linguistic (Dutch vs. Portuguese), domain (chronic vs. first-episode psychosis), and

methodological generalizability (semi-structured interview vs. picture description) were evaluated.

Methods: In the present Portuguese sample, speech was collected from 27 individuals who experienced a first episode of psychosis (FEP) and 37 controls using a picture description task. In our previous Dutch sample, speech from 63 patients with developed schizophrenia and 63 controls was collected using a semi-structured interview. Symptom severity was measured in patients with the Positive and Negative Syndrome Scale (PANSS).

Markers of syntactic complexity were obtained by quantifying structural properties of syntax trees with 11 network analysis measures: Leaf fraction, Node count, Diameter, Efficiency, Stress centrality, Leaf count, Degree, Betweenness centrality, LCC node count, LCC diameter, LCC degree. Syntax trees were obtained with LX Parser, a computational parser for the Portuguese language.

Two multivariate analyses of covariance (MANCOVA) were conducted to compare network measures between groups. The first included group and sex as factors, with age as a covariate; the second added education as a covariate.

Associations between network measures, PANSS, and chlorpromazine equivalent dose were examined using Bivariate Pearson Correlations. A random forest (RF) algorithm, trained with 10-fold cross-validation, classified participants into FEP or control based on syntactic measures.

Results: FEP patients and controls differed in age and education (both $p < .001$). Group and age had a significant effect on syntactic network measures ($(F(11,42) = 2.418, \text{Pillai's trace} = 0.388, p = .020)$, $(F(11,42) = 2.272, \text{Pillai's trace} = 0.373, p = 0.028)$, respectively). No effect of sex or interaction between sex and group was found (both $p > .05$). When education was added in the MANCOVA as a covariate, the effects of group and age on syntactic measures were not significant (all $p > .05$). When trained on syntactic network measures, the RF had an accuracy of 81%, with 85% sensitivity (68%–94% confidence interval) and 78% specificity (63%–89% confidence interval). The Area Under the Curve was 0.82 with confidence intervals 0.71–0.93. No association between psychotic symptoms, medication, and syntactic measures was found (all $p > .05$).

Discussion: This study shows that our previously developed NLP method to quantify the complexity of syntactic relations, is generalizable across languages (Dutch vs. Portuguese), illness stages (chronic vs. first-episode psychosis), and tasks (semi-structured interview vs. picture description). Significant differences in nearly all syntactic complexity measures were observed between FEP patients and healthy individuals. Using syntactic measures, a RF classified FEP patients vs. controls with 81% cross-validated accuracy.

When education was considered as a covariate, the effects of group and age on syntactic measures were not significant. This is likely due to differences in education between groups, making it challenging to disentangle the influence of diagnosis and education on syntax in this sample. Further research is needed to explore the relationship between formal education and syntactic development in individuals with psychosis.

T82. EXAMINING RETINAL VASCULAR FRACTIONAL DIMENSION AS AN ENDOPHENOTYPIC MARKER FOR SCHIZOPHRENIA

Veena R^{*1}, Anantha Padmanabha², Abhishek Appaji³, Suma H N³, Vijay Kumar², Naren P Rao⁴

¹National Institute of Mental Health and Neuro Sciences (NIMHANS), ²National Institute of mental health and neuro sciences (NIMHANS), ³BMS college of Engineering, ⁴Manoshanti mental health care center

Background: Recent research has emphasized on identifying endophenotypic markers as objective tools in psychiatric diagnoses. Vascular theories of schizophrenia propose microvascular brain abnormalities during development, impacting the functionality of brain. Given the shared embryological origin between the retina and brain, the retina serves as a window to observe brain abnormalities in-vivo. Retinal vascular fractal dimension indicates vascular branching complexity, helps understand developmental vascular abnormalities of the brain and is a potential endophenotypic marker for schizophrenia.

Our study aimed to examine the retinal vascular fractal dimension in individuals with schizophrenia, their unaffected first-degree relatives and in healthy controls.

Methods: We recruited 49 individuals with schizophrenia, 49 unaffected first-degree relatives and 101 healthy volunteers. Non-mydratic color fundus images of both the left and right eye were acquired using 3nethra classic Fundus Camera. Retinal vascular fractal dimension was calculated using the box-counting method (software used: MATLAB). Means of fractal dimension were compared across the three groups using ANOVA. Co-variates of age, sex and body mass index were accounted for using ANCOVA. The calculation of fractal dimension was computerized and rater bias did not confound the analysis.

Results: The groups were comparable across age ($p = 0.268$) and sex ($p = 0.830$). The individuals with schizophrenia had statistically significantly reduced retinal vascular fractal dimension (mean - 1.4732, SD - 0.0293) as compared to the healthy volunteers (mean-1.4874, SD - 0.0261) with p-value of 0.008, even after adjusting for the confounders (age, sex and BMI) with p-value of 0.009. There was no significant difference between the retinal vascular fractal dimension of individuals with schizophrenia and their first-degree relatives (mean - 1.4769, SD - 0.0261), with p-value of 0.777 (after adjusting for covariates, p-value of 0.926). There was trend towards significance noted between the retinal vascular fractal dimension values of first degree relatives of individuals with schizophrenia and healthy volunteers, with a p-value of 0.065 (after adjusting for confounders, p-value of 0.248). Individuals with schizophrenia had a negative correlation between the duration of schizophrenia and the retinal vascular fractal dimension.

Discussion: Our study suggested that the degree of complexity of retinal vascular branching patterns in unaffected first-degree relatives of individuals with schizophrenia was between the values for healthy populations and individuals with schizophrenia, with the latter having significantly reduced complexity of vascular branching pattern. This is suggestive of developmental abnormalities in the brain micro-vasculature associated with schizophrenia, providing further evidence to the ongoing research on the vascular etiology of schizophrenia. As the retina is easily accessible through fundus photography, the retinal vascular fractal dimension could serve as a proxy indicator for neuro-vascular changes associated with schizophrenia. Further studies are required to confirm the findings in a larger sample size and determine the quantitative cut-off values for using the retinal vascular fractal dimension as a biomarker for identifying individuals at risk for schizophrenia and aid in early intervention.

T83. RETINAL STRUCTURE AND ITS RELATIONSHIP WITH PREMORBID AND CLINICAL VARIABLES IN YOUNG SPANISH PATIENTS WITH EARLY-COURSE SCHIZOPHRENIA SPECTRUM DISORDERS

Neurosciences Institute. Hospital Clínic of Barcelona. University of Barcelona. IDIBAPS, CIBERSAM*

Background: Several studies have suggested that the retina structure is affected in schizophrenia spectrum disorders (SSD) (González-Díaz et al., 2022). This study aims to validate the hypothesis that individuals diagnosed with Schizophrenia Spectrum Disorders (SSD) within five years exhibit distinct retinal structures compared to matched healthy controls. These structural differences are expected to correlate with various clinical and course-related variables.

Methods: Employing a cross-sectional design, individuals diagnosed with SSD were compared to age- and gender-matched healthy controls (HCs). Participants with pre-existing retinal/ocular pathology, a history of craniocerebral or ocular trauma, previous ocular surgery, diabetes, or high blood pressure were excluded. The Peripapillary Retinal Nerve Fiber Layer (pRNFL), Macular Ganglion Cell Layer and Inner Plexiform Layer Thickness (GCL+IPL), Macular Volume and Macular Thickness were assessed with Optical Coherence Tomography. Data from each eye (i.e., right eye [OD] and left eye [OS]) were analyzed independently, and both global and quadrant information were assessed. Premorbid, Clinical, Functional, and Course-related data were assessed with several scales, including CGI (Guy, 1976), PANSS (Kay, 1987), FAST (Rosa, 2007), and PAS (Canoon-Spoor, 1982).

Results: Two HCs were included for each case to increase the power of the study (n=18 vs 36), with a similar proportion of genders in each group (n male cases: 10 (55.6%) vs. n male HCs: 20 (55.6%); $p=0.61$) and comparable age (Cases Mean age in years (SD): 30.17 (1.36) vs. Cases Mean age in years (SD): 30.11 (0.96); $p=0.96$). Consistent with existing literature, the macula was thinner in all quadrants in cases. Surprisingly, a statistically significant thickening in pRNFL was observed in SSD patients compared to HCs (OD: Mean (SD): 106.89 μm (9.64) vs. 100.11 μm (8.10), $t=2.720$, $p=0.009$; OS: 04.89 μm (9.00) vs. 99.08 μm (8.21), $t=2.373$, $p=0.021$). A mirrored pattern was observed in the GCL+IPL, with a thinning in the inner nasal and thickening in the outer nasal quadrant in the right eye (Inner Nasal: 93.00 μm (5.87) vs. 99.72 μm (7.72), $t=-3.248$, $p=0.002$; Outer Nasal (71.56 μm (6.20) vs. 67.83 μm (5.16), $t=2.335$, $p=0.023$) and a thinning in the inner temporal and thickening in the outer temporal quadrant in the left eye (Inner Temporal: 86.89 μm (6.12) vs. 93.19 μm (8.25), $t=-2.867$, $p=0.006$; Outer Temporal: 73.28 μm (6.51) vs. 69.08 μm (5.57), $t=2.467$, $p=0.017$). A negative correlation was found between macular measures and premorbid adjustment (OD: Macula Total Volume: $r=-0.488$, $p=0.040$; OS: Macula Thickness Outer Temporal Quadrant: $r=-0.476$, $p=0.046$) and symptom severity (OD: Macula Total Volume: $r=-0.476$, $p=0.046$). Untreated psychosis duration did not correlate with any retinal measure.

Discussion: Previous studies in the Spanish population have yielded analogous paradoxical findings, suggesting the absence of pRNFL thinning in recent psychotic episodes and implicating potential localized retinal inflammation. Our results suggest characteristics resembling papilledema, indicating possible retinal inflammation at the first stages of the illness in young patients. Alternatively, it raises the possibility of past generalized retinal edema resolving initially in the macula yet persisting in the optic disc. A previous meta-analysis from our group suggested that the macula would be better indicators of retinal thinning in patients with SSD (Gonzalez-Diaz et al., 2022). The findings in GCL+IPL align with the retrograde transsynaptic degeneration phenomenon (RTSD), in which the potential loss of occipital cortical tissue leads to the death of cell bodies in the GCL (Adámek et al., 2022; Lai et al., 2020). Several significant correlations between clinical variables and retina structure in a homogeneous sample of early-course SSD suggest that the macula might aid in identifying the most symptomatic patients, as it has been proposed in previous studies. However, to the best of our knowledge this is the first study to explore premorbid variables and its relationship with retinal measures. These findings underscore the complexity of retinal alterations in early-stage SSD, highlighting unexpected pRNFL thickening and nuanced changes in ganglion cell layers.

T84. ESCAPE GAME FOR MENTAL HEALTH

Trang Nu Thuy TON^{*1}, Marion Feron²

¹none, ²Service CRISALID CHI Clermont de l'Oise

Background: Half of all mental difficulties and disorders begin between the ages of 15 and 25.

JENESIS, an early intervention mental health service in a predominantly rural and landlocked area (Oise department, Hauts-de-France region, France), offers a fast-track approach to adolescents and young adults aged between 17 and 25 with a variety of mental health problems that have been evolving for less than 2 years, associated with a lasting functional impact of more than 1 month and less than 2 years, or with an emerging mental health problem.

The support offered is graduated and varied in nature (case-management, cognitive remediation, study support, psycho-education, integrative therapies) and mode of delivery (face-to-face or distance learning).

But the journey can be hampered by fear of stigmatization, lack of commitment and mood-dependent behaviors.

The idea is to use the game as support, such as an escape game, as a non-stigmatizing gateway to an early mental health intervention pathway (high-risk or ultra-high-risk clinical situations).

Methods: The escape game approach combines a playful experience with a multisensory educational approach to promote the appropriation of mental health awareness, empathy and mutual aid, and appears to be well suited to the target population.

It could meet the need for motivation and commitment, the development of psycho-social skills to reinforce empowerment, the prevention and management of crisis and emergency situations, and the fight against stigmatization.

The game is seen as a learning space where knowledge and skills are experimented with freely, and as a mediator for the transfer of skills.

Results: To meet this objective, JENESIS has linked up with SimUSanté.

This is a center for active pedagogy and simulation in healthcare, developed by the CHU Amiens Picardie in partnership with the Université Picardie Jules Verne. It helps to meet the training needs of all those involved in healthcare, but also of the general public. Their work has focused on escape games: Janus' Traps (raising awareness of depression among students); Lord Hades' Secrets (cyber security); and Ludantibio (the correct use of antibiotics).

Mobilizing a multi-professional, multi-expertise team (psychiatry, clinical psychology, educational sciences, edutainment, pedagogical engineering, technical support....) to co-construct the puzzles could facilitate primary and secondary prevention actions (substance abuse, self-injurious behavior) and provide skills and reflexive abilities.

A trained multi-professional team, including a peer health mediator, will lead the activity.

At the end, a supervised psychological debriefing (neuropsychologist, psychiatrist) will be carried out to initiate metacognitive work and collect verbatims.

Discussion: The mental health escape game will be proposed to the people concerned at the beginning of 2024.

The target population of people concerned by a clinical situation at risk will be 40 participants per year.

An ongoing qualitative and quantitative evaluation procedure will be undertaken in terms of acceptability, satisfaction, textual analysis of verbatims collected and impact criteria on secondary prevention (psycho-social skills, psychological flexibility, sense of self-efficacy, self-monitoring skills and coping strategies).

In a second phase, after training, a portable version could be proposed for national distribution.

T85. AN EXPLORATION OF CANNABIS USE AND SUICIDAL THOUGHTS AND BEHAVIORS AMONG ADOLESCENTS WITH HALLUCINATIONS

Elizabeth Thompson*¹, Sarah Thomas¹, Danae Papadea², Jennifer Wolff¹

¹*Alpert Medical School, Brown University*, ²*Rhode Island Hospital*

Background: Early psychosis is characterized as a high-risk period for suicidal thoughts and behaviors, especially during initial presentation for psychiatric care. Cannabis use is markedly prevalent among youth with psychosis-spectrum symptoms and associated with both acute and long-term symptomatology. Although adolescent substance use is considered a significant risk factor for suicidal ideation and attempts, the relations between concurrent use of cannabis and suicidality in youth with psychosis-spectrum symptoms is unclear. The present study aimed to explore the associations between acute suicidality, i.e., suicidal attempt within 30 days before hospitalization and suicidal ideation, concurrent cannabis use, and hallucinations among psychiatrically hospitalized adolescents. We hypothesized that current hallucinations and cannabis use would be associated with suicidal ideation and past 30-day attempt, and the relation between current hallucinations and suicide outcomes would be moderated by past 30-day cannabis use.

Methods: Upon hospital admission, teens completed self-report measures of suicidal ideation (Suicidal Ideation Questionnaire – Junior; score range 0-90), suicidal attempts, cannabis use, depressive symptoms (PROMIS Short Form; score range 8-40), and demographics, including age and sex at birth. Teens were also asked whether they experienced hallucinations (auditory or visual) within the past 30 days (yes/no) as part of a brief diagnostic interview.

Results: The full sample includes 368 teens (Mage = 14.97; 65% female at birth); 109 teens (29.6%) endorsed current hallucinations and 99 (26.9%) endorsed past 30-day cannabis use. Correlations indicated that endorsement of current hallucinations was associated with suicidal ideation ($r = .30$, $p < .001$) and depression ($r = .25$, $p < .001$), but not past 30-day suicide attempt or past 30-day cannabis use. Depressive symptoms were also positively correlated with suicidal ideation ($r = .72$, $p < .001$) and past 30-day suicide attempt ($r = .22$, $p = .001$). Surprisingly, past 30-day cannabis use was not associated with any variables besides age ($r = .25$, $p < .001$). Linear regression explored the association between current hallucinations and suicidal ideation. Suicidal ideation was statistically predicted by the presence of current hallucinations ($R^2 = .08$; $\beta = 0.28$, $t = 4.46$, $p < .001$). This effect remained significant ($\beta = 0.10$, $t = 2.16$, $p = .032$) when controlling for the effects of depressive symptoms ($\beta = 0.65$, $t = 13.52$, $p < .001$) and sex ($\beta = 0.17$, $t = 3.71$, $p < .001$), as well as the non-significant effects of past 30-day cannabis use and age ($R^2 = .56$). The relation between hallucinations and suicidal ideation was not moderated by past 30-day cannabis use. Moderation analyses revealed trend-level evidence of an interaction between current hallucinations and past 30-day cannabis use in the statistical prediction of past-30-day suicide attempt. For adolescents who used cannabis in the past 30 days, current hallucinations were associated with past-month suicide attempt at a trend level ($B = 0.98$, $z = 1.90$, $p < .06$). For adolescents who denied past-month cannabis use, there was no significant association between current hallucinations and past 30-day suicide attempt.

Discussion: Findings suggest that recent cannabis use may be associated with increased imminent risk for suicide attempt among youth with hallucinations. Further analyses for this presentation will include exploration of other characteristics of cannabis use (age of onset, motivations, and forms of intake) and their relation to hallucinations and suicide outcomes. Implications for treatment will be discussed.

T86. THE ASSOCIATION OF HYPERPROLACTINEMIA EXPOSURE WITH HEIGHT GROWTH AND TANNER STAGE IN CHILDREN AND ADOLESCENTS RECEIVING TREATMENT WITH ANTIPSYCHOTIC MEDICATION

Morten Thorsen*¹, Marlene Briciet Lauritsen², Anne Katrine Pagsberg³, Marianne Skovsager Andersen⁴, Ulla Schierup Nielsen⁵

¹*Research Unit for Child and Adolescent Psychiatry, Aalborg University Hospital,* ²*Aalborg University Hospital, Research Unit for Child and Adolescent Psychiatry, North Denmark Region,* ³*Child and Adolescent Mental Health Centre, Mental Health Services Capital Region of Denmark,* ⁴*Department of Endocrinology, Odense University Hospital,* ⁵*Research Unit for Child and Adolescent Psychiatry, Aalborg University Hospital,*

Background: Antipsychotic-induced hyperprolactinemia (AIH) is a common challenge during treatment of children and adolescents with antipsychotic medication. Children with hyperprolactinemia caused by prolactinoma may experience growth arrest and pubertal delay. However, the consequences of AIH on height growth and pubertal development is not known. This knowledge is essential, given that children and adolescents are treated with antipsychotics during an essential period of life for this growth and development. In this study we therefore aimed to investigate whether AIH is associated to disturbances in height growth and pubertal development.

Methods: In this retrospective cohort study, we included a population of children and adolescents aged 7-18 years, in treatment with antipsychotic medication. By using past prolactin measurements, we calculated total prolactin exposure during antipsychotic treatment was calculated as the area under the curve of prolactin level versus time. We investigated the association between total prolactin exposure and current height (adjusted for height of parents) and Tanner using regression analysis. Prolactin measurements that were assessed before estimated start of puberty were excluded from Tanner stage analysis.

Results: 90 patients were included. Sex distribution was 47/43 (male/female). Mean age at start of antipsychotic treatment was 13.9 years [Range: 7.9; 18.1]. Mean duration of antipsychotic treatment was 2.38 years [Range: 2.23; 9.82]. No association between prolactin exposure and height development was found (0.23 cm/1000 mIU prolactin, 95% CI: -0.0499; 0.5166, p=0.106). No association between prolactin exposure and pubertal development was found.

Discussion: This study did not find any association between AIH and respectively height growth and pubertal development. These are however preliminary data, where factors such as BMI, estradiol containing oral contraceptives and patients who had already reached target height at start of treatment has not been adjusted for. These data will be available at the conference.

T87. PSYCHOTIC EXPERIENCES AND RISK OF SUICIDALITY IN ADOLESCENTS: RESULTS BASED ON LONGITUDINAL DATA FROM A LARGE NATIONWIDE BIRTH COHORT

Stephen Austin*¹, Katrine Ineson², Merete Nordentoft³, Trine Madsen²

¹*Psychiatric Research Unit, Region Zealand Psychiatry,* ²*Danish Research Institute of Suicide Prevention, Copenhagen Research Center for Mental Health Mental Health Center Copenhagen,* ³*CORE - Copenhagen Research Centre for Mental Health, Copenhagen University Hospital*

Background: Psychotic experiences (PE) in childhood have been linked to suicidal ideation (SI) and suicide attempt (SA), however often in cross-sectional studies. Longitudinal research based on large samples with possibilities for confounder adjustments have been called for in a recent systematic review to better establish the association between childhood PE and suicidality. The aim of this study was to examine the association of PE with suicidality in The Danish National Birth Cohort (DNBC).

Methods: The study cohort included adolescents who participated at both the 11-year-follow-up and the 18-year-follow up of DNBC. The 11-year-follow-up included seven questions on PE and social environmental-, behavioural- as well as mental well-being factors. At the 18-year-follow-up the adolescents were asked about lifetime SI and SA. Data from DNBC were linked with individual level data from Danish Registers enabling further information on hospital contacts for SA and a range of parental socio-demographic variables to also be included. Associations were estimated using multinomial logistic regression models and adjusted for a wide range of social, behavioural, and mental well-being factors. Further, to account for sample selection, we applied inverse probability weighting, based on data from the entire national birth-cohort born in the same period as the DNBC-birth cohort participants.

Results: Out of the 27,657 participants 3,235 (11.7%) reported having had at least one psychotic experience at DNBC-11. At DNBC-18 this number was 2991 (11.2%). Those young people that had reported at least one psychotic experience at age 11 had an increased risk of suicidal ideation (OR=1.91, 95% CI 1.76-2.08) and suicide attempt (OR=3.37, 95% CI 2.81-4.04) at 18 years compared to those that had not reported a psychotic experience. The greater number of concurrent psychotic experiences reported, the greater the increased the risk of suicidality. For those youths that reported a psychotic experience at both 11 and 18 years there was markedly higher risk of both suicide ideation (OR=4.00, 95% CI 3.41-4.70) and suicide attempt OR=12.92, 95% CI 10.07-16.58) compared with those people that reported no PE's. Analysis of content of auditory hallucinations and suicidality revealed that those young people that reported voices that called their name or commented had an increased risk of suicide ideation (OR 3.80 95% CI 3.25-4.46) and (OR 12.84 95% CI 10.14-16.26) and suicide attempt (OR= 4.74, 95% CI 4.02-5.58) and (OR=20.03, 95% CI 16.02-25.04) respectively, compared to those that did not report auditory hallucinations. Young people that reported auditory hallucinations with negative comments had an increased risk of suicide ideation (OR=8.89, 95% CI 6.49-12.17) and a marked greater risk of suicide attempt (OR=66.15, 95%, CI 6.78-93.53) compared to those youths that did not report auditory hallucinations.

Discussion: This large longitudinal study found a significant increased risk of suicide ideation and suicide attempt in young people reporting psychotic experiences. The greatest risk of suicide attempt was associated with young people reporting auditory hallucinations with negative comments. Whilst acknowledging the limitations of self-report measures, the findings indicate the longitudinal association between childhood psychotic experiences and risk of suicidality during teenage life, even after extensive confounder adjustments. Implications of these results will be discussed.

T88. IT'S ALL ABOUT THE TIMING: SLEEP SPINDLE CLUSTERING IN INDIVIDUALS WITH YOUNG SCHIZOPHRENIA COMPARED TO HEALTHY CONTROLS

Maria E. Dimitriadis*¹, Alejandro Osorio-Forero², Susanne Walitza³, Reto Huber¹, Miriam Gerstenberg¹

¹*Psychiatric University Hospital Zurich, Kinderspital Zurich, University of Zurich,*

²*Netherlands Institute for Neuroscience,* ³*Psychiatric University Hospital Zurich, University of Zurich*

Background: Reductions in sleep spindles, a major electrophysiological oscillation during sleep, have been identified in patients with schizophrenia (SZ). Recently, sleep spindle clustering on a 50-second time scale has been shown to tightly regulate aspects of sleep-dependent memory consolidation and arousal driven by locus coeruleus activity in the healthy, adult population. As memory impairments, difficulties maintaining sleep, and locus coeruleus dysfunction are commonly reported in SZ, it is hypothesized that individuals with the disorder have irregular timing of sleep spindles during NREM sleep. Thus, we are assessing the presence and strength of sleep spindle clustering on a 50-second time scale in individuals with Early-Onset Schizophrenia (EOS) and healthy controls (HC).

Methods: Sleep electroencephalic data of patients with EOS (N=11, 16.38 +/- 1.43 years old; 36.4% female) and age- and sex-matched healthy controls (HC; N=11, 16.50 +/- 1.69 years old; 36.4% female) are analyzed.

Results: Preliminary results indicate that sleep spindles cluster on a 50-second time scale in both groups. The strength of the clustering comparing patients with EOS to HC is currently being investigated.

Discussion: Sleep spindle clustering on a 50-second time scale is detectable in children and adolescent populations. Early findings suggest that young patients with SZ may have differences in the timing of sleep spindle clustering. Next steps investigating the relationship between sleep spindle clustering, working memory, and arousal are underway.

T89. SEX-SPECIFIC INTERACTIONS BETWEEN STRESS AXIS AND REDOX BALANCE ARE ASSOCIATED WITH INTERNALIZING SYMPTOMS AND BRAIN WHITE MATTER MICROSTRUCTURE IN ADOLESCENTS

Zoé Schilliger*¹, Yasser Alemán-Gómez², Zeynep Celen³, Ben Meuleman³, Pascal Steullet¹, Kim Do¹, Philippe Conus⁴, Arnaud Merglen⁵, Camille Piguet³, Daniella Dwir¹, Paul Klauser¹

¹*Center for Psychiatric Neurosciences, Lausanne University Hospital,* ²*Connectomics Lab, Department of Radiology, Lausanne University Hospital and University of Lausanne,*

³*Department of Psychiatry, Faculty of Medicine, University of Geneva,* ⁴*Service of General Psychiatry, Department of Psychiatry, Lausanne University Hospital,* ⁵*Division of General Pediatrics, Geneva University Hospitals and Faculty of Medicine, University of Geneva,*

Background: While the prevalence of schizophrenia is comparable between sexes, women show differences in age of onset (3-5 years later than men) and symptoms, with more affective disturbances and depressed mood. Schizophrenia onset typically occurs during early adulthood but is frequently preceded by internalizing symptoms (depressed mood, anxiety) during adolescence. Incidentally, the adolescent period is critical for the maturation of brain networks of emotion and mood regulation and witnesses a peak incidence in internalizing disorders, especially in females. Altered Hypothalamic-Pituitary-Adrenal (HPA)-axis function and pro-oxidant/antioxidant imbalance have both been associated with internalizing disorders and schizophrenia and may represent critical factors for the development of

emotional and affective regulation during adolescence. Furthermore, glucocorticoids and impaired glutathione (GSH) antioxidant balance have been related to brain white matter alterations, which are commonly observed in both affective disorders and schizophrenia. However, sex-specific interactions between these biological factors, internalizing symptoms and brain white matter maturation remain unexplored.

Methods: Adolescents aged 13 to 15 from the general population ($n = 68$, 57% females) provided self-report of internalizing symptoms (STAI-trait and BDI), blood samples and underwent diffusion-weighted MRI. Peripheral glutathione-cycle redox homeostasis (i.e., antioxidant activity of the GSH-peroxidase (GPx) and reductase (Gred)) was measured in red blood cells and cortisol, its precursor 11-deoxycortisol and their ratio (cortisol/11-deoxycortisol ratio) were measured by LC-MS in the serum. Using linear regressions, we investigated sex-specific associations between blood markers, internalizing symptoms and indices of brain white matter microstructure (generalized fractional anisotropy (gFA)).

Results: Female adolescents displayed higher levels of trait anxiety and depressive symptoms, GPx activity and cortisol/11-deoxycortisol ratio than males. There was a strong correlation between GPx and Gred activities in females only. The cortisol/11-deoxycortisol ratio, related to HPA-axis activity, was associated with internalizing symptoms in both sexes, whereas GPx activity was associated with internalizing symptoms in females specifically. The cortisol/11-deoxycortisol ratio mediated sex-differences in internalizing symptoms and the association between anxiety and GPx activity in females specifically. In females, GPx activity was positively associated with generalized fractional anisotropy in widespread white matter brain regions.

Discussion: In summary, we found that higher levels of internalizing symptoms in female adolescents than in males relate to sex-differences in HPA-axis function. In females, our results suggest an important interplay between HPA-axis function and GSH-homeostasis, a parameter strongly associated with more advanced patterns of brain white matter maturation.

T90. CHILDHOOD ADVERSITY AND INCIDENT PSYCHOTIC EXPERIENCES IN EARLY ADULTHOOD: COGNITIVE AND PSYCHOPATHOLOGICAL MEDIATORS

Andrea Cortes Hidalgo^{*1}, Gemma Hammerton¹, Jon Heron¹, Koen Bolhuis², Paul Madley-Dowd¹, Henning Tiemeier³, Marinus van IJzendoorn⁴, Stanley Zammit¹, Hannah Jones¹

¹University of Bristol, ²Erasmus Medical Center Sophia Children's Hospital, Rotterdam, ³Harvard T.H. Chan School of Public Health, ⁴UCL

Background: Childhood adversity is often described as a potential cause of incident psychotic experiences, but the underlying mechanisms are not well understood. We aimed to examine the mediating role of cognitive and psychopathological factors in the relation between childhood adversity and incident psychotic experiences in early adulthood.

Methods: We analysed data from the Avon Longitudinal Study of Parents and Children, a large population-based cohort study. Childhood adversity was measured prospectively from birth to age 11 years, mediators (anxiety, depression, external locus of control (LoC), negative symptoms) were assessed at approximately 16 years of age, and incident psychotic experiences were assessed at ages 18 and 24 years. Mediation was examined via the counterfactual g-computation formula.

Results: In total, 7% of participants had incident suspected or definite psychotic experiences in early adulthood. Childhood adversity was related to more incident psychotic experiences

(ORadjusted = 1.34, 95% CI = 1.21; 1.49), and this association was partially mediated via all mediators examined (proportion mediated: 19.9%). In separate analyses for each mediator, anxiety, depression, external LoC, and negative symptoms were all found to mediate the link between adversity and incident psychotic experiences. Accounting for potential confounders did not modify our results.

Discussion: Our study shows that cognitive biases as well as mood symptomatology may be on the causal pathway between early-life adversity and the development of psychotic experiences. Future studies should determine which mediating factors are most easily modifiable and most likely to reduce the risk of developing psychotic experiences.

T91. A SYSTEMATIC REVIEW OF COGNITIVE REMEDIATION FOR ADOLESCENTS WITH PSYCHIATRIC DISORDERS: METHODOLOGICAL CONSIDERATIONS AND RECOMMENDATIONS FOR FUTURE RESEARCH

Caroline Cellard^{*1}, Audrey Cayouette¹, Matteo Cella², Kelly Allott³, Frederic Haesebaert⁴, Caroline East-Richard¹

¹Université Laval, ²Institute of Psychiatry, Psychology and Neuroscience King's College London, ³Orygen and Centre for Youth Mental Health, The University of Melbourne, ⁴PSYR2 Team, INSERM U1028, CNRS UMR5292, Lyon Neuroscience Research Center, Université Claude Bernard Lyon

Background: The clinical and functional effects of cognitive remediation have been widely documented in adults with psychiatric disorders. However, the specific effects in adolescents with psychiatric disorders remain poorly documented. The purpose of this review and meta-analysis is twofold: 1) to determine the effects of cognitive remediation on cognition for adolescents with psychiatric disorders and 2) to evaluate the methodological quality of studies that investigate the effects of cognitive remediation among adolescents with psychiatric disorders – such as schizophrenia spectrum disorders.

Methods: A systematic review and meta-analysis were conducted with randomized controlled trials on cognitive remediation with psychiatric adolescent population. Specifically, searches were conducted in Pubmed, PsycInfo and Embase for studies pertaining to cognitive remediation therapy (CRT) effects on cognition, social functioning, and clinical symptoms. Methodological quality was assessed using the Clinical Trials Assessment Measure (CTAM).

Results: Fifteen studies (N=15) were included in the review, with 12 independent samples (k=12, 641 participants). Participants had various psychiatric disorders (e.g., psychotic disorder, mood disorder, attention deficit hyperactivity disorder, eating disorder). A significant negligible to small effect was found for CRT on cognition (g=0.16, p LESS THAN 0.05). Nonsignificant effects were found for clinical symptoms (g=0.06, p=0.40) and social functioning (g=0.06, p=0.39). Follow-up studies revealed few sustained improvements compared to the control groups. Methodological quality of included studies was variable, ranging from poor to good quality.

Discussion: Included studies showed a negligible to small significant effect of CRT on cognition, and nonsignificant effects on clinical symptoms and social functioning in adolescent with psychiatric disorders. Some factors may explain the lack of effects, such as the motivation during treatment, the absence of an inclusion criterion regarding cognitive deficits, and the absence of a CRT therapist. Core features for CRT have been identified by

an expert working group in adults with schizophrenia population. Such core ingredients should be considered for designing future CRT studies with adolescents.

T92. TDCS-MODULATED COGNITIVE TRAINING AS A POTENTIAL INTERVENTION FOR TREATING COGNITIVE IMPAIRMENT IN SERIOUS MENTAL ILLNESS

Lingyan Yu¹, Rebecca Kazinka¹, Lei Xuan¹, Donovan Roediger¹, Bryon Mueller¹, Kelvin Lim¹, Angus MacDonald*¹

¹*University of Minnesota*

Background: Cognition-based intervention has long been used and studied for treating neuropsychiatric patients with cognitive deficits, particularly those with serious mental illness (SMI). In patients with schizophrenia, the frontoparietal control network was found to be implicated in the cognitive deficits of schizophrenia and responsive to cognitive remediation (Ramsay et al., 2015). Due to mixed evidence on the generalizability of treatment outcomes, cognition-based interventions have been paired with various neuromodulation techniques to promote neuroplasticity, which then facilitates learning transfer to patients' overall cognitive functioning. Research on the synergy of transcranial direct current stimulation (tDCS) and cognitive training just accumulated over the last decade for tDCS's ease of use and focal noninvasive stimulation (Bikson et al., 2013). In this study, we aimed to test the incremental benefit of concurrent tDCS on cognitive training and to understand the change mechanism by examining the control network utilization in response to training.

Methods: We recruited 58 healthy adults with an estimated IQ between 70 and 115 for a gamified cognitive training protocol with three 45-minute training sessions each week for 12 weeks. Each session consisted of training on working memory (N-back paradigm), context processing (Dot Expectancy paradigm), and inhibitory control (Flanker paradigm), and the first 20 minutes of each session were paired with prefrontal tDCS, where participants were randomized into left anodal tDCS (L-tDCS), right anodal tDCS (R-tDCS), and sham tDCS with triple blinding. fMRI scanning and the MATRICS Consensus Cognitive Battery (MCCB; Nuechterlein et al., 2008) were administered at baseline, mid-point, and post-training, and the scanning was paired with an untrained N-back task. We used the Yeo-17 Networks atlas (Schaefer et al., 2018) to locate the control network to look at the 2-over-0-back brain activations.

Results: 38 participants completed all training. Completers performed better on the untrained 2-back task ($F(2, 68) = 21.57$, $p < .001$) and the MCCB ($F(2, 66) = 24.29$, $p < .001$) from baseline to midpoint and post-training, though no tDCS group effect or time-group interactions was found. Task-based brain activations in the control network decreased significantly from baseline to midpoint and post-training ($F(2, 68) = 46.55$, $p < .001$). In the left frontal control regions, there was a significant main effect for tDCS ($F(2, 68) = 25.84$, $p = 0.02$), where the left tDCS group showed the greatest task-based activations. The decrease in task-based control network activations was not associated with improvement in the untrained 2-back or the MCCB. Improvement in the MCCB was however predicted by improvement in the untrained 2-back ($F(1, 30) = 5.62$, $p = .02$), and there was a trend-level interaction between 2-back improvement and tDCS treatment group ($F(2, 30) = 2.72$, $p = .08$).

Discussion: Our results support a generalization of training outcomes, though the incremental effect of concurrent tDCS still needs further investigation. TDCS-modulated cognitive

training appears to be a feasible and well-tolerated intervention with the potential to be used to target the under-treated cognitive impairment in SMI patients.

T93. A CLINICAL QUALITY REVIEWER CALIBRATION MODEL: ENHANCING RELIABILITY IN PANSS SCORING ACROSS DIVERSE REGIONS

Kia Crittenden-Ward*¹

¹*Signant Health*

Background: Successful clinical trials depend on accurate and precise diagnostic assessments and symptom severity ratings [1]. A calibrated team of Clinical Quality Reviewers (CQRs) can be utilized to independently review site-administered interviews, offering feedback and remediation of aberrant interview techniques and scoring practices [2]. This proactive approach serves as an important early warning system, identifying and addressing data quality issues promptly [3]. The effectiveness relies on the high calibration and standardization of CQRs. However, challenges arise from variability in symptom presentation across global clinical trial regions [4, 5]. This report describes an innovative training methodology tailored to address this challenge, emphasizing training and calibration for North America, Asia Pacific, and Eastern Europe.

Methods: We present Positive and Negative Syndrome Scale (PANSS) scoring patterns of 48 CQRs in a global phase III schizophrenia trial. CQRs monitored data in local languages grouped by North America (English and Spanish), Asia Pacific (Chinese, Japanese, Korean), and Eastern Europe (Bulgarian, Croatian, Latvian, Polish, Romanian, Russian, Serbian, Ukrainian). Twenty-one CQRs reviewed only Eastern European data, 12 Asia Pacific, and 13 North America. Two CQRs reviewed data from Eastern Europe and North America.

Before participating, each CQR completed rigorous training and qualification exceeding site rater requirements. Credential vetting and curriculum covering scale and subject matter training were mandatory. Forty-eight CQRs completed the study-specific training and calibration program. Their qualified status required ongoing participation in an In-Study CQR Quality Assurance program, including calibration events every 4 months. Events aimed to harmonize CQRs in PANSS assessment, falling into two categories: 1) All CQR PANSS Calibration using the same English dataset, and 2) Language-Level PANSS Calibration with language-specific subgroups using local datasets.

Results: Over the 3-year focus of this descriptive review, four All-CQR calibration events occurred. Twenty-three CQRs participated in all, eight CQRs participated in three, five participated in two, and 12 participated in only one exercise. Twenty-seven Language-Level calibrations took place across 10 languages. The calibration details will be described with a reporting of scores and measure of inter-rater reliability for two English PANSS interviews conducted with actors trained to portray a typical trial participant and two English interviews recorded from consenting patients. Country- and language-specific interviews were scored with greater differences predicted for the Eastern Europe and Asia Pacific regions when using real data compared to scripted sessions. The ratings for PANSS items P1 Delusions, P3 Hallucinatory behavior, and P6 Suspiciousness/persecution, were highly consistent across regions. Larger differences were observed in N1 Blunted affect, with more variability in Actor ratings vs. Patient ratings.

Discussion: Cross-regional calibration of rating symptoms of psychosis requires attention to both universal standardization and appreciation of regional differences in symptom presentation and the rating of symptoms. Combined use of both universal training with region-specific calibration can ensure that ratings are consistent across the study and can address nuances that might be present within certain cultures and regions.

T94. ULOTARONT DELAYS GASTRIC EMPTYING TIME IN SCHIZOPHRENIA PATIENTS WITH METABOLIC SYNDROME (NCT05402111)

Seth Hopkins^{*1}, Snezana Milanovic², nina dedic³, Rob Lew⁴, Michael Camilleri⁵, Kenneth Koblan⁶

¹*Sumitomo Pharma America, Cambridge,* ²*Snezana.Milanovic@us.sumitomo-pharma.com,*
³*nina.dedic@us.sumitomo-pharma.com,* ⁴*robert.lew@us.sumitomo-pharma.com,*
⁵*camilleri.michael@mayo.edu,* ⁶*kenneth.koblan@us.sumitomo-pharma.com*

Background: Metabolic syndrome, which can be induced or exacerbated by the current class of antipsychotic drugs, is highly prevalent in schizophrenia patients and presents challenges to lifetime disease management. Ulotaront is a TAAR1 agonist in clinical development for schizophrenia. In line with other TAAR1 agonists, ulotaront improves glycemic control and reduces body weight in rodent models via peripheral effects on glucose homeostasis as well as central regulation of energy balance. Given that TAAR1 agonists improve oral glucose tolerance in rodents by delaying gastric emptying (a mechanism implicated in the beneficial effects of GLP-1 receptor agonist), our aim was to assess the effect of ulotaront on gastric emptying in schizophrenia patients with metabolic syndrome at high risk to develop diabetes.

Methods: Twenty seven schizophrenia patients with metabolic syndrome were randomized to receive in open-label fashion either a single dose of ulotaront (150 mg) or their prior antipsychotic in a 2-sequence crossover design. Subjects were required to maintain a stable dose and regimen for one of 4 antipsychotics as treatment for schizophrenia at the time of screening (risperidone, olanzapine, quetiapine, or aripiprazole). Subjects fulfilled at least 3 of 5 metabolic syndrome criteria, and to demonstrate glycemic-derived insulin resistance by either HbA1c values between 5.7% and 6.4% or fasting HOMA-IR values equal or above 2.22. Prior to the single dose of ulotaront, subjects underwent a washout period (of 3 to 16 days) of their prior antipsychotic drug. Following an overnight fast, subjects received a single dose of either ulotaront or the prior antipsychotic medication, underwent scintigraphic measure of solid gastric emptying, and after receiving a 99mTc-labeled meal (320kcal, 30% fat meal), successive γ camera abdominal images (anterior and posterior) were performed every 60 minutes over a 4 hour period. Primary endpoints were gastric emptying half-time, T1/2 (GE T1/2) and gastric retention (%GR) at 4h. Secondary endpoints were %GR at 1h and 2h.

Results: Following single-dose of 150 mg ulotaront, gastric emptying was delayed (T1/2 = 145 ± 17 min; median $\pm$ SE) compared to subjects receiving a single dose of their prior antipsychotic drug (125 ± 4 min, p-value 0.0028). The median percent gastric retention post-dose (1h, 2h, 4h) was significantly greater following ulotaront (83%, 66%, 17%) compared to prior antipsychotic (76%, 51%, 7%, respectively).

Discussion: Ulotaront significantly delayed gastric emptying following a single dose. In this first study of its kind, we enrolled schizophrenia patients with metabolic syndrome, and who were at high risk for diabetes. The within-subject crossover design allowed the comparison of the effect of ulotaront in each subject to the effects of their prior antipsychotic medication.

Further studies of ulotaront in this patient population (NCT05463770, NCT05542264) will be required to elucidate its potential for benefit on glycemic control and body weight.

T95. FUNCTIONAL OUTCOME OF FIRST-EPISODE PSYCHOSIS AND LONG-TERM SCHIZOPHRENIA

Olsson Anna-Karin^{*1}, Torill Ueland², Linn Sofie Sæther³, Christine Mohn³

¹*NU-Hospital Groups*, ²*NORMENT Norwegian Centre for Mental Disorders Research*, ³*NORMENT, Division of Mental Health and Addiction, Oslo University Hospital and Institute of Clinical medicine, University of Oslo*

Background: Impaired functional outcome has been documented in both first-episode psychosis (FEP) and long-term schizophrenia spectrum disorders (SZ), but has seldom been directly compared between the two groups. Functional outcome can be described using real world measures of functioning as well as measures of functional capacity. Both types of measures have been found to be related to cognitive functioning. In the current study, we compare participants with FEP and SZ on measures of functional capacity, real world functioning and a measure of cognition.

Methods: The participant group consisted of 349 patients, 156 with FEP and 193 with SZ. The FEP group consisted of 103 men and 53 women, mean age 26.7 (SD 6.9) years, while the SZ group consisted of 128 men and 65 women, mean age 49.3 (SD 9.9) years. In the FEP group, 60% had a diagnosis of schizophrenia while the corresponding number in the SZ group was 70%. The groups were compared on socio-demographic characteristics, clinical symptoms, and functional outcome. Symptoms were measured with the Positive and Negative Syndrome Scale (PANSS) and the Global Assessment of Functioning Scale-symptom (GAF-symptom). Real world functioning was measured with the Global Assessment of Functioning Scale-function (GAF-function), functional capacity was assessed with the University of California, San Diego Performance-Based Skills Assessment-Brief (UPSA-B), and processing speed was assessed with the Trail Making Test A (TMT-A).

Results: There was no significant gender difference between the groups. The FEP group was significantly younger than the SZ group ($t = -24.05$, $p < .001$). In the FEP group, 74 individuals were employed or currently studying, and in the SZ group the number was 25 ($X^2 = 74.43$, $p < .001$). There were no differences in symptom levels between the groups as measured by the PANSS. However, the GAF-symptom score was lower in the SZ group ($t = 3.71$, $p < .001$). The FEP group had significantly higher real world function (GAF-function, $t = 2.87$, $p < .005$) and functional capacity (UPSA-B total, $t = 5.28$, $p < .001$) compared to the SZ group. Moreover, the sub scales of the UPSA-B also showed better function in the FEP group (Finances $t = 9.38$, $p < .001$ and Communication $t = 3.54$, $p < .001$). Finally, performance on a measure of processing speed, the TMT-A, was significantly lower in the FEP group ($t = -6.78$, $p < .001$), indicating better cognitive function.

Discussion: Despite similar psychosis symptom levels, the FEP group exhibited better real-world functioning, functional capacity, and cognitive functioning compared to the SZ group. This finding could suggest that the capacity to perform practical everyday activities and cognitive function of FEP patients be better preserved if interventions and support targeting these outcomes are performed early in the course of illness. Such interventions may not only hinder the deterioration of functions, but also can facilitate for these patients to complete education and gain employment.

T96. BEYOND NUMBERS: UNRAVELING THE FREQUENCY OF NEUTROPENIA AND AGRANULOCYTOSIS IN CLOZAPINE USERS

Natalia Daher*¹, Ary Gadelha¹, Raffael Massuda², Pedro Lorencetti¹, Renan Biokino¹, Mateus Diniz¹

¹Federal University of Sao Paulo, ²Universidade Federal do Parana

Background: Treatment-resistance affects approximately 37% of patients with schizophrenia and is defined by the failure of two antipsychotics used at appropriate dosage, duration, and adherence levels (DINIZ et al., 2023, HOWES et al., 2017). Only one antipsychotic medication has proven to be more effective for these patients, which is clozapine. Each antipsychotic tried before clozapine in treatment-resistant schizophrenia reduces the likelihood of a response to clozapine by about 8 to 11%. On the other hand, the chance of improvement in functionality decreases by 15% for each year of delay in starting clozapine (NIELSEN et al., 2010). Various hematologic disorders can be encountered, including leukopenia, neutropenia, agranulocytosis, thrombocytopenia, anemia, and eosinophilia. Agranulocytosis, a rare complication of clozapine, affects 0.4% of users (LI XH et al., 2020). There are few studies addressing hematologic dyscrasias in Brazil, none in the central area of the country.

Methods: This is a real-world study in which data available at a clozapine distribution reference center were analyzed. A total of 6,160 complete blood counts from patients at the CEMAC - High-Cost Medication Center Juarez Barbosa, covering the years 2011 to 2018, were examined. This center is a reference facility in the state of Goiás for dispensing clozapine and oversees approximately 900 patients in total. The patient group consists of adults and seniors, ranging from 18 to 73 years old, diagnosed with a chronic psychotic disorder and currently using clozapine. The demographic characteristics were collected by the administrative staff of CEMAC.

Results: The study sample comprised 486 patients monitored between 2011 and 2018, who underwent a total of 6,180 complete blood counts. Analyzing by the total number of blood counts, neutropenia rates were 1.10%, with mild neutropenia at 0.99%, moderate at 0.11%, and severe at 0%. No cases of agranulocytosis were identified in any blood count. On the other hand, analyzing by the total number of patients, neutropenia rates were 4.32%, with mild neutropenia at 3.7%, moderate at 0.62%, and severe at 0%. No cases of agranulocytosis were found in any patient. For male patients, the neutropenia rate was 3.96%, while for female patients, it was 4.68%. Among patients aged 20 to 29, 9% exhibited neutropenia. For those aged 30 to 39, the neutropenia rate was 6%, while for those aged 40 to 49, it was 3.5%. Among those aged 50 to 59, the neutropenia rate was 1%, and for those aged 60 or older, it was 10%. While examining recurrent neutropenia - defined by two consecutive blood exams, 21 out of the 486 patients exhibited neutropenia, with 9 showing recurrent mild neutropenia (42.85%) and 2 showing recurrent moderate neutropenia (9.5%).

Discussion: Clozapine is globally underutilized due to clinicians' reluctance to prescribe it, even for treatment-resistant patients. Studies indicate that the main reason for this reluctance is concern about adverse reactions and the difficulty in monitoring complete blood counts. The data collected reveal low rates of neutropenia overall, especially recurrent neutropenia, and no cases of agranulocytosis. This database can provide insights into monitoring complications associated with clozapine use in low- and middle-income countries (LMICs). These results contribute compelling information from the South American population and could assist in guiding clinical and public health decisions to ease blood monitoring guidelines for clozapine users.

T97. FOOD FOR BRAIN DISORDERS: DESIGN OF THE BRAIN ANTI-INFLAMMATORY NUTRITION DIET AND 'NO GUTS, NO GLORY' STUDY - AN OPEN-LABEL RCT

Sophie van Zonneveld*¹, Greetje Huisman¹, Ellen van den Oever¹, Emmy Grandjean², Ondine van de Rest², Benno Haarman¹, Iris Sommer¹

¹University Medical Center Groningen, ²Wageningen University and Research Wageningen

Background: Elevated systemic inflammation, stemming from increased intestinal permeability, significantly affects brain functioning in a subset of patients. Gut health offers a promising avenue for therapeutic intervention, with an anti-inflammatory dietary pattern potentially altering the course of brain disorders. Patients are eager to know what foods can optimize their brain health; however, comprehensive dietary guidelines are currently lacking. To address this gap and provide guidance to patients, a narrative review was conducted to offer an overview of the current evidence at the food group level. Drawing upon this evidence, the Brain Anti-Inflammatory Nutrition (BrAIN) diet was formulated. Presently, the efficacy of this anti-inflammatory diet on global functioning and (gut)health of patients with schizophrenia spectrum disorders (SSD), bipolar disorder (BD), and Parkinson's disease is researched in the 'No Guts, No Glory' clinical trial (NL9851).

Methods: A comprehensive review was conducted to assess the potential effects of various food groups on gut health, inflammation, and symptoms in schizophrenia spectrum disorders (SSD), bipolar disorder (BD), and Parkinson's disease. Based on this evidence the Brain Anti-Inflammatory Nutrition (BrAIN) diet was designed, that is researched in a randomized controlled open-label trial with a cross-over intervention lasting 12 weeks and a 24-week wash-out period. The study population comprised patients with SSD (n=25), BD (n=25), and PD (n=50). All visits occurred at the patient's home or UMC Groningen. Primary outcome is global functioning assessed with Outcome Questionnaire 45 (OQ-45).

Results: The BrAIN diet contains a minimum of 30-40 grams of dietary fiber a day from fruits, vegetables, legumes, wheat, and wholegrain products. Furthermore, fatty fish, fermented dairy (such as yoghurt, kefir, and buttermilk), nuts, olive oil, herbs, and spices are recommended. In contrast, red meat, other dairy products, and sugar should be limited. Finally, ultra-processed foods, salt, alcohol, and sweetened beverages should be avoided. The results of the clinical trial were not available during abstract submission.

Discussion: This comprehensive review focuses on anti-inflammatory properties of foods providing a foundation for future dietary guidelines in this domain. Furthermore, our clinical study explores the therapeutic potential of an anti-inflammatory dietary pattern in modifying the course of brain disorders through the gut-brain axis. Additionally, we present the Brain Anti-Inflammatory Nutrition (BrAIN) diet, developed based on evidence linking food groups to gut health, inflammation, and symptoms in psychiatric and neurodegenerative disorders.

T98. ESKETAMINE FOR NEGATIVE AND DEPRESSIVE SYMPTOMS IN SCHIZOPHRENIA – PRELIMINARY OBSERVATIONS FROM AN ONGOING RANDOMIZED CONTROLLED CLINICAL PILOT STUDY

Matthäus Willeit*¹, Ulrich Sauerzopf², Cornelia Diendorfer², Fridolin Stockreiter², Lisa Müller², Irena Dajic², Katharina Landesmann², Lucie Bartova², Martin Bauer³, Ana Weidenauer², Nicole Praschak-Rieder²

¹Medical University of Vienna, ²Department of General Psychiatry, Medical University of Vienna, ³Social psychiatric outpatient clinic Donaustadt - SPA 22, PSD Vienna

Background: Negative symptoms account for a large proportion of the socioeconomic burden associated with schizophrenia (SCZ). They are persistent, severely disrupt social relationships, and lead to poor clinical and psychosocial outcomes. Conventional treatments have only marginal effects, even when administered over many weeks. Ketamine, a non-specific NMDA receptor antagonist, has recently gained wide acceptance as a fast-acting and effective antidepressant. However, most likely due to its reported psychotogenic properties, evidence on using ketamine to treat depressive or negative symptoms in SCZ remains anecdotal (1, 2).

Here we report on the protocol and preliminary observations from an ongoing prospective, monocentric, randomized, double-blind, placebo controlled, phase III pilot study.

Methods: The trial aims at studying 20 patients with a diagnosis of schizophrenia according to DSM-5. Main inclusion criteria are a minimum score of 39 (at least moderate severity across all items) on the Brief Negative Symptom Scale (BNSS; 3) or a minimum score of 22 on the Montgomery-Åsberg Depression Rating Scale (MADRS; 4), and stable pharmacological or psychosocial treatments for at least one month prior to inclusion. Main exclusion criteria are the presence of unstable arterial hypertension, cardiovascular disorders, or acute suicidal or homicidal ideations. Patients are randomized to receive either six doses of intravenous esketamine (first dose 0.25mg/kg, then 0.5mg/kg body weight) over approximately two weeks, then, after a two-week washout period, intravenous diphenhydramine (first dose 30mg, then 60mg), or vice versa. Changes in negative and depressive symptoms are measured using BNSS and MADRS. Possible changes in positive symptoms are quantified using the positive and general psychopathology items of the Positive and Negative Symptom Scale (PANSS; 5).

Results: To date, blinded clinical trial data are available for eight patients. Both interventions were well tolerated and there were no serious adverse drug reactions. Importantly, none of the patients enrolled to date have experienced psychotic exacerbation or worsening in any symptom domain.

Discussion: Statements on the efficacy of esketamine in the treatment of negative and depressive symptoms will have to await unblinding at the end of the study. However, our preliminary data suggest that esketamine is well tolerated and does not exacerbate positive symptoms in patients with SCZ.

T99. A FAMILY-CENTERED PSYCHOEDUCATIONAL PROGRAM FOR EARLY PSYCHOSIS: IMPACT FOR YOUNG PEOPLE AND THEIR FAMILIES AND FEEDBACK FROM HEALTH PROFESSIONALS

Claire Rasclé*¹, Emilie Musset², Marina Pivette³, Marie-Cécile Bralet⁴

¹University Hospital Lille, ²CSN2R HDF CHU de Lille, ³CSN2R HDF CHU de Lille, ⁴CRISALID-HDF-Pole PRERPS-Centre Hospitalier Isarien-EPSM Oise

Background: A Family-Centered Psychoeducational Program for Early Psychosis : Impact for young people and their families and feedback from caregivers.

Psychoeducational programs in early intervention should be a key tool improving outcomes, increasing understanding of psychosis. We promote an adaptable program, based on cooperative pedagogy, free choice, concerted objectives, led by a trained multidisciplinary team (including peer health mediator) as a key element of recovery. We shared the program with French early intervention health teams and Transition network.

Methods: We provided a short unifamilial program tailored for each individual need with a collaborative approach. The program targeted subjective dimensions (self esteem, empowerment, understanding, trust in future) for young people and their families with a pre-post evaluation. We present a qualitative practice analysis feedback (efficiency on commitment, wellness, hope and recovery,...) of health professionals.

Results: We showed the improvement of various subjective dimensions. Self-esteem improves for youngs and caregivers. Self-esteem profiles are changed in youngs towards higher self-esteem as well as sense of understanding of the health accident and ability to seek out more information on their own. We showed that Trust in future stay stable both in youngs and families.

We showed in health professionals the variations of a subjective feelings of the psychoeducational program.

Discussion: Psychoeducational programs based on personal needs and resources supports efficiently personal and family's recovery. They are shared freely (with training and team support). They enlighten specific tools in early intervention. It rolls with the implementation of Early Intervention care on the territory. Our aim is to sustain meaningful and hopeful cares for young people and their families in early intervention in psychosis.

T100. EVALUATION OF M4 MUSCARINIC RECEPTOR OCCUPANCY BY EMRACLIDINE USING [11C]MK-6884 PET IN HEALTHY VOLUNTEERS

Sridhar Duvvuri¹, Philip Iredale*¹, Sokhom Pin¹, Deborah Smith¹, Jianbo Zhang¹, Amy Giugliano¹, Michel Koole², Koen Van Laere², Jan de Hoon², Vasily Belov³, Nicolas Guehl³, Georges El Fakhri³, Marc Normandin³

¹Cerevel Therapeutics, ²University Hospitals Leuven, ³Gordon Center for Medical Imaging, Massachusetts General Hospital, Harvard Medical School

Background: Emraclidine, a novel highly-selective M4 muscarinic acetylcholine receptor-positive allosteric modulator, is currently in clinical development for the treatment of schizophrenia and Alzheimer's disease psychosis (Krystal et al. Lancet. 2022;400:2210-2220). Emraclidine showed favorable brain penetration and direct target engagement in preclinical rodent studies and exhibited robust in vivo antipsychotic-like activity in animal models (e.g., reversal of amphetamine-stimulated locomotion and prepulse inhibition). In recent positron emission tomography (PET) imaging studies evaluating M4 receptor occupancy (RO) as a function of emraclidine dose and plasma concentration in nonhuman primates, in vivo target engagement and overall exposure-occupancy relationship of emraclidine were confirmed using the [11C]MK-6884 radioligand (Duvvuri et al. Presented at ACNP 2021). This PET imaging trial evaluated RO of emraclidine in human volunteers.

Methods: Healthy adult volunteers were enrolled across 3 cohorts in this phase 1, open-label trial (NCT04787302) using an adaptive study design. M4 RO from each cohort informed emraclidine dose selection (single dose) in the subsequent cohort. Participants in the first cohort received the maximal dose of 30 mg, anticipated to achieve ~80-90% M4 RO based on in vitro binding affinity data. A baseline PET/magnetic resonance imaging (MRI) scan was performed up to one week before emraclidine dosing and a second PET/MRI scan was performed immediately after dosing, with intravenous administration of 10-20 mCi [¹¹C]MK-6884 and 90-minute scanning with arterial blood sampling and metabolite analysis for full tracer pharmacokinetic (PK) modeling. Blood samples were obtained 30, 60, and 90 minutes after emraclidine dosing for PK analysis during the PET scan. The primary endpoint was estimation of emraclidine RO (%) in the striatum (averaging values from caudate and putamen), with the cerebellum as a reference region. Overall M4 RO (%) was calculated as the difference from baseline in M4 nondisplaceable binding potential (BP_{nd}) after emraclidine dosing (BP_{nd} [baseline] and BP_{nd} [dose]), divided by BP_{nd} [baseline]. An exposure-response model informed by the maximum estimated RO (E_{max}), emraclidine plasma concentration (C), and the concentration at which 50% of maximum RO is achieved (EC₅₀) assessed the relationship between M4 RO and emraclidine plasma exposure (assuming a Hill coefficient [γ] of 1): $RO = (E_{max} \times C_{\gamma}) / (EC_{50}^{\gamma} + C_{\gamma})$

Results: A total of 9 participants received a single dose of emraclidine 30 mg, 15 mg, or 5 mg (n=3 for each dose). Emraclidine PK exposure parameters decreased with decreasing emraclidine dose (median [range] average plasma concentration during the scan duration: 30-mg dose, 634 [425-888] ng/mL; 15 mg dose, 347 [186-374] ng/mL; 5 mg dose, 143 [128-167] mL). Mean (SD) M4 RO in the striatum was 52.7% (1.31%), 41.8% (11.9%), and 20.1% (7.30%) after a single 30-, 15-, or 5-mg dose of emraclidine, respectively. A positive relationship was observed for M4 RO in the striatum versus emraclidine plasma concentration, with RO ranging from 14% to 54%; RO GREATER THAN 50% was observed across emraclidine plasma concentrations ranging from 350 to 900 ng/mL. The mean (SE; 95% CI) E_{max} was 80.1% (17.6%; 46.8%-113%) and the corresponding mean (SE; 95% CI) EC₅₀ was 321 (157; 23.9- 618) ng/mL.

Discussion: These data demonstrate M4 RO of ~60% across a wide range of emraclidine plasma concentrations, suggesting potential receptor saturation. Overall, these results corroborate recent emraclidine data obtained in primates using the same radiotracer and confirm the target binding of emraclidine to M4 receptors in the striatum of humans.

T101. AN OVERVIEW OF LOW ENROLLING SITES ACROSS 15 SCHIZOPHRENIA CLINICAL TRIALS

Alan Kott^{*1}, Xingmei Wang¹, Petra Reksoprodjo¹, David G Daniel¹

¹*Signant Health*

Background: Clinical trials rely on research sites to identify and recruit adequate study population and to provide valid and reliable assessments of study participants' symptom severity and its changes over the course of the trial. Low recruiting sites represent a large financial burden for the trial sponsor and may pose a risk to the trial success because of possible suboptimal study participant selection or high prevalence of data quality issues.

Methods: Data were obtained from 15 trials in early schizophrenia. Sites were categorized as low recruiting if the number of study participants randomized was five or less. Additionally, as extremely low recruiting sites we identified those site that randomized a single subject

only, and as non-contributing sites those sites that did screen at least one potential study participant but failed to randomize any. Descriptive summary statistics are provided.

Results: Data were extracted from 633 sites (342 unique sites) from 15 protocols in schizophrenia. A total of 5,963 subjects were screened and 3,888 subjects randomized with a randomization rate of 65%. Of the 633 sites in the database, 79 (12.5%) sites did not randomize any study participants, 93 (14.7%) sites randomized a single study participant. A total of 390 (61.6%) sites did randomize no more than 5 subjects. Taking the Pareto principle, 288 (45.5%) sites randomized 80% of all the study participants, the remaining 345(54.5%) sites randomized the remaining 20% of the study participants.

Discussion: Our retrospective analysis identified that there is a substantial proportion of participating sites that contribute very little if at all to the study. These sites represent a potential risk to the trial as data quality concerns and suboptimal subject selection are typically seen during the initial weeks and months of each site participation and decrease over time with feedback and remediation provided. Additionally, these sites represent considerable financial burden to the study sponsor related to site initiation and study personnel training. Additional analyses are planned to quantify the contribution of these low recruiting sites to data concerns.

T102. EMPOWERING THE NEXT GENERATION: A PHASE 2 PROGRAM TO EVALUATE EMRACLIDINE, A SELECTIVE M4 POSITIVE ALLOSTERIC MODULATOR (PAM), FOR THE TREATMENT OF SCHIZOPHRENIA

George Konis¹, Erica Koenig*², Koji Takahashi², Philip Iredale², Meera Tugnait², Javier Waksman², Ih Chang², Shauna Blackmon², Matthew Leoni², Raymond Sanchez²

¹Woodland International Research Group, ²Cerevel Therapeutics, LLC

Background: Emraclidine is a novel, highly selective positive allosteric modulator of M4 muscarinic acetylcholine receptors currently in development for the treatment of schizophrenia and Alzheimer's disease psychosis. By selectively activating M4, emraclidine may reduce excess dopamine signaling in the striatum, potentially leading to a reduction in psychotic symptoms. The phase 2 EMPOWER program will fully evaluate the efficacy, safety, tolerability, and dose range of once-daily (QD) emraclidine in patients with schizophrenia.

Methods: EMPOWER-1 and EMPOWER-2 are two adequately powered, multicenter, randomized, double-blind, placebo-controlled, parallel group, 6-week inpatient studies of emraclidine monotherapy at fixed doses (EMPOWER-1, 10 mg QD and 30 mg QD; EMPOWER-2, 15 mg QD and 30 mg QD). The trials are enrolling adult participants with schizophrenia who are experiencing an acute exacerbation of psychosis with a Positive and Negative Syndrome Scale (PANSS) Total Score between ≥ 85 and ≤ 120 and a Clinical Global Impression – Severity (CGI-S) score ≥ 4 at baseline. De novo participants and those who complete EMPOWER-1 or EMPOWER-2 are eligible to participate in EMPOWER-3, a 52-week open label extension trial evaluating the long-term safety and tolerability of emraclidine in adults with stable schizophrenia.

Results: Detailed study designs for the EMPOWER program will be presented. The primary outcome measure for EMPOWER 1 and 2 is change from baseline in PANSS total score at Week 6. Other outcome measures include change from baseline in CGI-S score at Week 6. Data from EMPOWER-3 will contribute to the overall safety and tolerability evaluation of emraclidine in adults with schizophrenia.

Discussion: The EMPOWER program aims to establish the efficacy, safety, tolerability, and appropriate dose-range of emraclidine in the treatment of schizophrenia.

T103. CLASSIC TRIAL DESIGN AND DIGITAL HEALTH IN SCHIZOPHRENIA: SOUND METHOD OR BLIND ALLEY?

Sean Kidd¹, Jessica D'Arcey^{*2}, Leah Tackaberry-Giddens³, Toni-Rose Asuncion³

¹University of Toronto, ²University of Toronto Scarborough, Centre for Addiction and Mental Health, ³Centre for Addiction and Mental Health

Background: The rationale regarding the need for validated digital health tools in schizophrenia service delivery has been made clear by patients and care providers. However, the development of effective and accessible digital health tools for schizophrenia populations has been a fraught path to date. For those seeking to use rigorous research approaches to develop and validate digital tools, there have been significant challenges in applying gold-standard trial methods derived from pharmacological and behavioral intervention science. These challenges, paired with the even more daunting commercialization and implementation hurdles, have made for slow progress, leaving patients and providers frustrated. This presentation considers digital health research for schizophrenia populations and reviews trends in a literature characterized by one-off pilots and failed trials, connecting trend-level patterns to the findings of two recent randomized controlled trials (RCTs) of digital interventions.

Methods: The presentation highlights gaps and future directions from a recent systematic review of research examining digital health intervention trials in schizophrenia and observations from RCTs of a text-based intervention in an early psychosis clinic (n=70) and a mobile health intervention for broader schizophrenia populations (n= 91). Both trials were conducted in a large urban tertiary care setting and leveraged several data sources, including interviews and self-reports, clinician-reported data, technology engagement metrics, and electronic medical records.

Results: The literature review raises questions about the fit between traditional trial designs and most digital health intervention approaches. The text-based trial found that individuals in the active group displayed improved attitudes toward medication but decreased attendance rates compared to the control group, with significant differences in secondary subscale findings (e.g., social functioning and aspects of therapeutic rapport). While affected by the pandemic, the mobile health intervention trial evidenced no difference between the treatment as usual control and the intervention arm across symptom, treatment adherence and quality of life metrics.

Discussion: Schizophrenia populations continue to face significant barriers with respect to accessing evidence-based care. Yet, the promise of digital health remains untapped despite advances in core technologies and improved access to such technologies by people with schizophrenia. The two trials presented here, and lessons learned from the existing literature, suggest the need for a different approach than the traditional research pipeline of pilot to RCT to implementation trials. Such approaches include the need for iterative and dynamic co-design embedding industry partners in the process, reflexive integrated clinical trials in open and randomized formats, an emphasis on implementation science frameworks, and centring technological and contextual feasibility based on best practices.

T104. EFFECTS OF LAMOTRIGINE, THE PDE9 INHIBITOR BI 409306, AND GLYT1 INHIBITOR BI 425809 ON ATTENUATION OF KETAMINE-INDUCED MEMORY IMPAIRMENT: AN EXPLORATORY STUDY IN HEALTHY SUBJECTS

Christian Schultheis*¹, Holger Rosenbrock², David Walling³, Larry Ereshefsky⁴, Howard Hassman⁵, Anja Hoch², Janos Zambori⁶, Yury Shatillo¹

¹Boehringer Ingelheim Pharma GmbH and Co. KG, ²Boehringer Ingelheim Pharma GmbH and Co. KG, Biberach an der Riss, ³CenExel - CNS, ⁴Follow the Molecule: CNS Consulting and CenExel Research, ⁵CenExel - HRI, ⁶Boehringer Ingelheim International GmbH

Background: There are currently no pharmacotherapies available for the treatment of cognitive impairment associated with schizophrenia (CIAS). Lean and fast studies for early testing of clinical effects are desirable for the development of novel treatments. One promising approach is the attenuation of ketamine-induced cognitive deficits in healthy subjects, which resemble, at least partly, impairments observed in patients. To validate this clinical model, several pharmacological treatments have been evaluated for attenuation of ketamine-induced cognitive deficits.

Methods: A randomized, placebo-controlled, double-blind, double-dummy, 3-way crossover Phase I study was conducted at 2 sites in the US. Healthy males (aged 18–55) were randomized to 1 of 18 treatment sequences, comprising 3 single doses of placebo, and 2 of 3 active treatments (lamotrigine 300 mg, BI 409306 50 mg (a phosphodiesterase 9 [PDE9] inhibitor), and BI 425809 25 mg (a glycine transporter 1 [GlyT1] inhibitor). At the anticipated time of maximum exposure for each treatment, subjects received an intravenous ketamine infusion (bolus of 0.26 mg/kg over 1 min, followed by continuous infusion of 0.0073 mg/kg/min over 89 minutes [reduced by 10% every 15 min]). Cognitive testing was performed before and during ketamine infusion using the following tasks from the Cantab Battery (Cambridge Cognition, Cambridge, UK): Paired Associates Learning (PAL; total errors adjusted 28) for episodic memory, Spatial Working Memory (SWM; between errors 468) for working memory, and Rapid Visual Information Processing (RVP; RVPA') for attention. Treatment effects relative to placebo were analyzed using a linear mixed-effects model. The study was designed to detect a numerical effect size of treatments; 0.35 would be considered clinically meaningful.

Results: Of 40 randomized subjects, 35 completed the trial. Across treatment sequences, n=33 treatments for placebo, n=21 for BI 425809, n=21 for BI 409306 and n=24 for lamotrigine were used for analysis. Ketamine elicited consistent worsening of cognitive performance assessed with all 3 tasks in placebo-treated subjects: PAL (+10.3 errors, standard deviation (SD) 14.8), SWM (+5.9 errors, SD 9.2) and RVP (-0.047, SD 0.052). Treatment with either lamotrigine, BI 425809, or BI 409306 elicited limited placebo-corrected effects with standardized effect sizes (SES) LESS THAN 0.35 (except for lamotrigine and RVP): Lamotrigine: PAL (-1.9; 95% confidence interval [CI]: -11.0, 7.2; SES -0.11), SWM (-2.1; -6.5, 2.4; SES -0.23), RVP (0.031; 0.01, 0.05; SES 0.62); BI 409306: PAL (4.3; 5.2, 13.8; SES +0.26), SWM (-0.3; 5.0, 4.4; SES -0.03), RVP (0.006; -0.01, 0.02; SES 0.11); BI 425809: PAL (-0.4; -10.0, 9.1; SES -0.03), SWM (0.9; -3.7, 5.5; SES 0.10), RVP (-0.002; -0.02, 0.02; SES -0.03). All adverse events (AEs) were mild to moderate, with no serious AEs reported. One AE on placebo led to discontinuation. The most frequent AEs were nausea, somnolence, and vomiting. Most AEs occurred after ketamine infusion.

Discussion: In line with published data, ketamine led to consistent worsening of cognitive performance. Treatment with lamotrigine, BI 425809, or BI 409306 elicited limited effects on cognition and did not demonstrate a relevant attenuation of episodic or working memory

impairment. Potential reasons for the low treatment effects may relate to study design (e.g., ketamine dose, drug dose, cognition tasks used), be specific for the tested treatments (targeting NMDAR signaling) or indicate that ketamine-induced cognitive deficits are not a suitable human model for early clinical testing of investigational drugs.

Funding: Boehringer Ingelheim International GmbH (NCT04602221).

T105. THE NORTH QUEENSLAND DIETARY INTERVENTION TRIAL (NQDIT) IN PSYCHOSIS: A RANDOMISED, PLACEBO CONTROLLED CLINICAL TRIAL OF KETOGENIC DIET IN COMMUNITY PATIENTS WITH BIPOLAR DISORDER AND SCHIZOPHRENIA

Calogero Longhitano*¹, Sabine Finlay², Omer Sherif³, Shaileigh Gordon³, Jaymee-Leigh Swift⁴, Flavia Fayet-Moore⁵, Isabella Peachey², Brett McDermott⁶, Christopher Palmer⁷, Shebani Sethi⁸, Zoltan Sarnyai²

¹James Cook University, ²James Cook University, ³Townsville University Hospital, ⁴Mater Hospital and Aurora Health Care, ⁵FoodIQ, University of Newcastle, ⁶University of Tasmania, ⁷Harvard Medical School, ⁸Stanford University,

Background: Bipolar Affective Disorder and Schizophrenia are severe and enduring psychotic disorders presenting with high comorbidity of metabolic disorders, leading to a reduced life expectancy of up to 25 years. Nutritional ketosis has been successfully used to treat a range of neurological disorders to include treatment resistant epilepsy and migraines. Preclinical data has convincingly shown potential for its use in animal models of psychotic disorders and recent clinical data in uncontrolled clinical trials and case series has pointed towards a significant reduction in psychotic, affective and metabolic symptoms in both schizophrenia and bipolar affective disorder. The intervention was well tolerated and feasible in this patient population. However, no randomised controlled clinical trials exist.

Methods: We propose a 14-week controlled dietary intervention in a north Queensland outpatient chronic psychotic population with co-morbid metabolic disorders. We aim to investigate the efficacy of a Well Formulated Ketogenic Diet (WFKD) in adult non-hospitalised participants with either bipolar disorder or schizophrenia. Participants will be randomly assigned to one of two groups: the experimental (KD) and the control (Australian Guide to Healthy Eating - AGHE) diet. Face-to-face clinical assessments by psychiatrists and dietitians will be obtained at week 0, week 8, and week 14. Up to 100 participants will be recruited and randomly allocated to one of the dietary groups if they meet diagnostic and safety criteria, and consent to the dietary changes. The participants will be blind to the study hypothesis and interact with clinicians who are, in as far as possible, blind their group allocation. Participants in both groups will be treated identically in all respects except for the intervention being tested. Participants will receive baseline psychiatric, cognitive and dietary assessments and asked to adhere to their allocated diet for a period of 12 weeks following an introductory 2 week period. They will receive detailed dietary instructions and material to foster independent meal preparation. Progress will be supported using a parallel group design that includes weekly group supervision and daily individualised monitoring obtained with a mixture of face to face and telematic means. Dietary education consisting in specialised information about the dietary requirements of their allocated group and existing evidence base for nutrition in mental health will be provided. Participants will be treated identically in

all respects except for the intervention being tested. Pre-existing psychiatric and metabolic treatment will continue as per treating team's advice. Metabolic medication might be adjusted for those in the KD group in collaboration with their physician in order to minimise the risk of hypoglycaemia. Capillary blood ketones and glucose levels will be measured daily and strictly monitored.

Results: Participants will be assessed for a range of psychiatric and metabolic outcome measures, to include the Positive and Negative Syndrome Scale: PANSS, the Affect Liability Scale: ALS-18, the Young Mania Rating Scale: YMRS, the WHO Disability Assessment Schedule-2: WHODAS-2, the Cambridge Cognitive Battery: CANTAB, the Beck Depression Inventory: BDI. Additionally, metabolic measures will be taken to include liver and renal function, lipid profile, insulin resistance and cardiovascular health indicators. Biometric testing will be taken via wearable devices (OURA ring and EMBRACE wristband) in the form of skin conductance, oximetry, continuous monitoring of pulse, respiratory rate, movement tracking and sleep quality. A small hair and a stool sample will be taken at baseline and endpoint, to measure for changes in stress hormones and gut microbiota. Any adverse effects will be strictly monitored and reported. Adherence to the dietary regime and feasibility of both diets in a chronic psychotic population will be recorded and measured.

Discussion: Brain energy deficits are increasingly considered central in the pathophysiology of psychotic disorders. Putative mechanisms put forward include altered kinase, ion channels, oxidative phosphorylation processes and insulin receptor like dysfunctions in neuronal mitochondria and membranes, ultimately resulting in ineffective glycolytic pathways. Epigenetic modulation may play a role in the translation of developmental trauma and lifestyle factors in susceptible populations. The KD fundamentally bypasses cellular glycolysis to promote energy production via ketone cycles, Krebs and TCA, thus restoring neural function. Based on the encouraging results from established preclinical research and clinical data from other neurodevelopment disorders as well as from soon to be published open trials in bipolar and schizophrenia, we predict that the intervention will be well tolerated and result in significantly improved metabolic and psychiatric outcome measures as well as global measures of social and community functioning. We predict that a significant correlation will exist between the level of ketosis achieved and the metabolic, cognitive and psychiatric outcomes measured in the treatment group.

T106. EFFICACY AND SAFETY OF ICLEPERTIN (BI 425809) IN PATIENTS WITH SCHIZOPHRENIA: CONNEX, A PHASE III RANDOMISED CONTROLLED TRIAL PROGRAMME

Corey Reuteman-Fowler^{*1}, Zuzana Blahova², Satoru Ikezawa³, Stephen R. Marder⁴, Peter Falkai⁵, John H. Krystal⁶

¹Boehringer Ingelheim Pharmaceuticals, Inc., ²Boehringer Ingelheim RCV GmbH and Co. KG, ³International University of Health and Welfare, Mita Hospital, ⁴Semel Institute for Neuroscience at UCLA, David Geffen School of Medicine, ⁵Ludwig Maximilians University Munich, ⁶Yale University School of Medicine

Background: Cognitive impairment associated with schizophrenia (CIAS) is a core feature of the disease and a major determinant of poor functional outcomes. Currently, there are no approved pharmacotherapies for the treatment of CIAS. Deficits in glutamatergic signalling play a key role in the neuropathology of schizophrenia, particularly in cognitive symptoms. Iclepertin (BI 425809), a novel inhibitor of glycine transporter-1, enhances N-methyl-D-

aspartate receptor signalling in the brain by increasing synaptic levels of its co-agonist glycine. A 12-week, Phase II, proof-of-clinical-concept trial (NCT02832037) that included 509 patients demonstrated that iclepertin was well tolerated and significantly improved cognition in patients with schizophrenia. The Phase III CONNEX programme aims to confirm the efficacy, safety and tolerability of iclepertin in improving CIAS and functioning using a larger cohort of patients with schizophrenia.

Methods: CONNEX consists of three replicate randomised, double-blind, placebo-controlled parallel-group trials in patients with schizophrenia (NCT04846868, NCT04846881, NCT04860830) currently stable on antipsychotic treatment. Each trial aims to recruit ~586 patients, 18–50 years old, treated with 1–2 antipsychotic medications (≥ 12 weeks on current drug; ≥ 35 days on current dose prior to treatment), who have functional impairment in day-to-day activities and interact ≥ 1 hr per week with a designated study partner. Patients with cognitive impairment due to developmental, neurological or other disorders, or receiving cognitive remediation therapy within 12 weeks prior to screening, will be excluded. Participants will be recruited from 41 countries in Asia, Australia, New Zealand, North and South America and Europe, and randomised 1:1 to receive either oral iclepertin 10 mg (n=293) or placebo (n=293) once-daily over 26 weeks. The primary efficacy endpoint is change from baseline in the MATRICS Consensus Cognitive Battery (MCCB) overall composite T-score. Key secondary efficacy endpoints are change from baseline in Schizophrenia Cognition Rating Scale total score and change from baseline in the adjusted total time in the Virtual Reality Functional Capacity Assessment Tool. Long-term safety and tolerability data will be collected in an open-label safety extension study (CONNEX-X).

Results: The studies are currently recruiting (first participants were enrolled Aug–Sept 2021), with completion expected in Quarter 1 of 2025. Here we present an overview of the current study status, including any information relating to screening failures and the experience of collecting these data as part of a large multicountry, multicentre study.

Discussion: To date, most large, industry-sponsored studies testing various compounds to address cognitive function have failed to show proof-of-clinical concept. Demonstration of efficacy of iclepertin in improving cognition in this Phase III programme would provide important insight into the role of glutamate in cognitive symptoms, that may also have relevance for other cognitive disorders. Iclepertin may represent the first efficacious medication for cognitive impairment associated with schizophrenia.

This study is funded by Boehringer Ingelheim (NCT04846868, 1346-0011; NCT04846881, 1346-0012; NCT04860830, 1346-0013).

T107. THE EFFICACY OF LUMATEPERONE 42 MG IN THE TREATMENT OF SCHIZOPHRENIA SYMPTOMS ASSOCIATED WITH SOCIAL FUNCTIONING: POST HOC ANALYSIS OF AN ACUTE PLACEBO- AND ACTIVE-CONTROLLED TRIAL

Philip Harvey¹, Suresh Durgam², Jason Huo², Hassan Lakkis², Tobie Escher², Kimberly E Vanover², Robert E Davis², John Edwards^{*3}

¹Miller School of Medicine, University of Miami, ²Intra-Cellular Therapies, Inc, ³Intra-Cellular Therapies, Inc.

Background: Deficits in social functioning are a core feature of schizophrenia and may be due to the interaction of multiple factors including negative symptoms, mood states, and

deficits in social cognition. Social and functional impairment in schizophrenia can be difficult to treat, commonly does not correlate with improvements in psychotic symptoms, and has been associated with poor long-term patient outcomes. Lumateperone is an FDA-approved antipsychotic to treat schizophrenia and depressive episodes associated with bipolar I or bipolar II disorder. Lumateperone is mechanistically novel, simultaneously modulating serotonin, dopamine, and glutamate neurotransmission. In a Phase 2, randomized, double-blind, placebo- and active-controlled trial (Study 005, NCT01499563), lumateperone 42 mg significantly improved schizophrenia symptoms compared with placebo and had a favorable safety profile in adults with an acute exacerbation of schizophrenia. This post hoc analysis of Study 005 evaluated the effects of lumateperone 42 mg on schizophrenia symptoms associated with social function by the Positive and Negative Syndrome Scale (PANSS)-derived Prosocial factor (PANSS items P3, P6, N2, N4, N7, G16), which has been utilized previously to evaluate the efficacy of various antipsychotics on this functional domain.

Methods: Eligible adults (18-55 years, inclusive) with an acute exacerbation of schizophrenia were randomized to 28-day inpatient treatment with lumateperone 42 mg, placebo, or risperidone 4 mg. Change from baseline in the PANSS Prosocial factor was assessed in the intent-to-treat (ITT) population and in patients with prominent negative symptoms (PNS, score ≥ 4 on ≥ 3 negative symptom items) or moderate-to-severe depression symptoms (Calgary Depression Scale for Schizophrenia [CDSS] ≥ 6) at baseline. Inferential analysis was conducted using a mixed-effects model for repeated measures.

Results: The ITT population comprised 231 patients (placebo, $n=80$; lumateperone 42 mg, $n=76$; risperidone 4 mg, $n=75$); the PNS and CDSS ≥ 6 populations comprised 110 and 54 patients, respectively. Lumateperone 42-mg treatment was associated with significantly greater improvement compared with placebo on the PANSS Prosocial factor at Day 28 (least squares mean difference vs placebo [LSMD], -2.7 ; $P < .001$). Risperidone also was superior to placebo on the PANSS Prosocial factor (LSMD, -1.8 ; $P < .05$). Similar treatment effects for lumateperone 42 mg were seen on the PANSS Prosocial factor in patients with PNS at baseline (LSMD, -2.6 ; $P < .01$). Conversely, in patients with PNS, risperidone treatment showed small and non-significant treatment effects on the PANSS Prosocial factor (LSMD, -0.4 ; $P=.707$). In patients with moderate-to-severe depression symptoms at baseline, marked and significant improvements on the PANSS Prosocial factor were seen in lumateperone-treated patients (LSMD, -4.9 ; $P < .001$) but not in risperidone-treated patients (LSMD, -1.3 ; $P=.397$).

Discussion: Lumateperone 42 mg significantly improved socially-relevant schizophrenia symptoms in patients with an acute exacerbation of schizophrenia. In contrast to risperidone, lumateperone was associated with similar or greater treatment effects on the PANSS Prosocial factor in patients with PNS or moderate-to-severe depression symptoms at baseline. These results suggest that lumateperone has benefits on schizophrenia symptoms associated with social function with multiple potential means of influence.

T108. DESIGN OF A POTENTIALLY PIVOTAL, PHASE 3, INTERNATIONAL, RANDOMIZED, DOUBLE-BLIND, PLACEBO-CONTROLLED CLINICAL TRIAL EVALUATING EVENAMIDE AS ADD-ON TREATMENT FOR TREATMENT-RESISTANT SCHIZOPHRENIA (TRS) PATIENTS

Ravi Anand^{*1}, Alessio Turolla², Giovanni Chinellato³, Francesca Sansi², Rodolfo Giuliani², Richard Hartman⁴

¹Anand Pharma Consulting, ²Newron Pharmaceuticals SpA, ³Newron pharmaceuticals, ⁴NeurWrite LLC

Background: Treatment resistant schizophrenia is associated with higher hospitalization rates, comorbidity, suicidality, and mortality (Solanki et al., 2009; Pompili et al., 2017). Most patients with TRS are maintained on antipsychotic (AP) polypharmacy, despite evidence that this strategy is not effective but increases side effects (Pandarakalam et al., 2019). Increasing evidence suggests that glutamatergic abnormalities, rather than excessive dopamine synthesis, are noted in these patients; such findings are confirmed by neuroimaging studies in TRS patients (Demjaha et al., 2014). This may explain the failure of 5HT₂/D₂ antipsychotics to produce a beneficial response in TRS patients and suggest that glutamate modulation may constitute a promising therapeutic alternative (Potkin et al., 2020).

Evenamide, an orally available NCE, is a voltage-gated sodium channel blocker devoid of biological activity at GREATER THAN 130 CNS targets. Pre-clinical studies demonstrated its efficacy in normalizing excessive glutamate release induced by aberrant sodium channel activity, without affecting basal glutamate levels. Evenamide was associated with benefit in animal models of psychosis, both as monotherapy and add-on to 5HT₂/D₂-blocking APs, suggesting synergies in mechanisms that could be beneficial for patients responding poorly to APs (Anand et al., 2018). Increasing and sustained benefit of evenamide in TRS patients has been demonstrated across all efficacy measures (PANSS, CGI-S, CGI-C and LOF) in a pilot, phase II, open-label, rater-blinded, 1-year study, in addition to a substantial proportion of patients meeting a clinically important level of response up to 1 year (Anand et al., 2023).

Methods: Study 016 is a prospective, potentially pivotal, phase 3, randomized, double-blind, placebo-controlled, 1-year international study that will evaluate the efficacy and tolerability of evenamide as add-on treatment in TRS patients. Eligible patients will be randomized equally to either two fixed doses of evenamide (15 and 30 mg bid) or placebo. The study will enrol GREATER THAN 500 patients diagnosed with TRS according to the TRIP criteria (Howes et al., 2017), requiring a history of failure on at least 2 APs (2 different chemical classes; at least one second-generation AP) given at therapeutic doses for an adequate period (GREATER THAN =6 weeks); moreover, the 6-week screening period will confirm treatment-resistance by determining plasma levels of the background AP to ensure compliance with treatment. Selection criteria include schizophrenia diagnosis (DSM-V-TR), CGI-S score 3-6; BPRS total score GREATER THAN 45, with a score GREATER THAN =18 on positive symptoms of psychosis, and PANSS total score GREATER THAN 70. Patients will be enrolled based on acceptability of their screening data by an Independent Eligibility Committee. Patients improving GREATER THAN =20% on the BPRS or GREATER THAN =1 category on the CGI-S during the 6 week screening period will be excluded. Plasma levels of the background APs and study medication will be determined at selected visits. Efficacy and safety will be evaluated at regular intervals, with the pivotal efficacy endpoint at Week 12 and long-term efficacy endpoints at Week 26 and Week 52.

Efficacy measures include: PANSS total, CGI-S, CGI-C, Q-LES-Q-SF and PSP scales, assessment of cognition and pharmacoeconomic outcomes. Safety measures include vital signs, ECG, laboratory tests, physical/neurological/eye examinations, ESRS-A, CDSS, and C-SSRS.

Results: The results of the study will demonstrate if evenamide, a selective modulator of excessive glutamate release, can benefit TRS patients receiving adjunctive APs, thus confirming the benefit seen in the 1-year pilot study.

Discussion: Positive results from this phase 3 study could change the current management of TRS patients, demonstrating the effectiveness of glutamate modulation as a new therapeutic strategy for this condition.

T109. EFFECT OF PSYCHOACTIVE DRUGS ON NATURAL LANGUAGE PROCESSING MARKERS OF SPEECH: A SYSTEMATIC REVIEW

Sachin Ahuja*¹, Farida Zaher², Lena Palaniyappan³

¹*Schulich School of Medicine and Dentistry*, ²*McGill University*, ³*Douglas Mental Health University Institute*

Background: Language disturbance is a core component of psychosis, and natural language processing (NLP) analysis of speech is promising for the clinical assessment of psychosis patients. Psychoactive drugs including psychedelics, cannabinoids, entactogens and psychostimulants can exert symptoms and speech effects similar to those of psychosis, thus are a potential complication to NLP-based assessment of patients with psychosis symptoms. This systematic review summarizes the effects of those psychoactive drugs on NLP markers, providing an important comparative reference for research and implementation of NLP in psychosis.

Methods: We systematically searched the Medline and Embase databases in June of 2023 and included studies that report natural language processing analyses of psychoactive drug-influenced speech collected in controlled settings. This included drugs from psychedelic, hallucinogen, entactogen, cannabis/cannabinoid, and psychostimulant classes.

Results: 15 studies were included, revealing that psychoactive drugs induce diverse speech alterations. Findings include that ketamine can increase repetitiveness and decrease verb density; LSD has complex effects suggesting simpler, more disconnected language; MDMA can increase cognitive process words and semantic proximity to concepts like friend and empathy; psychostimulants like methamphetamine and d-amphetamine can increase verbosity and decrease pause duration; and cannabis affects vowel production.

Discussion: Replication studies are required to confirm the effects of psychoactive drugs on NLP markers to complement ongoing research on NLP in psychosis management.

T110. LONGITUDINAL DYNAMICS OF THE TRANSDIAGNOSTIC PRODROME TO SEVERE MENTAL DISORDERS: A TEMPORAL NETWORK ANALYSIS INFORMED BY NATURAL LANGUAGE PROCESSING AND ELECTRONIC HEALTH RECORDS

Maite Arribas*¹, Joseph M Barnby², Rashmi Patel³, Robert McCutcheon⁴, Daisy Kornblum⁵, Hitesh Shetty⁵, Kamil Krakowski⁶, Daniel Stahl⁷, Nikolaos Koutsouleris⁸, Philip McGuire⁹, Paolo Fusar-poli¹⁰, Dominic Oliver⁹

¹*Kings College London*, ²*Royal Holloway University of London*, ³*Institute of Psychiatry, Psychology and Neuroscience, King's College London*, ⁴*Institute of Psychiatry, Psychology and Neuroscience*, ⁵*BRC Nucleus, South London and Maudsley NHS Foundation Trust*, ⁶*Department of Brain and Behavioural Sciences, University of Pavia*, ⁷*Institute of Psychiatry, Psychology and Neuroscience, King's College London*, ⁸*Ludwig-Maximilian-University*, ⁹*University of Oxford*, ¹⁰*King's College London and University of Pavia*

Background: Modelling the prodrome to severe mental disorders (SMD), including unipolar mood disorders (UMD), bipolar mood disorders (BMD) and psychotic disorders (PSY), should consider both the dynamics of symptoms and substance use (prodromal features), and their interactions over time. This need can be addressed by employing a network analysis, where each prodromal feature is a node and the connections (edges) between nodes indicate the predictive strength of these features over time. The centrality of nodes – their interconnectedness – could reveal insights into which symptoms most strongly predict the onset of disorders and identify potential intervention targets. We aimed to construct a global transdiagnostic SMD network, capturing the temporal relationships among 65 prodromal features. Our secondary aim was to compare diagnosis-specific sub-networks using permutation analysis.

Methods: We analysed a cohort from the South London and Maudsley NHS Foundation Trust (SLaM) Electronic Health Record (EHR) who were diagnosed with an SMD. Using validated natural language processing (NLP) algorithms, we extracted the occurrence of 65 prodromal features every three months from two years before to six months before SMD onset. To construct temporal networks of prodromal features, we employed Generalized Vector Autoregression (GVAR) panel analysis, adjusting for age, gender, ethnicity, and medication at diagnosis, and the frequency and length of EHR entries at each follow-up point. In each network, the strength of connections between features (edge weights) was estimated as correlation coefficients (z), and categorised into 3 types: autocorrelative (node predicts itself in the next time point), unidirectional (node predicts another, without reciprocation) and recursive (mutual prediction between two nodes). Centrality was calculated as the sum of edge weights leaving (out-centrality, c -out) or entering (in-centrality, c -in) a node. To assess if there were statistically significant differences in the edge weights across the three sub-networks (UMD, BMD, PSY) we conducted a permutation analysis, with p -values adjusted for multiple comparisons.

Results: The final sample consisted of 7,049 individuals (UMD:2,306, BMD:817, PSY:3,926). The global SMD network showed the strongest autocorrelation for tearfulness ($z=.10$), unidirectional positive relationships for irritability-agitation ($z_{12}=.03$) but not in the opposite direction ($z_{21}=.01$), mood instability-tearfulness ($z_{12}=.03$, $z_{21}=.01$) and irritability-aggression ($z_{12}=.03$, $z_{21}=.01$). Concerning recursive edges, positively recurring pairs were observed for aggression-hostility ($z_{12}=.04$, $z_{21}=.03$), delusions-hallucinations ($z_{12}=.04$, $z_{21}=.03$) and aggression-agitation ($z_{12}=.03$, $z_{21}=.03$). The most central features included aggression (c -out=.082) and tearfulness (c -in=.124). From the PSY network, positive psychotic symptoms were involved in the strongest unidirectional (hallucinations-disturbed sleep, $z_{12}=.04$, z_{21} LESS THAN 0.05) and recursive (delusions-hallucinations, $z_{12}=.04$, $z_{21}=.03$) edges, whilst agitation (c -out=.117) and aggression (c -in=.139) were highly central. From the permutation analysis, PSY showed few significant differences in edge weights compared to UMD (0.04%) and BMD (0.02%).

Discussion: This study represents the most extensive network analysis to date on the dynamic interplay of prodromal features in SMD. Our findings support the potential of transdiagnostic early detection services, provide potential targets for future interventions and underlines the importance of understanding dynamic symptom changes.

T111. DISORGANIZATION INDEX: MEASURING THE LOSS OF NARRATIVE COMPLEXITY DUE TO NEGATIVE SYMPTOMS

Marina Ribeiro*¹, Bárbara Malcorra², Tamara Meletti², Luísa Jensen², Natália Mota³

¹*Federal University of Rio Grande do Nortmarin*, ²*Mobile Brain*, ³*Federal University of Rio de Janeiro*

Background: In the past decade, the use of natural language processing tools has helped track language oddities under psychosis, but the use for clinical practice needs to understand and disentangle confounding factors, such as access to formal education. Word-recurrence graphs could map the increased narrative complexity during typical development, with an essential input of formal education. By mastering grammar and syntax rules from the academic use of the language, narratives change from a short-range recurrence to a long-range recurrence pattern. Still, in the course of psychosis, there is an abrupt decrease in this connected pattern (mainly a decrease in long-range recurrences). Here, we aim to verify how we can use word-recurrence graphs applied to emotional narratives to define predictive indexes considering typical development (weighted by years of education) and atypical development (weighted by severity of negative symptoms).

Methods: We interviewed a diverse sample of 232 participants: 65 with psychotic symptoms, 167 without psychosis, spanning from 2 to 60 years old, and none to more than 20 years of education. They narrated emotional stories (such as dreams or stories based on affective pictures) that were recorded and transcribed to be represented as a word-recurrence graph (each word was considered a node, and directed edges represented the sequence). We used sliding windows of 30 words to control for verbosity differences, with a 50% overlap between windows. We then calculated the number of Nodes (proxy to lexical diversity), repeated edges – RE (or short-range recurrence), nodes inside the largest strongly connected component – LSC (connectedness or long-range recurrence), average shortest path – ASP (graph size), and their similarities to a random graph distribution of graphs (by shuffling the word trajectories 100 times per window). Narrative complexity (NC) was defined as a multilinear correlation between word-recurrence graph attributes and years of formal education (proxy of typical development of language in contact with written language), and a multilinear correlation with the total of negative PANSS subscale defined Disorganization Index (DI). Then, we defined a normative curve by years of education for NC and severity in the negative PANSS subscale for DI, returning a comparative index in percentiles. We used a Naive Bayes classifier to find a cutoff of loss of narrative complexity (related to formal education) to predict the risk of psychosis, using both information from NC and DI as predictors. We also studied the association between both indexes and descriptive comparisons between groups.

Results: As predicted, there was a significant association between word-recurrence graph attributes and the severity of negative symptoms (Multilinear Regression: $R^2 = 0.34$, $p = 0.0088$). Using the percentiles of NC and DI, we found a cutoff: A narrative complexity (NC) below the 20th percentile was informative of the risk of psychosis with 75% accuracy, with more than 90% sensitivity for the group under psychosis. NC and DI also had a negative association (Spearman correlation: $Rho = -0.31$, $p \text{ LESS THAN } 0.0001$).

Discussion: As initially predicted, under psychosis, the narrative complexity drops below what was expected by years of formal education. These results point to a loss of narrative complexity associated with symptomatology (the more the impact of negative symptoms in narratives (the higher disorganization index), the lower the narrative complexity). This allows for measuring the impact of symptoms in communication patterns, which is clinically helpful for follow-up patients in psycho-social recovery.

T112. MACHINE LEARNING APPLICATIONS FOR THE IMMUNE PROFILING AND STRATIFICATION OF FIRST EPISODE PSYCHOSIS

Paolo Enrico^{*1}, Giuseppe Delvecchio², Nunzio Turtulici², Marcella Bellani³, roberto furlan⁴, Paolo Brambilla⁵

¹University of Milan, ²IRCCS Ca' Granda, Ospedale Maggiore Policlinico, Milano, ³Section of Psychiatry, Azienda Ospedaliera Universitaria Integrata Verona, ⁴San Raffaele Hospital, ⁵University of Milan

Background: Psychosis onset is a transdiagnostic event that leads to a range of psychiatric disorders, which are currently diagnosed through clinical observation. The integration of multimodal biological data could reveal different subtypes of psychosis onset to target for the personalization of care. In this study, we tested the existence of subgroups of patients affected by first-episode psychosis (FEP) with a possible immunopathogenic basis.

Methods: To do this, we designed a data-driven unsupervised machine learning model to cluster a sample of 127 FEP patients and 117 healthy controls (HC), based on the peripheral blood expression levels of 12 psychosis-related immune gene transcripts. To validate the model, we applied a resampling strategy based on the half-splitting of the total sample with random allocation of the cases. Further, we performed a post-hoc univariate analysis to verify the clinical, cognitive, and structural brain correlates of the subgroups identified.

Results: The model identified and validated two distinct clusters: 1) a FEP cluster characterized by the high expression of inflammatory and immune-activating genes (IL1B, CCR7, IL12A and CXCR3); 2) a cluster consisting of an equal number of FEP and HC subjects, which did not show a relative over or under expression of any immune marker (balanced subgroup). None of the subgroups was related to specific symptoms dimensions or longitudinal diagnosis of affective vs non-affective psychosis. FEP patients included in the balanced immune subgroup showed a thinning of the left supramarginal and superiorfrontal cortex (FDR-adjusted p-values LESS THAN 0.05).

Discussion: Our results demonstrated the existence of a FEP patients' subgroup identified by a multivariate pattern of immunomarkers involved in inflammatory activation. This evidence may pave the way to sample stratification in clinical studies aiming to develop diagnostic tools and therapies targeting specific immunopathogenic pathways of psychosis.

T113. MODELLING DECISION-MAKING IN A TRANSDIAGNOSTIC SAMPLE TO INVESTIGATE DISEASE SPECIFIC AND DISEASE GENERAL ALTERATIONS

Pritha Sen^{*1}, Franziska Knolle², Adam Culbreth³, Kathrin Koch², Felix Brandl⁴

¹Technische Universitat Munchen, ²Technical University of Munich, ³Maryland Psychiatric Research Center, University of Maryland School of Medicine, ⁴Department of Psychiatry and Psychotherapy, Technical University of Munich, School of Medicine

Background: Alterations in decision-making have been suggested to underlie different psychiatric illnesses, such as schizophrenia, depressive disorder (MDD), and obsessive-compulsive disorder (OCD). Studies report overlapping and divergent alterations in individuals diagnosed with those disorders and have been linked to symptoms of the respective disorders. As these disorders often co-occur, it is crucial to disentangle alterations in decision-making that are unique to specific disorders, from those that occur across diagnostic boundaries. Recent developments in computational modelling enable a

mechanistic deconstruction of decision-making processes, facilitating the identification of disease specific and disease general alterations. Therefore, to understand how decision-making alterations relate to disease specific as well as symptoms that occur across a range of psychiatric disorders (such as anhedonia, depression), we conducted a transdiagnostic study using two computational modelling approaches to a two-step Markov decision task combining individuals diagnosed with schizophrenia, OCD and MDD.

Methods: In this study, three patient groups—schizophrenia (in remission) (n=27), OCD (n=25), MDD (n=23)—and healthy controls (n=25) completed a behavioral two-step reinforcement learning task distinguishing habitual (model-free) and goal-directed (model-based) decision-making. We used two computational modelling methods hierarchical logistic regression, capturing independent contributions of choices at the subject level; and hierarchical Bayesian modelling where we employed four differently complex models exploring different parameters underlying model-free and model-based belief updating. The winning model, selected based on the lowest leave-one-out information criterion, featured six parameters, allowing investigation of learning rate, inverse temperature (decision-noise) at both stages, perseverance (repetitiveness), and model-based weight (model-based relative to model-free behavior).

Results: The results revealed an overall reliance on model-free decision-making behavior across all groups compared to healthy controls. Additionally, schizophrenia patients exhibited the lowest learning rate in stage one and the highest switching rate (lowest perseverance) compared to other groups. were more random in their response profiles than controls in stage two, with schizophrenia patients showing the highest levels of randomness, while OCD patients were additionally more random in stage one compared to controls and MDD patients. Importantly, the findings indicated a correlation between increased model-free behavior and elevated depressive symptoms, while more model-based choices were associated with lower levels of anhedonia across all patients.

Discussion: This study demonstrates significant disease-specific and general decision-making alterations in individuals with MDD, OCD, and schizophrenia, with the most pronounced deficits observed in schizophrenia. Completely random choice behavior on the two-step task may serve as a useful indicator for schizophrenia patients in remission, though further exploration is needed. Additionally, the results suggest that impaired decision-making behaviors are linked to depressive and anhedonia symptoms across all patient groups, indicating a shared behavioral mechanism as a potential starting point for behavioral interventions. Taken together, this underscores the potential of transdiagnostic studies to identify important avenues for interventions in psychiatric disorders.

T114. ONLINE X OFFLINE INTERVIEWS: FEASIBILITY OF REMOTE NLP-BASED ASSESSMENTS ON SSD

Renato Piccolo^{*1}, Matheus Carvalho¹, Diego Augusto Soares², Ana Clara Accioly³, Natália Bezerra Mota²

¹Federal University of Rio de Janeiro, Faculty of Medicine, ²Federal University of Rio de Janeiro; Research Department at Mobile Brain, ³Columbia University

Background: Psychosis is a common psychiatric syndrome shared by many mental disorders, of which Schizophrenia is the most prevalent. Its symptoms vary greatly and are characterized by but not limited to altered perception of reality, emotional disturbance, disorganized thought, impaired insight, and disruption in social functioning. The diagnosis of psychotic disorders are often difficult, resource, and time-consuming, often demanding long-

term observation of the condition's evolution, making its treatment hard especially in remote or impoverished communities. Computational psychiatry has emerged as a new tool to facilitate the diagnosis of Schizophrenia and other psychiatric conditions through word recurrence graph analysis (speech-graphs) of standardized interviews yet in development. In addition, conducting such interviews at a distance could make extending specialized psychiatric care to remote locations easier. The present study aims to investigate possible differences in the word-recurrence graph connectedness of the discourse of patients under psychosis obtained in remote (Online) and in-person (Offline) settings, which could be a significant limitation to the use of telemedicine in computational psychiatry.

Methods: We interviewed 20 patients with a diagnosis of chronic psychosis in SSD (7 females) in two conditions: offline (face-to-face interview) and online (remote interview through Google Meet), in a random order. In both conditions, the interviewer asked the participants to report affective narratives (such as dreams reports, as well as stories based on positive affective pictures), and non-affective reports (such as daily activities). All the reports were orally recorded, transcribed, and represented as word-recurrence graphs (nodes represented different words, and directed edges represented word sequence in a narrative). To control for verbosity differences, we used sliding windows of 30 words.

Results: Neither affective nor non-affective reports presented significant differences in narrative connectedness related to different conditions (online or offline interviews). Although not significant, dream reports showed a trend: higher connectedness related to lexical diversity (nodes in LCC) in offline interviews (face-to-face) compared to online conditions (Google Meet interview) (Offline LCC 23.12 ± 0.02 , Online LCC 22.28 ± 0.02 , $p = 0.0583$), different from affective image reports (Offline LCC 22.85 ± 0.02 , Online LCC 22.10 ± 0.02 , $p = 0.0835$) and daily reports (Offline LCC 24.06 ± 0.01 , Online LCC 23.42 ± 0.01 , $p = 0.4566$).

Discussion: The results point to a feasible solution that allows for a remote assessment of oral narratives. It is important to consider that the small sample size is an important limitation in this cohort, and to possible differences related to the nature of the narrative topic. However, in low-income countries, digital mental health solutions could add to the increment of mental health assessment in isolated locations, reducing the burden of not having mental health specialists to cover larger and remote areas.

T115. "ASK" VS. "INQUIRE": QUANTIFYING LEXICAL COMPLEXITY IN PSYCHOSIS USING WORD ETYMOLOGIES

Matthew Cotter^{*1}, Alessia McGowan¹, Zarina Bilgrami², Cansu Sarac³, Johanna Bayer⁴, Jessica Spark⁵, Marija Krcmar⁴, Melanie Formica⁵, Kate Gwyther⁴, Jessica A Hartmann⁵, Sophia Shuster¹, Alexandria Selloni¹, Jai Shah⁶, Shaynna Herrera¹, Patrick McGorry⁵, Alison Yung⁷, Barnaby Nelson⁵, Romina Mizrahi⁶, Guillermo Cecchi⁸, Stephen Heisig¹, Cheryl Corcoran¹, Agrima Srivastava¹

¹Icahn School of Medicine At Mount Sinai, ²Emory University, ³Long Island University, ⁴University of Melbourne, ⁵Orygen Youth Health Research Centre, ⁶McGill University, ⁷Deakin University, ⁸IBM Research

Background: Individuals with psychotic symptoms have less complex language. This deficit may be related to greater use of short, common words of Proto-Germanic origin (eg, “ask,” “old”) vs. more formal Old French/Latinate words (“inquire,” “ancient”). We hypothesized that individuals with early course psychosis (ECP) possess less lexical diversity and use

relatively more words with Proto-Germanic etymology and fewer with Old French/Latinate etymology, and that these features are related. We expected that those at clinical high risk for psychosis (CHR) would have findings intermediate between that of healthy comparisons (HC) and those with ECP.

Methods: We studied a cohort of 92 individuals with ECP, 144 CHR individuals, and 173 HC subjects, similar in demographics. The data were collected as part of an R01 that aimed to assess group differences and population variance in coherence and complexity of spoken language during open-ended interview. Interviews were transcribed and pre-processed using standard measures, including lemmatization, the conversion of different word inflections to the same basic inflection (e.g. “is”, “am” both become “be”). Only nouns, adjectives, verbs and adverbs were retained for analysis as etymology of filler words or articles such as “the” was not a focus. For etymology, we used both Etymonline and Wiktionary, ultimately focusing on Wiktionary as both its Germanic and Old French etymology were highly correlated with one another ($r = 0.99$), and because Wiktionary data was more structured in its presentation and more reliable to parse. To assess associations of speech etymology with lexical diversity, we also calculated Brunet and Honore statistics from transcripts, which are calculated using the number of unique words spoken and the total length of speech elicited. Brunet’s Index uniquely includes the number of words spoken exactly once in its calculation. Linguistic metrics of etymology were also evaluated for associations with demographics, including IQ.

Results: Our main hypotheses were supported in analyses that adjusted for age, sex, recruitment site and education. Namely, individuals with ECP used fewer words of Old French origin ($p < .01$) and more words of Germanic origin ($p < .01$), as compared with HC. Interestingly, the same pattern was found for CHR individuals as compared with HC, with fewer words of old French origin ($p < .01$) and more words of Germanic origin ($p < .01$). Further, these comparisons remained ($p < .01$) for Germanic and Old French for both ECP and CHR individuals) even when adjusting for IQ in the subset ($n = 270$) of individuals who had IQ testing available. Additionally, IQ had a positive correlation with old French word use ($r = 0.2$, $p < .02$), and a negative correlation with Germanic word use ($r = -0.3$, $p < .01$). Lexical diversity was also reduced in both ECP and CHR individuals, as compared with HC, using both Honore’s Statistic and Brunet’s Index (all p ’s $< .05$). Like IQ, lexical diversity had a positive correlation with Old French use (e.g., Honore: $r = 0.33$, $p < .01$) and a negative correlation with Germanic word use ($r = -0.35$, $p < .01$).

Discussion: Lower rates of Old French word use may indicate less use of sophisticated words and may be related to differences in intended speech formality. Also, CHR individuals were more similar to ECP than HC in terms of speech etymology content and lexical diversity. Speech etymology may be a trait marker of psychosis risk, and this may indicate that lexical features have utility for predicting risk for symptom worsening. For future directions, we hope to examine the specificity of this finding to schizophrenia and how speech etymology content may vary in different speaking contexts.

T116. COGNITIVE MODELLING OF THE INTRA-EXTRA DIMENSIONAL SET SHIFT TASK IN CHILDREN AT FAMILIAL HIGH RISK OF SCHIZOPHRENIA OR BIPOLAR DISORDER

Arndis Simonsen*¹, Oskar Hougaard Jefsen², Nicoline Hemager³, Ditte Lou Gantriis⁴, Birgitte Klee Burton⁵, Ditte Ellersgaard⁶, Kerstin J. Plessen⁷, Anne A.E. Thorup⁸, Jens Richardt Møllegaard Jepsen⁹, Merete Nordentoft¹⁰, Ole Mors¹¹, Aja Neergaard Greve¹², Riccardo Fusaroli¹³

¹Psychosis Research Unit, Aarhus University Hospital, ²Psychosis Research Unit, Aarhus University Hospital, Central Denmark Region, ³Research Unit at Mental Health Center and The Lundbeck Foundation Initiative for Integrative Psychiatric Research (iPSYCH), ⁴The Lundbeck Foundation Initiative for Integrative Psychiatric Research, Psychosis Research Unit, Aarhus University Hospital, ⁵Child and Adolescent Mental Health Centre, Copenhagen University Hospital, ⁶Copenhagen Research Centre for Mental Health (CORE), Mental Health Centre Copenhagen, Copenhagen University Hospital, ⁷Research Unit at Child and Adolescent Mental Health Center and The Lundbeck Foundation Initiative for Integrative Psychiatric Research (iPSYCH), ⁸Mental Health Services – Capital Region of Denmark, Child and Adolescent Mental Health Centre and The Lundbeck Foundation Initiative for Integrative Psychiatric Research, iPSYCH, ⁹Copenhagen Research Center for Mental Health – CORE; The Lundbeck Foundation Initiative for Integrative Psychiatric Research (iPSYCH); Child and Adolescent Mental Health Center, University of Copenhagen; Center for Clinical Intervention and Neuropsychiatric Schizophrenia Research (CINS) and Center for Neuropsychiatric Schizophrenia Research (CNSR), ¹⁰Mental Health Services - Capital Region of Denmark, Mental Health Centre Copenhagen, The Lundbeck Foundation Initiative for Integrative Psychiatric Research, University of Copenhagen - Faculty of Health and Medical Sciences, ¹¹The Lundbeck Foundation Initiative for Integrative Psychiatric Research (iPSYCH); Psychosis Research Unit, Aarhus University Hospital, ¹²Psychosis Research Unit, Aarhus University Hospital Psychiatry, ¹³Department of Linguistics, Semiotics and Cognitive Science, The Interacting Minds Center - Institute of Culture and Society,

Background: Deficits in executive functions have been suggested as intermediate phenotypes of schizophrenia and bipolar disorder. The Intra-Extra-Dimensional Set Shift task (IED) is widely used to measure executive functioning, in particular cognitive flexibility. However, traditional performance measures of the IED conflate general learning and attention shifting. Explicit cognitive modelling formalizing different cognitive processes at stake can help disentangle potential impairments. This is crucial to get a better understanding of the cognitive underpinnings of these mental disorders.

Methods: In this study, we investigated cognitive flexibility in children of parents with schizophrenia or bipolar disorder. We relied on data from the Danish High-Risk and Resilience Study VIA7, a multisite population-based cohort of 7-year-old children extracted from the Danish registries. Participants included 186 children at familial high risk of schizophrenia (FHR-SZ), 114 children at familial high risk of bipolar disorder (FHR-BP) and 196 population-based controls. Learning and attention shifting were assessed with the IED. We implemented Bayesian multilevel versions of two sequential learning models in Stan based on Talwar et al. (2021) and Yearsley et al. (2021), with partial pooling only within group. The first model considers each feature separately and includes a simple learning rate applied to each of them. The second model includes separate learning rates for positive and negative feedback, as well as a measure of attention shift between dimensions as a function of feedback. Model comparison relied on estimated Leave-One-Out out-of-sample predictive error.

Results: The model including learning rate from positive and negative feedback, and extra-dimensional attention shift was reliably the best model across all three groups. Extra-dimensional attention shift was generally low (circa 0.01) and not reliably different across groups (ERs LESS THAN 3 and GREATER THAN 0.3). Children generally learned more from negative (circa 0.4) than from positive feedback (circa 0.03). FHR-BP children presented reliably higher learning rates than the two other groups, albeit the effect was more reliable for learning from positive (0.02, se = 0.01, credibility: 0.91, ER= 10) than negative feedback (0.02, se = 0.03, credibility: 0.75, ER= 3). FHR-SZ children were not reliably distinguishable from population-based controls (ERs LESS THAN 3 and GREATER THAN 0.3).

Discussion: The results suggest that impairments in attention shifting, as measured with IED, are not identifiable at an early age in children at FHR-SZ or FHR-BP. However, the identified alterations in learning in children at FHR-BP, in particular positive feedback learning, may be related to symptoms such as impulsivity. The next step will be to identify whether the model-based parameters are related to relevant symptoms.

T117. REWARD-ORIENTED BEHAVIOR AND AMOTIVATION IN PATIENTS WITH EARLY PSYCHOSIS: AN EXPERIENCE SAMPLING STUDY

Vivian Shi Cheng Fung¹, Joseph Ching Yui Chan¹, Sandra Chi Yiu Wong¹, Corine Sau Man Wong¹, Wing Chung Chang^{*2}

¹The University of Hong Kong, ²University of Hong Kong

Background: Negative symptoms refer to deficits in motivation, experience of pleasure and/or emotional expression. It is a key target in early intervention among psychosis patients but remains to be an unmet therapeutic need. Experience sampling methodology (ESM) provides an opportunity to investigate momentary symptoms over time and their associated contextual factors. Although it has been shown to be a promising approach in measuring negative symptoms, including diminished motivation, it has rarely been applied to patients in early psychosis. The present study aimed to examine early psychosis patient's everyday experience of motivation and reward-oriented behaviors by comparing to that among healthy controls.

Methods: The ESM assessment lasted for 6 consecutive days, with 10 signals emitted each day. At each signal, participants were asked to complete a brief questionnaire that assessed momentary affect, current activity and social engagement, and their respective appraisals on pleasantness. Passive leisure activities such as watching TV, reading, browsing social media, and doing nothing or resting were considered as passive activities. All items were examined using multiple-choice questions and 7-point Likert scales. Prior to the start of the ESM assessment procedure, a short training session was held to explain the study procedures and to complete a practice survey. A total of 75 participants were recruited and provided ESM data. All patients were clinically stabilized and within 3 years of treatment in early intervention services for first-episode psychosis. Seven patients were excluded due to a low response rate (i.e., fewer than 20 valid responses). The final sample consisted of 33 early psychosis patients and 35 demographically matched healthy controls.

Results: Between-group comparison on the time spent in passive activities revealed a significantly increased engagement in passive activities among patients ($t=-5.09$, p LESS THAN 0.001). Reward-oriented behaviour was operationalized as the interaction between enjoyment and engagement for current activity at previous signal (i.e., $t-1$) was predictive of engagement in current activity at the present (i.e., t). Our results showed that engagement x

enjoyment at t-1 interaction was significant ($\beta=1.01$, $p < 0.001$) but no group differences were found in reward-oriented behaviour ($\beta=1.00$, $p=0.235$). The interaction effects remained unchanged after adjusting for educational attainment and employment status.

Discussion: We found that patients engaged in more passive activities compared to their matching controls. Our results suggest apparently intact activity-related reward-oriented behavior in early psychosis. Further research is required to verify our preliminary findings. Future investigation clarifying whether there is impairment in reward-oriented behavior in social contexts among patients with early psychosis.

T118. AN EXAMINATION OF RISK AND RESILIENCE FACTORS INFLUENCING PARANOIA ENDORSEMENTS ACROSS BLACK AND WHITE AMERICANS

J Wolny^{*1}, Jake Isenman², Alexandra Moussa-Tooks², Allen Bailey³, Angus MacDonald, III⁴, Joshua Mervis⁵, William P. Hetrick²

¹Indiana University, ²Indiana University-, ³Harvard Medical School/McLean Hospital, ⁴University of Minnesota, Department of Psychology, ⁵Temple University

Background: Paranoia has been demonstrated to be consistently elevated amongst Black Americans (e.g., Combs et al., 2002; Wolny et al., under review) with researchers positing that such elevations may reflect culturally compelled (i.e., adaptive) responses to systematic racial oppression and marginalization (Grier and Combs, 1980; Mosley et al., 2017). Researchers propose that such elevations may signify adaptive responses to systemic racial oppression and marginalization (Grier and Combs, 1980; Mosley et al., 2017). Despite this, there exists a notable dearth of quantitative research delving into the mechanisms underpinning these elevations, particularly within contemporary dimensional paranoia measures. The present investigation aims to address this gap by (i) exploring whether racial discrimination serves as a key explanatory factor driving the substantial increases in self-reported paranoia among Black Americans compared to their White counterparts, and (ii) investigating whether racial identification—a recognized protective factor among minority groups—may mitigate the potential relationship between racial discrimination and paranoia specifically among Black Americans.

Methods: A total of 921 individuals, self-identifying as either ‘Black/African American’ or ‘White,’ were recruited through Amazon’s Mechanical Turk (MTurk) using demographic filtering. The final analytical sample comprises 400 non-Hispanic White and 396 non-Hispanic Black participants who completed the R-GPTS, provided complete demographic data, and passed rigorous quality control checks. Research has shown that participants recruited through the MTurk platform are more demographically diverse and closely representative of the true American population compared to undergraduate samples (Buhrmester et al., 2011).

Results: Data analysis is currently underway, with the hypothesis that self-reported experiences of discrimination will partially mediate the relationship between race and self-reported paranoia. This supports the idea that experiences of discrimination act as a pivotal explanatory factor for the observed elevated levels of self-reported paranoia among Black Americans. Additionally, it is anticipated that racial identification will moderate the relationship between discrimination and paranoia among Black, but not White Americans, suggesting that high racial identification serves as a protective factor for Black Americans specifically.

Discussion: This research is poised to offer a more comprehensive and socioculturally informed exploration of paranoia across and within Black and White Americans. Such work is imperative for advancing equity in the conceptualization and measurement of the psychosis spectrum in ethnoracially diverse individuals.

T119. THE RELATIONSHIP BETWEEN SEXUAL DYSFUNCTION, SYMPTOMS, AND PSYCHOTROPIC SIDE EFFECTS AMONG INDIVIDUALS WITH SCHIZOPHRENIA

Pernille Kølbæk^{*1}, Ida Borg Hansen¹, Jonas Amstrup Riess¹, Marie Gamborg¹, Charlotte Hauge¹, David Dines¹, Yoon Fredriksen¹, Søren Dinesen Østergaard¹

¹*Psychosis Research Unit, Aarhus University Hospital - Psychiatry*

Background: Adverse sexual effects such as decreased libido, orgasmic dysfunction, and sexual arousal difficulties often accompany schizophrenia and are associated with reduced quality of life, which may contribute to reduced treatment adherence. Sexual dysfunction in this context may stem from the mental disorder itself (e.g., delusions with sexual content) and the use of psychotropic medications (e.g., prolactin-raising antipsychotics). Unfortunately, clinicians often under-recognize sexual dysfunction, and its investigation in clinical trials remains limited. The study aims to examine the relationships between sexual dysfunction and (i) positive and negative symptoms and (ii) side effects of psychotropic medications among individuals with schizophrenia.

Methods: A total of 80 participants will be recruited from the psychiatric outpatient clinics and bed units in the Central Denmark Region. Participants will be at least 18 years old, meet the ICD-10 diagnostic criteria for schizophrenia (F20.x), understand written and spoken Danish, and provide written informed consent. Patients will be ineligible to participate if they are subjected to coercive treatment measures, have an organic mental disorder or mental retardation or are under the influence of any substances of abuse. Participants will complete the Patient-Reported Outcomes Measurement Information System Sexual Function and Satisfaction Measure, the 5-item World Health Organization Well-being Index, the Aarhus Side effect Assessment Questionnaire, and the Trauma History Questionnaire. Subsequently, a trained clinician will interview and rate participants on the 6-item Positive And Negative Syndrome Scale and the Udvalg for Kliniske Undersøgelser psychotropic side effect scale. Finally, the temporal relationships between reported adverse sexual effects, symptoms, and psychotropic side effects will be evaluated through a semi-structured interview.

Results: The study is ongoing, with results expected in January 2024 and presentation at the SIRS 2024 conference.

Discussion: This study holds promise for advancing our understanding of the complex relationship between sexual dysfunction, symptoms, and psychotropic side effects in individuals with schizophrenia. The findings may provide insights for developing more comprehensive treatment approaches and enhancing overall quality of life.

T120. INVESTIGATING THE OVERLAP: AN OBSERVATIONAL STUDY ON AUTISM SPECTRUM DISORDER AND PSYCHOSIS IN ADULTS

Martina Pelle*¹, Yael Sonnino², Michele Ribolsi³, Federico Fiori Nastro², Damiano Elisa², Esposto Eleonora², Prosperi Porta Davide², Giuliano Albergo³, Di Lorenzo Giorgio², Corinto Fernando²

¹*Tor Vergata University of Rome*, ²*Tor Vergata University of Rome, Rome*, ³*Psychiatry Unit, Campus Bio-Medico University*,

Background: Autism Spectrum Disorder (ASD) is a neurodevelopmental disorder characterized by impairments in social interaction, communication, and restricted, repetitive patterns of behavior, interests, or activities. ASD exists on a continuum of clinical severity. Diagnostic criteria, initially formulated with a focus on childhood presentations, do not fully capture the nuanced manifestations in adults with ASD. Recognizing and identifying ASD requires a comprehensive understanding of the spectrum's diverse presentation across different age groups. Moreover, individuals with ASD frequently develop several comorbid psychiatric disorders, including psychotic disorders, which can impact the individual's quality of life, health, and prognosis. While traditionally viewed as discrete entities, emerging evidence suggests an intriguing intersection between ASD and psychosis; however, the overlap is not yet fully understood. This study aims to explore the interplay between ASD and other psychopathological dimensions in an adult clinical sample.

Methods: Data from 24 patients who accessed the psychiatry outpatient service of the University Campus Bio-Medico of Rome were collected. All patients were 18 years or older, and informed consent was obtained from all participants. Anamnestic interviews were conducted with the patients and their parents, when present and available. Additionally, all subjects underwent a battery of self-administered tests to investigate the presence of various psychopathological dimensions and comorbidities (BDI-II, PQ-16, ASI, LCB, SCL-90-R, CAPE, and AQ). Trained clinicians and researchers administered the Autism Diagnostic Observation Schedule (ADOS-2) Module 4 for adults to ascertain the diagnosis.

Results: The sample consists of 15 males (62.5%) and 9 females (37.5%) with a mean age of 28.2 years old (SD ± 8.33). Thirteen (54.2%) subjects fulfilled a diagnosis of ASD based on ADOS-2. A correlation matrix was performed to analyze and establish the relationship between measured variables, providing valuable insights into their interdependence and associations. Significant inverse correlations were observed between the 'Communication' dimension of ADOS and both the 'depressive frequency' and 'depressive distress' dimensions of CAPE ($r = -0.455$, $p = 0.044$, and $r = -0.460$, $p = 0.041$).

Discussion: This study presents preliminary data from ongoing research. Primary results show a statistically significant correlation between inadequacy in communication, observed by clinicians, and the frequency and distress of depressive manifestations, reported by patients with ASD. The recognition of psychosis in patients with ASD still represents a complex challenge even for expert psychiatrists, mostly due to phenotypical overlap between schizophrenia negative symptoms and autistic symptomatology. In this sense, a deep qualitative investigation of the subjective experience in ASD subjects and the investigation of the subjective feeling of depression might represent a valuable next step in achieving greater diagnostic accuracy. The small sample size, representing a major limitation, may affect the significance of the results. Further longitudinal studies are needed to expand the study's sample size and to follow up on the observed trends over an extended period, providing a more comprehensive understanding of the phenomena under investigation.

T121. NEGATIVE SYMPTOMS $\nrightarrow$ LOW SOCIAL FUNCTION

Rasmus Handest*¹, Ida-Marie Mølstrøm², Carsten Hjorthøj³, Mads Gram Henriksen⁴, Julie Nordgaard⁵

¹University of Copenhagen, ²Mental Health Center Amager, ³Copenhagen University Hospital, Mental Health Center Copenhagen, ⁴Mental Health Center Amager, Department of Clinical Medicine, Faculty of Health Sciences, University of Copenhagen, Denmark, ⁵Mental Health Centre Amager, Denmark. Department of Clinical Medicine, Faculty of Health Sciences, University of Copenhagen, Denmark

Background: Impaired social functioning in patients with schizophrenia is a crucial focus in psychiatry. The modern notion of recovery emphasizes both clinical and social remission, but the relationship between these two domains in patients with schizophrenia remains insufficiently explored. The prevailing model suggests that negative symptoms exert the most significant impact on social functioning. However, the empirical support for this hypothesis is uncertain. This study conducts a systematic review and meta-analysis to investigate the relationship between psychopathology and social functioning.

Methods: This systematic review and meta-analysis assessed cross-sectional data to examine the association between psychopathology and social functioning. We categorized social functioning into overall scores and subdomains (Socially useful activities, Personal and social relationships, and Self-care). We divided psychopathology outcomes into overall scores and subdomains (Positive symptoms, Negative symptoms, General symptoms, Disorganized symptoms, and Depressive symptoms). Univariate meta-regression was computed to examine the moderating effects of patient age or gender.

Results: We included 36 of 1,288 screened studies, comprising 4,742 patients with a mean age of 38.4 years, and 66.8% were men. All psychopathological domains exhibited a significant association with social functioning. No moderating effects of patient age or gender were observed.

The analysis of the association between overall social functioning and overall psychopathology revealed a negative correlation of -0.51 (95% CI [-0.63; -0.37]). All five psychopathological subdomains showed significant negative correlations ($P < .01$) with overall social functioning. Exploration of the association between subdomains of social functioning and psychopathology indicated that "Personal and social relationships" demonstrated associations with overall psychopathology ($P = 0.02$), positive and negative symptoms (both $P < 0.01$), but no association with depressive symptoms. "Socially useful activities" correlated with negative symptoms ($P < .001$), while "Self-care" showed associations with positive and negative symptoms (both $P < 0.01$).

Interpretation of the literature should be approached cautiously due to heterogeneity in results and measurement methods publication bias, and overlapping measures of psychopathology and social functioning. High heterogeneity was observed in results and measurement methods, with 13 different scales used to measure psychopathology. The study also indicated potential publication bias in the association between positive symptoms and overall social function. Measures of psychopathology and social functioning often overlapped, particularly for negative symptoms and general psychopathology.

Discussion: Contrary to the assertion that negative symptoms are the most significant symptom group regarding social functioning, our findings suggest that all examined symptom domains are significantly associated with social functioning. A possible interpretation is that the affected social functioning is not a consequence of a specific group of symptoms but

rather an integral part of the disease itself for some patients, akin to other symptom groups on par with the classical descriptions of autism by Bleuler or Minkowski.

T122. SOCIAL DEPRIVATION AS A SOURCE OF NEGATIVE SYMPTOMS OF SCHIZOPHRENIA: A SYSTEMATIC REVIEW

Silvia Monari^{*1}, Silvia Bolano², Matthias Kirschner², Stefan Kaiser², Michel Sabé²

¹*Division of Adult Psychiatry, University Hospitals of Geneva*, ²*Division of Adult Psychiatry, Department of Psychiatry, University Hospitals of Geneva*

Background: Schizophrenia is a persistent and disabling disorder characterized by positive, negative and cognitive symptoms. Negative symptoms treatment remains an unmet challenge. While primary negative symptoms are inherent to the disease, secondary negative symptoms can arise from various factors, including residual positive symptoms, antipsychotic side-effects, substance abuse, depression, and social deprivation. There is a lack of a systematic review exploring the association between social deprivation (or its perception, such as loneliness) and secondary negative symptoms. This study aims to fill this gap by investigating the relationship between social deprivation and negative symptoms in individuals with schizophrenia.

Methods: Following PRISMA guidelines (CRD CRD42022259295), we conducted a systematic search using keywords and MeSH terms such as 'schizo*', 'social isolation,' 'social withdrawal,' and 'social deprivation.' We included cross-sectional, case-control, clinical trials, and longitudinal studies involving adults with schizophrenia spectrum disorders.

Results: The systematic search yielded 1,104 references. After title, abstract, or trial protocol screening, 285 articles remained. Of these, 29 studies with various designs were retained. The findings highlight the multifaceted nature of social deprivation, involving both external and internal factors that contribute to the complexity of negative symptomatology in individuals with schizophrenia. Common external factors included institutionalization, deinstitutionalization, forced social isolation (e.g., during the COVID-19 pandemic), stigma, and rejection from primary caregivers. Noteworthy outcomes included positive effects associated with deinstitutionalization, such as improved quality of life and reduced alogia, while motivational deficits were prevalent in institutionalized settings. Internal factors, such as depressive symptoms, experienced stigma, loneliness, impaired social cognition, and residual positive symptoms, also played significant roles in social deprivation.

Discussion: The systematic review sheds light on the limited but critical research on the role of social deprivation as a causative factor for secondary negative symptoms in schizophrenia. The findings underscore the multifaceted nature of social deprivation, encompassing both external and internal factors that contribute to the complexity of negative symptomatology in individuals with schizophrenia. In addition, the increase attempt to digitally phenotype negative symptoms by means of biobehavioral is discussed as an unprecedented opportunity for tracking, understanding and treating social deprivation within schizophrenia.

T123. EXPLORING VIRTUAL REALITY-ASSISTED THERAPY FOR AUDITORY HALLUCINATIONS IN SCHIZOPHRENIA SPECTRUM DISORDERS THROUGH THE LENS OF PHENOMENOLOGY

Lisa Charlotte Smith*¹, Mariegaard Lise¹, Ditte Lammers Vernal², Gry Jørgensen¹, Annette Gosvig Christensen³, Fatime Zeka⁴, Nikolai Albert⁵, Julie Midtgaard⁶, Neil Thomas⁷, Carsten Hjorthøj⁸, Louise Birkedal Glenthøj⁹, Merete Nordentoft⁵

¹Copenhagen Research Center for Mental Health - CORE, VIRTU Research Group, ²Aalborg University Hospital, Psychiatry, Research Unit for Child and Adolescent Psychiatry, Aalborg, Denmark, ³Esbjerg Psychiatric Hospital, Region of Southern Denmark, Denmark, ⁴Copenhagen Research Center for Mental Health - CORE, VIRTU Research Group, University of Copenhagen, Department of Psychological Sciences, ⁵Copenhagen Research Center for Mental Health-CORE; Mental Health Center Copenhagen, Copenhagen University Hospital, Denmark, ⁶Centre for Applied Research in Mental Health Care (CARMEN), Mental Health Center Glostrup, University of Copenhagen, Copenhagen, Denmark; Faculty of Health and Medical Sciences, Department of Clinical Medicine, University of Copenhagen, Copenhagen, Denmark, ⁷Brain and Psychological Sciences Research Centre, Swinburne University and Monash Alfred Psychiatry Research Centre, Melbourne, Australia, ⁸CORE- Copenhagen Research Centre for Mental Health, Mental Health Center Copenhagen, Capital Region of Denmark; University of Copenhagen, Section of Epidemiology, ⁹Copenhagen Research Center for Mental Health (CORE), VIRTU Research Group, Mental Health Center Copenhagen, University of Copenhagen, Faculty of Social Sciences, Department of Psychology,

Background: In a currently active randomised controlled clinical trial (CHALLENGE), the efficacy of a novel virtual reality (VR)-assisted psychotherapy for persistent auditory verbal hallucinations (AVH, i.e. hearing voices) is tested. The patients enrolled in the trial are suffering from schizophrenia spectrum disorders. Based on an analysis of qualitative data from a smaller experimental sub-study (N=15), the focus of this oral presentation is on presenting phenomenological aspects of participants' experiences with VR-assisted therapy. The experimental sub-study's primary aims are to improve therapy effectiveness through minor software modifications, meanwhile also conducting an in-depth qualitative exploration of participants' experiences with VR-assisted therapy.

Methods: During the VR-assisted therapy, participants create an avatar that corresponds to their visual perception (or imagination) of the source of their most dominant voice. Additionally, and with the use of a software program the voice of the therapist is transformed into sounding like the voice heard by the participant. Part of therapy is conducted in VR as roleplay with the therapist taking on the role of the avatar. The focus of therapy is on gradually altering the relationship between the participant and the avatar with the avatar becoming less dominant. In the current sub-study, all participants were interviewed after finishing therapy. The semi-structured interviews covered themes such as 'acceptability', 'effectiveness', and 'transferability'. Broad, open-ended questions were asked to capture participants' immediate experiences. For this oral presentation the interviews were analyzed with the use of phenomenological and postphenomenological theory to capture how subjectivity and intersubjectivity may be experienced and transformed in VR-assisted therapy through the situated mediations occurring within the virtual world (user-environment relations) and outside VR (human-world relations).

Results: Themes of different types of realities emerged in the data: 1) the private psychotic reality, 2) our shared social (and physical) reality, and 3) virtual reality. Phenomenological similarities between psychotic experiences and VR were identified, especially pertaining to perception and language. The very real relationship between participants and their voices (AVH) are apparent in the interviews – with voices experienced as being present in therapy with a subjectivity of their own. During the course of therapy, the realities of VR and

psychosis occasionally merged, e.g. creating illusions of the VR avatar being the dominant voice from the psychotic reality. For participants who achieved a better relationship with their voices, possibilities of the self to perform particular activities (e.g. reading books, participating in social events) were regained, hence creating a larger field of opportunities for the self in the world (i.e. outside VR). Additionally, creating and sharing the avatar as a simulation of the most dominant voice enabled participants to communicate perceptual aspects of their auditory hallucinations to the therapist and relatives, thus possibly enhancing intersubjectivity regarding previously private experiences.

Discussion: This study highlights potential points of action that arise from the particular situatedness of participants positioned in this type of individualized VR environment. The dialogue with the avatar (embodied by the therapist) encompassed verbal acts constituting a possibility for change in the self and in the relationship with the dominant voice. Preliminary quantitative findings indicate that the method of conducting therapy with the use of an avatar in VR is promising. Understanding phenomenological aspects of psychosis and VR is key if we are to improve therapeutic methods that employ VR in the treatment of schizophrenia spectrum disorders.

T124. DISABILITY CASES COMPLICATED BY PSYCHOSIS AND SCHIZOPHRENIA SPECTRUM DISORDERS

Brad Booth*¹, Sarah Mamane², Dominique Bourget³

¹*University of Ottawa Faculty of Medicine*, ²*Royal Ottawa Hospital, Department of Schizophrenia*, ³*Royal Ottawa Mental Health Hospital*

Background: Independent medical evaluations (IMEs) are often sought by third parties to clarify psychiatric issues relevant to criminal or civil law. In criminal law, this might include determination of criminal responsibility, fitness to stand trial, or risk. In civil law, this might include determination of eligibility for disability benefits, fitness to work, and civil litigation for psychological damages. At times, individuals with obvious or subtle psychosis present in the context of these IMEs. Employed stable patients with psychotic disorders may have a relapse; alternatively, a new onset of psychosis can occur, causing them to be disabled and potentially qualifying them for disability insurance. They might also be sent for fitness for work or to clarify causality from accident or trauma. The current study reviews psychosis and schizophrenia spectrum disorders in IMEs for disability claimants.

Methods: The authors have completed a retrospective chart review of approximately 705 consecutive disability independent medical examinations (IMEs) dating back to 2010 drawn from forensic work by BDB. Data was extracted for patients who consented to research where a primary psychotic disorder was likely or suspected. For the current review, other medico-legal issues such as fitness to work and psychological harm, were excluded.

Results: Out of the approximately 705 consecutive IMEs, 27 (3.8%) were found to have a likely psychotic element to their presentation, such as schizophrenia spectrum diagnosis. Of this sample, 23 consented to use of their data in research. Nearly all were diagnosed with a new-onset psychotic disorder. There were 13 men (56.5%) and 10 women (43.5%). The average age was 45. Of the 23 patients, 7 had a previous disability leave with the average time from current leave from work to assessment being 864 days. In the study, the average patient had 2.5 comorbid DSM diagnoses suggesting high comorbidity. Diagnoses in descending frequency were: GAD, Depressive disorders, Social phobia, Substance use

disorders, and ADHD. For those with substance use disorders, 6 were using more than one substance; 8 were using cannabis, 5 were using alcohol, and 2 were using stimulants. Evaluatees had high baseline deficits in attention and impulsiveness at baseline and at the time of assessment as measured by the ASRS. Their PHQ-9 scores showed moderate depression and GAD-7 showed mild anxiety. Their BPAQ scores suggested average levels of aggression, anger, and hostility. They showed self-esteem deficits on the Rosenberg Self Esteem Scale and impression management on the PDS. The AUDIT and DAST suggested no issues with alcohol and substances. Lastly, the WHODAS-2.0 suggested mild-mod impairment overall. Evaluatees listed stressors contributing to the onset of illness/disability, with the most common workplace stressors being problem with supervisors and bullying. The most commonly reported personal stressors were death/illness in relatives and physical health.

Discussion: Experts involved in IMEs and other forensic evaluations must be aware of the potential of unrecognized/subtle psychotic signs. In approximately 3.8% of a large disability sample, psychosis was the likely cause of disability. Many had not been recognized as being psychotic and were not on appropriate treatment. Once the correct diagnosis of a schizophrenia spectrum disorder is made, the clinician can comment on the potential for improvement over a predictable course. The expert will be in a position to offer recommendations, such as pharmacological treatment, psychiatric and psychological follow-up, and other relevant advice.

T125. PREDICTING THE DIFFERENTIAL COURSE OF EVERY-DAY LIFE PSYCHOTIC EXPERIENCES ACROSS THE PSYCHOSIS LIABILITY SPECTRUM

Frederike Schirmbeck*¹, Uli Reininghaus², Mathias Zink³, GROUP Investigators⁴, Inez Myin-Germeys⁵

¹Central Institute of Mental Health, University of Heidelberg, ²Central Institute of Mental Health, Mannheim, ³Central Institute of Mental Health, Department of Psychiatry and Psychotherapy, Medical Faculty Mannheim, ⁴GROUP, ⁵Department of Neuroscience, KU Leuven- Leuven University,

Background: Over the last decades, extensive research has been conducted to identify predictors for the development and prospective course of psychotic symptoms. Prospective cohort studies mainly focused on categorical outcome over a longer period of time, whereas experience sampling methods (ESM) investigated potential predictors of moment-to-moment fluctuation in everyday life psychotic experiences. Interestingly, both cohort studies, as well as ESM studies have highlighted the impact of experienced stressful events and affective disturbances on the prospective course of psychotic symptoms. Some authors have even hypothesized an affective pathway to psychosis. Both study designs come with specific limitations, large assessment intervals in cohort studies and the focus on categorical outcome (transition, remission, relapse rates), might overlook relevant variation and cannot rule out unmeasured confounding effects, on the other hand very small assessment intervals in moment-to-moment (hour-to-hour) investigations might be too small to observe relevant changes.

To further unravel potential mechanisms in the course of psychotic experiences we choose an ‘in-between’ window of observation (day-to-day) and broadened our perspective of potential predictors. We aimed to identify and predict differential trajectories of day-to-day change in

psychotic experiences over a period of one week, focussing on the predictive validity of experienced events, coping strategies and affective disturbances on identified trajectories.

Methods: Analyses were conducted using ESM data from subjects across the psychosis liability spectrum, who previously took part in the INTERACT or GROUP study. The combined sample (n=340) included patients with psychotic disorder in a later illness stage, first episode patients (FEP) with psychosis and subjects at clinical high risk for psychosis (CHR-P). Latent class mixed model analysis (LCMM) were used to identify and visualize clusters of participants with similar distinct outcome trajectories of every-day life psychotic experiences. In a subsequent step, the prognostic validity of risk and resilience factors on these unconditional trajectories and within-subject day-to-day changes were explored by multilevel regression analyses.

Results: LCMM resulted in a 5-class solution. Mean class probabilities were moderate to high (0.70- 0.88), suggesting individuals had a 70-88% probability to be correctly assigned to one of the five latent classes. After visual inspection, identified trajectories could be defined as: (i) low (n=83), (ii) middle (n=142), (iii) high (n=78), (iv) decreasing (n=26), and (v) increasing (n=11) psychotic experiences. Compared to persistently low psychotic experiences, exploratory analyses showed that higher baseline stress and more negative affect increased the likelihood to belong to the high or middle trajectory, whereas higher levels of daily life self-esteem was associated with a lower likelihood for the increasing trajectory.

Discussion: Findings suggest that daily-life experienced stress and affective disturbances may have a negative effect on the subsequent course of experienced (subthreshold) psychotic symptoms over the course of one week. In contrast positive self-esteem might represent a protective factor for symptomatic increase.

T126. PRECISION PSYCHIATRY FOR SCHIZOPHRENIA SPECTRUM DISORDERS: PREDICTING PREDICTABILITY

Edwin van Dellen*¹

¹UMC Utrecht

Background: Precision psychiatry is an emerging field that aims to provide individualized approaches to schizophrenia spectrum disorders. Multivariate analysis and machine learning are used to create outcome prediction models based on clinical data such as demographics, symptom assessments, genetic information, and brain imaging. While much emphasis has been placed on technical innovation, the complex and varied nature of mental health presents significant challenges to the successful implementation of these models.

Methods: A review of ten challenges of precision psychiatry applications in schizophrenia spectrum disorders.

Results: Current datasets used to train precision prediction models do not reflect real-world populations and fail to incorporate realistic clinical outcome definitions. Treatment-related factors such as placebo effects and non-adherence to prescriptions are not considered. Fairness, prospective validation in comparison to current practice and implementation studies of prediction models are other key issues that are currently understudied.

Discussion: A shift is proposed from retrospective studies based on linear and static concepts of disease towards prospective research that considers the importance of contextual factors and the dynamic and complex nature of mental health in patients with schizophrenia spectrum disorders.

T127. RELIABILITY AND VALIDITY STUDY OF TURKISH VERSION OF SCHIZOPHRENIA COGNITION RATING SCALE (SCORS) WHICH ASSESS COGNITIVE IMPAIRMENT IN THE DAILY LIFE OF SCHIZOPHRENIA PATIENTS

Nedim Özak¹, Emine Iğın Hosgelen^{*2}, Bilge Targıtay Öztürk³, İ. Tolga Binbay³, Berna Binnur Akdede³, Köksal Alptekin³

¹M.D., Private Office, Balıkesir, ²Dokuz Eylül University, Institute of Health Science, ³Dokuz Eylül University, School of Medicine, Department of Psychiatry

Background: Schizophrenia is characterized by significant dysfunction in cognitive domains including memory, attention, processing speed, executive functions, and language skills. Despite its crucial role in clinical appearance and prognosis, cognitive assessments are difficult to perform in an outpatient setting due to the time-consuming nature of neurocognitive assessments. A scale named SCoRS “Schizophrenia Cognition Rating Scale” developed by Keefe et al (2006) provides a concise cognitive evaluation tool by obtaining information from the patient, informant, and interviewer in approximately 12 minutes. SCoRS also exhibits sensitivity to treatment effects (Keefe et al, 2015). This study aimed to establish the validity and reliability of the Turkish version of the “Schizophrenia Cognition Rating Scale” (SCoRS-TR) in schizophrenia patients.

Methods: The study’s sample comprised a total of 170 volunteers, including 130 schizophrenia patients (SchP) who met DSM-V criteria for schizophrenia and 40 healthy controls (HC). After gathering the sociodemographic data, the clinical characteristics of the patients were evaluated by using the Positive and Negative Syndrome Scale (PANSS). Structured Clinical Interview for DSM-V (SCID) was conducted for HCs to screen mental disorders. The Schizophrenia Cognition Rating Scale-Turkish Version (SCoRS-TR) was administered to both SchP and HC groups. Neurocognitive test battery which included Rey Auditory Verbal Learning and Memory (RAVLT), Trial Making A and B Forms (TMT-A and B), Stroop Color and Word Test (SCWT), Digit Symbol, Digit Span test, Category Fluency, Controlled Oral Word Association Test (COWA), and Wisconsin Card Sorting Test (WCST) was used to assess the correlation between SCoRS-TR and neurocognitive domains. For assessing the reliability of this new scale, internal consistency, test-retest, and interrater reliability analyses were conducted. The validity of the scale was assessed with similar scale validity, factor analysis, and differential validity methods.

Results: We found significant evidence for the reliability and validity of SCoRS for the Turkish population in our study. Conducted factor analysis shows SCoRS is structured with 4 factors (memory, attention/vigilance, executive functions, psychomotor activation subscales) which defined %63,4 of overall variance and has an acceptable internal consistency (for patient form $r=0.937$, for informant $r=0.940$, for interviewer form $r=0.937$). We also determined high interrater reliability (patient form $r=0.90$, informant $r=0.95$, for interviewer form $r=0.98$), high test-retest reliability (patient form $r=0.990$, informant $r=0.977$ and interviewer form $r=0.976$) and high differentiation capacity between patients and healthy volunteers ($p < 0.001$). We indicated similar scale validity between SCoRS-TR and neurocognitive tests. There were significant correlations between SCoRS subdomains (patient, informant, and interviewer) and RAVLT late recall (ranging $r:-0.46 - r:-0.51$), TMT-B (ranging $r:0.34 - r:0.37$), Verbal Fluency test ($r:-0.42 - r:-0.47$), and WCST (ranging $r:-0.35 - r:-0.39$) scores.

Discussion: In this study SCoRS-TR has demonstrated significant reliability and validity scores that may be useful in evaluating cognitive dysfunction in patients with schizophrenia.

Schizophrenia Cognition Rating Scale Schizophrenia (SCoRS) may contribute to determine severity of neurocognitive impairments evident in schizophrenia patients and trace progression of cognitive impairments during follow-up in clinical studies.

T128. REAL-ENVIRONMENT BASED VIRTUAL REALITY INTERVENTION PROGRAM FOR PSYCHOSOCIAL FUNCTIONING IN INDIVIDUALS DIAGNOSED WITH SCHIZOPHRENIA

Emine Ilgın Hosgelen*¹, Markus Berger², Faik Kartelli², Fatma Şimşek³, Berna Binnur Akdede⁴, Köksal Alptekin⁴

¹Dokuz Eylul University, Institute of Health Science, ²Dokuz Eylul University Faculty of Fine Arts Department of Film Design Animation Film Design and Directing, ³Department of Psychiatry, Community Mental Health Center, Bakırçay University Education and Research Hospital, ⁴Dokuz Eylul University, Faculty of Medicine, Department of Psychiatry

Background: Virtual Reality (VR) presents a promising intervention method for psychosocial impairments in schizophrenia. In this study, we aimed to study the effect of a real-environment-based VR in improving psychosocial functioning in schizophrenia. Here we present preliminary findings of an ongoing study.

Methods: The data was obtained from the patients who were registered at Bakırçay University Çiğli Regional Education Hospital, Community Mental Health Center (CMHC). The study included 19 individuals who were diagnosed with schizophrenia based on the diagnostic criteria outlined in the DSM-V. The study was conducted with two groups: one experimental group that received VR sessions (VRG, n=11) and a control group (CG, n=8) with non-interventional face-to-face sessions, once a week for 12 weeks. Participants were randomly assigned to the study. The severity of schizophrenia symptoms of the patients was evaluated by using the Positive and Negative Syndrome Scale (PANSS). Psychosocial functioning was evaluated by using the Personal and Social Performance Scale (PSP) and Social Functioning Scale (SFS). Social cognition was evaluated by using Dokuz Eylul Theory of Mind Index (DEZIKO), Facial Emotion Identification (FEIT), and Facial Emotion Discrimination (FEDT) tests, and Reading Mind in the Eyes (RMET). Additionally, the Turkish version of the Observable Social Cognition–A Rating Scale (OSCARS-TR) was used to evaluate social cognition by caregivers of the patients. Neurocognition was evaluated by using the Turkish version of Screen for Cognitive Impairment In Psychiatry (SCIP). The assessments were conducted at both baseline and post-test stages. Socio-demographic variables and baseline assessments were compared using the Mann-Whitney U test. The hypothesis was tested using repeated measures ANOVA.

Results: The mean age was for VRG 37.27±9.95 and CG 40.75±7.96. The mean for total education years was for VRG 11.27±4.00, and CG 10.12±3.04. There was no difference in terms of age (p=.34) and education (p=.30) between the groups. There was also no significant differences between PANSS (p=.46), PSP (p=.65), DEZIKO (p=.30), FEIT (p=.74), FEDT (p=.93), OSCARS-TR (p=.13), and SCIP (p=.32) at the baseline assessments. However, there was a significant difference in SFS (p=.030), and its two subscales, interpersonal skills (p=.21) and prosocial activities (p=.016), at baseline between groups. The main effect of time was significant indicating that PSP [F(1,17)=39.38, p LESS THAN .001], SFS [F(1,17)=10.22, p=.005], DEZIKO [F(1,17)=13.58, p=.002], SCIP global [F(1,17)=15.21 p=.001] score significantly increased and PANSS [F(1,17)=85.91, p LESS THAN .001] score significantly decreased. However, there was no time x group interaction in these assessments.

The main effect of time and time x group interaction was not significant as following, respectively; for OSCARS-TR [$F(1,15)=.78$, $p=.39$; $F(1,15)=1.95$, $p=.18$], FEIT [$F(1,17)=0.20$, $p=.90$; $F(1,17)=2.16$, $p=.16$], FEDT [$F(1,17)=.22$, $p=0.64$; $F(1,17)=1.51$, $p=.78$], RMET [$F(1,17)=1.80$, $p=.18$; $F(1,17)=0.16$, $p=.70$].

Discussion: While VR is a promising tool for psychosocial skills training, these preliminary findings of this study did not strongly support this hypothesis of VR improvement in psychosocial functioning. Instead, individuals diagnosed with schizophrenia showed a significant increase in psychosocial functioning when engaged in weekly appointments over a 12-week period.

T129. INVESTIGATING THE CONCORDANCE BETWEEN DIFFERENT MEASURES OF FORMAL THOUGHT DISORDER SEVERITY

Georgia Zamperoni¹, Philip Sumner², Susan Rossell³, Eric Tan*⁴

¹*Centre for Mental Health and Brain Sciences, School of Health Sciences, Swinburne University of Technology, Melbourne,* ²*Centre for Mental Health and Brain Sciences, School of Health Sciences, Swinburne University of Technology,* ³*Centre for Mental Health and Brain Sciences, School of Health Sciences, Swinburne University of Technology, Department of Psychiatry, St Vincent's Hospital, Melbourne, Australia.,* ⁴*National University of Singapore*

Background: Disorganized speech, or formal thought disorder (FTD), is a core symptom of psychosis, with various measures and rating scales being used in both clinical and research settings. These range from general to more comprehensive measures, leading to significant heterogeneity in mechanistic and prognostic investigations of FTD. To date, how these different measures relate to each other, and thus the salience of this heterogeneity, has yet to be assessed. This study thus aimed to examine how different FTD measures rated the severity of FTD symptomatology using a single sample of speech. In particular, this study focused on assessing the agreement between measures (scale of measurement), as opposed to construct validity.

Methods: Speech recordings from 21 individuals diagnosed with DSM-5 schizophrenia-spectrum disorder or bipolar disorder were rated using 5 published measures of disorganized speech: the Thought Language and Communication (TLC) scale Global score, the FTD subscale from the Scale for the Assessment of Positive Symptoms (SAPS), the alogia subscale from the Scale for the Assessment of Negative Symptoms (SANS), items P2 Conceptual Disorganization and N6 Lack of Spontaneity and Flow of Conversation from the Positive and Negative Syndrome Scale (PANSS), and the Communication Disturbances Index (CDI) overall score. Agreement was assessed using the Bland-Altman plots procedure, where the relationships between two measures were graphically depicted and linear regressions used to test for proportional bias in the respective ratings. These were done only for measures that showed significant positive Spearman's correlations, which were used to confirm construct validity between two different measures.

Results: Our results suggested strong agreement between the TLC Global score and both SAPS FTD and SANS alogia, the TLC Global and PANSS P2 but not PANSS N6, SANS alogia and both PANSS P2 and N6, and SAPS FTD and PANSS P2. No significant agreement was found between the CDI and any other measure.

Discussion: Our findings demonstrate the interconnectedness of various assessment tools quantifying FTD, with strong relationships between selected comprehensive measures like

the TLC, and more general assessments like PANSS P2, SAPS and SANS, but not PANSS N6. This could contribute to a unified framework in FTD evaluation across diverse clinical and research contexts. For example, our data suggests that these measures could be used interchangeably, pending on context of usage, without significant differences in assessment outcomes. Until a consensus approach to FTD assessment is achieved, the current findings will go some way to improving interpretations across studies.

T130. INCREASED MORTALITY AMONG PATIENTS WITH SUBSTANCE INDUCED PSYCHOSIS (SIP) IN SCANDINAVIA

Eline Rognli¹, Carsten Hjorthøj², Anette Erlangsen³, Heidi Taipale⁴, Pihla Sassi⁵, Solja Niemelä⁶, Ina Heiberg⁷, Jørgen Bramness^{*8}

¹*Oslo University Hospital*, ²*Copenhagen University Hospital, Mental Health Center Copenhagen*, ³*Copenhagen Research Center for Mental Health – CORE, Mental Health Center Copenhagen*, ⁴*Karolinska Institutet*, ⁵*Department of Psychiatry, University of Turku*, ⁶*Department of Psychiatry, University of Turku, Turku, Finland*, ⁷*UiT - Arctic University of Norway*, ⁸*Norwegian Institute of Public Health*

Background: People with substance induced psychosis have a disorder that in some contexts is considered neither a drug use disorder nor a “proper” psychiatric disorder. There are almost no guidelines informing its treatment and most often stopping substance use is considered to the best (and only) way forward. Still as many as one in three people with SIP receive a diagnosis of schizophrenia in the time following a SIP-diagnosis, indicating that SIP is a serious disorder.

Methods: In this study we utilize data from Norway, Sweden, and Denmark to investigate the mortality of SIP. Data were taken from national patient registries in the three countries and involved all patients admitted with a diagnosis of SIP (ICD-10 F1x.5) from the first possible date using ICD-10 in each country (from 2008-2020) for patients age 18-79. Figures on total and cause-specific causes of death will be presented as standardized mortality ratios (SMRs). Cause specific mortality will include a) suicides, b) poisonings, c) accidents, d) cancer, e) cardiovascular and f) respiratory organs.

Results: Data are collected currently, and all data will be analyzed in January 2024.

Discussion: Initial preliminary findings indicate a 10-20 times increased mortality per year compared to age and gender matched controls. Detailed, but still preliminary findings will be reported at SIRS.

T131. THE JOHNS HOPKINS SCHIZOAFFECTIVE DISORDER PRECISION MEDICINE CENTER OF EXCELLENCE: AN APPROACH TO REDUCING THE HETEROGENEITY OF SCHIZOPHRENIA AND RELATED DISORDERS BASED ON TREATMENT RESPONSE

Russell Margolis^{*1}, Frederick Nucifora¹, Yifan Mo¹, Andor bodnar¹, Claire Mcaulley¹, Leslie Nucifora¹, Peter Zandi¹, Christopher Ross¹, Vidya Kamath¹, Tilak Ratnanathar¹, Gayane Yanokyan¹, Elizabeth Gerber¹, Hanna Jaaro-Peled¹, Allison Brandt¹

¹*Johns Hopkins*

Background: The heterogeneity of schizoaffective disorder (scz-aff), here defined broadly to include schizophrenia with and without extensive affective symptoms, has been recognized since the construct of schizophrenia was first developed in the late 19th and early 20th Century. We hypothesize that heterogeneity can be reduced by defining three subtypes of scz-aff based on treatment response: response to conventional antipsychotics (non-treatment resistant), response only to clozapine (treatment resistant), and lack of response to any antipsychotic medicine (ultra-treatment resistant). The goals of our program are therefore: 1) To develop methods that distinguish these subtypes prior to the onset of treatment, as a guide to choosing among current treatments. 2) To determine the neurobiological underpinnings of the subtypes, using a strategy to identify those factors in common to all subtypes, and those factors that distinguish each group. 3) To use health system data to understand and change clinical practice.

Methods: We propose to achieve these goals through 6 aims. In Aim 1, we will intensely study the large clinical population of patients with scz-aff disorder treated at Johns Hopkins to establish the phenotypes of the three scz-aff subtypes. Analyses will include detailed cross-sectional and longitudinal assessments of clinical symptoms, cognition, olfaction, function. In Aim 2, we will examine the patients and control with novel imaging techniques and ultra-high field (7 Tesla) technology to determine structural, connectivity, and neurovascular signature of each of the scz-aff subgroups. In Aim 3, we will generate iPSCs and induced neurons from individuals from each subtype of scz-aff and controls. Cells will be examined at different stages of differentiation, and compared to iPSCs engineered to contain rare mutations associated with high risk of scz-aff. Blood samples will be obtained for genetic analyses and to explore extracellular vesicles. In Aim 4, we will use mouse models to explore recently discovered genetic risk factors for scz-aff, and which may shed light on subtype specific pathophysiology. In Aim 5, we will determine EEG differences among scz-aff subtypes with an emphasis on sensory gating and attentional parameters. In Aim 6, we will take advantage of Hopkins EMR data, and eventually other data sets, to determine factors associated with the use and lack of use of clozapine, and the extent of treatment response to clozapine.

Results: Preliminary efforts have now demonstrated the feasibility of all 6 aims. Preliminary results will be detailed in other posters.

Discussion: If successful, our efforts, combined with the efforts of many others working on related projects, will lead to 1) increase in the use of clozapine, 2) targeting of clozapine to the correct patients at the correct time, 3) improved patient stratification in pharmacological trials for scz-aff treatment, 4) development of new therapeutic targets. This work was supported by the Abramson Fund, the ABCD Chairtable Trust, the NIMH, and Johns Hopkins inHealth.

T132. RESEARCH PRIORITIES FOR THE AUSTRALIAN EARLY PSYCHOSIS COMMUNITY

Joanna Fitzsimons^{*1}, Andrew Thompson², Karine Fernandez³, Eleanor Brown², Isabel Zbukvic², Deanna De Cicco³, Patrick McGorry², Kelly Allott², Stephen Wood²

¹University of Melbourne, ²University of Melbourne and Orygen, ³Orygen

Background: Although psychosis is a low prevalence disorder, the burden of disease is substantial, with considerable individual, community and societal costs and the need for innovation to prevent and treat mental health problems has never been greater. The Australian Early Psychosis Collaborative Consortium (AEPCC) has been established with

Wellcome Trust funding to drive national collaboration across the research, clinical and lived experience sector, to build a Clinical Trials and Translation Network, Clinical Quality Registry and Lived Experience Network, nationally. A key priority activity for Clinical Trials Networks (CTNs) is the development of research priorities for the sector, driven by all relevant stakeholder groups. CTNs can then facilitate national research collaboration, broad clinical service participation and ensure meaningful and purposeful involvement of lived experience communities, which in turn result in improved funding success rates, as funding bodies are clear the proposed large scale clinical trial proposal have been developed from real-world engagement, are more likely to success in reaching recruitment targets and build bridges across research-clinical-lived experience silos to ensure the questions being investigated are important to the whole sector and the findings will more likely be translated back in to clinical settings, should the findings be positive.

Methods: AEPCC set out to identify the most important research questions for the Australian early psychosis community. The AEPCC Scientific Committee reviewed and endorsed the proposed methods. A variety of methodologies were employed across an 18 month period including scoping of previous priority setting activities, online survey, online and in-person facilitated consultations, ranking survey and a final poll where participants were asked to pick the 2 most important questions, from a list of 10. Thematic analysis was conducted on the transcribed data.

Results: Across the multiple consultations, more than 600 responses were collated. In person or online consultations involved over 100 people from across all Australian States and Territories. More than 500 people participated in online surveys or polls. Data from the scoping surveys and in-person consultations were transcribed and thematic analysis conducted to identify key themes. An initial in-person forum was held in Melbourne, Australia to begin an early identification process of important clinical trial ideas based on 5 key priority themes (1) Causes and risks associated with developing early psychosis, 2) Models of care for early psychosis, 3) Comorbidity and complexity in early psychosis (e.g. physical health and early psychosis, trauma and early psychosis), 4) Diagnosis and treatment of early psychosis, and 5) Impact and long-term outcomes of early psychosis). This process demonstrated the need for further refinement and subsequently a poll was developed in consultation with research, clinical and lived experience community members where participants results of the poll will be discussed, highlighting differences between research, clinical and lived experience community priorities.

Discussion: Research priority setting is an important and challenging process for a sector to undertake, however the rewards in listening to and understanding the views and priorities of different stakeholders is a valuable reward that can result in better outcomes for lived experience members, as well as increased engagement in clinical trials. These benefits and challenges will be discussed along with the next steps that AEPCC will undertake with the sector to refine the trial questions and facilitate the development of a truly collaborative, national clinical trial based on the priorities identified in partnership.

T133. THE AUSTRALIAN EARLY PSYCHOSIS CLINICAL QUALITY REGISTRY - DEVELOPMENT AND IMPLEMENTATION IN REAL WORLD CLINICAL SETTINGS

Andrew Thompson^{*1}, Jo Fitzsimons², Karine Fernandez¹, Carolyn Sanderson¹, Yehudi Saling¹, Deanna De Cicco¹, Patrick McGorry²

¹Orygen, ²University of Melbourne and Orygen

Background: Over the last few decades research into early psychosis has increased dramatically. Early Intervention services have been established in an increasing number of countries internationally including clinical services for those at high risk of developing a psychotic disorder. However, the quality of service delivery is often not adequately monitored, data collection not systematized and the understanding of long term outcomes outside of research settings is lacking. Clinical Quality Registries (CQR's) are tools for monitoring the quality of care delivered to a specific diagnostic group or procedure. They are widespread in Australian healthcare outside of mental health. They involve the collection of minimum clinical and service data on a wide number of individuals in real-world clinical settings with opportunities for wider linkage to other routinely collected health care data such as mortality and prescribing. In this sense they fulfill the criteria of a learning health care tool. As part of the recently established Australian Early Psychosis Collaborative Consortium initiative we are establishing a CQR for early and emerging psychosis (FEP and UHR) Australia wide.

Methods: We describe the process of establishing the Minimum Dataset (MDS) and the CQR infrastructure. A series of panel discussions with an establishment of committee of clinicians' research and lived experience experts has guided the development of the MDS and implementation of the CQR in diverse services across the country.

Results: The current state of the national CQR infrastructure and the challenges in implementing this in the 5 demonstrator sites will be discussed.

Discussion: The establishment of a national CQR for early psychosis is the first of its kind for mental health in Australia. The CQR will lead to an improved collection of minimum data on outcomes, establish and improve risk profiling in practice, allow services benchmarking and improve quality and also understand long term outcomes in early psychosis.

T134. EXAMINING EARLY FUNCTIONAL RECOVERY AND SYMPTOM REMISSION RATES IN FIRST EPISODE SCHIZOPHRENIA

Joseph Ventura^{*1}, Felice Reddy², Kenneth Subotnik³, Gerhard Hellemann⁴, Keith Nuechterlein⁵

¹*UCLA*, ²*University of North Carolina at Chapel Hill*, ³*University of California, Los Angeles Psychiatry and Behavioral Sciences*, ⁴*University of Alabama, Birmingham*, ⁵*UCLA Semel Institute for Neuroscience and Human Behavior*

Background: Schizophrenia is no longer thought of as necessarily chronically disabling or as inevitably a deteriorating condition. Advances in pharmacological treatment and psychosocial interventions have increased expectations for positive outcomes including early functional recovery and symptom remission. Functional remission, a key component of early recovery, focuses on restoring and individual's ability to engage in daily activities, maintain employment, and build meaningful relationships. Negative symptoms, characterized by deficits in emotional expression, motivation, and social engagement, pose specific challenges to recovery in the early phases of schizophrenia. Addressing negative symptoms is integral to achieving comprehensive recovery and improving overall quality of life. Ongoing investigations seek to refine our understanding of early recovery processes to promote innovative interventions tailored to the unique functional and symptoms reduction needs of individuals experiencing their first episode of schizophrenia.

Methods: Participants were sixty-two young individuals with FES (psychosis onset LESS THAN 2 years at study entry) from the UCLA Aftercare Research Program enrolled in a 12-

month comprehensive early intervention program who had complete 12-month data. Treatment included medication management, weekly case management and individual supportive therapy, and psychoeducation for individuals and families. Using a longitudinal measurement approach, the patients were administered measures by raters trained to reliability to assess daily functioning using the Global Functioning Scale: Social 1= Extreme Social Isolation and 10=Superior Social/Interpersonal Functioning and Role 1= Extreme Role Dysfunction and 10= Superior Role Functioning. Symptoms were assessed with the SANS (Expressive and Experiential Domains) and SAPS Positive Symptom domains (Hallucinations and Delusions combined) where ratings of 0=none and 5=severe. Assessments were conducted at Baseline and subsequently every 3 months for one year. Baseline assessments were administered shortly after study entry. Our control sample was comprised of n=91 age- and demographically-matched healthy controls. Definition of Functional Recovery was determined by an analysis of the healthy control data showing that at study entry a large majority met the recovery criteria on the GFS Social (91%) and Role (92%) rating of 7 or above out of 10. Regarding negative and positive symptoms, we used the SANS and SAPS remission criteria (Andresen et al 2005) where remission is defined as a rating of mild = 2 or below out of 5.

Results: Regarding social functioning, we found that 43% of our sample either met recovery from the Baseline point or recovered within 3 months and maintained recovery for 12 months. Whereas 11% were slow in recovering, 5% did not maintain recovery criteria, and 55% never achieved full social recovery. For role functioning, we found that 29% of the sample met recovery from Baseline or recovered within 3 months and maintained recovery for 12 months. Whereas 18% were slow in recovering, 8% did not maintain recovery criteria, and 45% never achieved full social recovery. Regarding expressive negative symptoms, we found that 29% met remission criteria from Baseline or remitted within 3 months and maintained remission for 12 months. Whereas 17% were slow in remitting, 8% did not maintain remission criteria and 32% never achieved full expressive symptom remission. For experiential negative symptoms, we found that 21% met remission criteria from baseline or remitted within 3 months and maintained remission for 12 months. Whereas 10% were slow in remitting, 6% did not maintain remission criteria, and 64% never achieved full experiential symptom remission. Regarding positive symptoms (hallucinations and delusions combined), we found that 45% met remission criteria from Baseline or remitted within 3 months and maintained remission for 12 months. Whereas 8% were slow in remitting, 19% did not maintain remission criteria (mostly likely due to a positive symptom relapse), and 29% never achieved full positive symptom remission.

Discussion: This longitudinal analysis of essential elements of functional recovery and symptom remission criteria in an urban first episode sample of young individuals with schizophrenia sheds light on meaningful cut-offs and recovery and remission percentages. This information could be used in clinical trials and clinical settings to identify treatment targets and clinically meaningful changes in response to treatment interventions. We believe that the proportion of patients meeting recovery criteria is reduced when experiential negative symptoms are included, and this sheds light on exactly what those levels of negative symptoms may be that portend regarding better or worse functional outcomes.

T135. ENGAGING STAKEHOLDERS IN THE DEVELOPMENT OF STANDARDS FOR A CANADIAN RAPID LEARNING HEALTH SYSTEM IN EARLY INTERVENTION SERVICES FOR PSYCHOSIS: A CONSENSUS DEVELOPMENT CONFERENCE

Manuela Ferrari*¹, Amal Abdel-Baki², Emmanuelle Seery³, Jai Shah⁴, Marc-André Roy⁵, Phil Tibbo⁶, Ridha Joober⁷, Donald Addington⁸, Lili Zeng⁹, Gabriel Julien², Andrea Legros⁹, Francois Leblanc⁹, Elissa Zavaglia⁹, Hope Burko⁹, Megan Davies¹⁰, Sahar Fazeli⁴, Srividya Iyer¹⁰

¹McGill University and Douglas Mental Health Institute, ²Centre Hospitalier de l'Université de Montréal, ³Ministère de la Santé et des Services Sociaux, ⁴McGill University, ⁵Université Laval Faculty of Medicine, ⁶Dalhousie University, Department of Psychiatry, ⁷McGill University, Douglas Mental Health University Institute, ⁸University of Calgary, ⁹Douglas Hospital Research Institute, ¹⁰McGill University and Douglas Hospital Research Institute

Background: Psychotic disorders have profound personal and social impact. Consensus has emerged over three decades that early intervention services (EIS) providing high-quality care and reduced treatment delay may improve outcomes, especially in the first episode of psychosis. In Canada, four provinces have led EIS policy development and support strong EIS networks: Ontario (EPION), British Columbia (EPI APP), Québec (AQPEP), and Nova Scotia (NSEPP). Currently, 131 EIS operate in Canada. EIS guidelines identify elements and evidence-based standards of care essential to sustain high-quality services. Yet despite superior outcomes, multidisciplinary research has identified gaps between evidence-based guidelines, best practices, and the actual implementation of EIS. Use of a Rapid Learning Health System (RLHS) may provide a remedy, as the RLHS promotes rapid data gathering in routine clinical practice, a culture of shared clinician-patient responsibility, as well as engagement by patients, clinical teams, and managers in training and dissemination of evidence. Successful implementation of a RLHS in EIS also demands standards that ensure safety, accountability, evidence-based practice, and quality care, while fostering competitiveness and innovation. Building on the knowledge and experience of a multi-stakeholder team, this presentation describes the processes used to develop guidelines and acceptable practices in: 1) selecting indicators and competencies for rapid learning, and 2) identifying guidelines for creating a culture of rapid learning and improvement in a Canadian RLHS in EIS for psychosis.

Methods: To advance this multi-phase, multi-stakeholder project, we organized a Consensus Development Conference (CDC) in Montreal on Nov. 30-Dec. 1, 2023, inspired by a model from the U.S. National Institute of Health used by many countries in developing consensus statements to shape practices in medical disciplines. CDCs convene stakeholders (citizens, decision-makers, topic experts) to address specific issues, present scientific evidence to a panel/jury and generate joint recommendations. At least one program per Canadian province was invited to our CDC, 2-3 programs in larger provinces, ensuring diversity (e.g., urban and rural areas).

Results: Multi-stakeholder group aggregated to act as CDC panelists (11 people). Canadian EIS sent a delegation of service users, families, clinicians, researchers, and policymakers. A total of 114 attended the pre-conference activities (webinars on a Delphi survey), and 110 participated at the CDC, including seven peer support workers, eight service users and 11 family members. We used arts-based methods to enhance participant engagement (11 video capsules showcasing many participating EIS and three short movies made by former service users). The event was co-facilitated by two former service users and two family members. Formal presentations by Canadian EIS experts (researcher and peer-researchers) were

featured, and two small consensus workshops (10 working groups) met to discuss two key topics: quality of life and recovery; and service engagement and program satisfaction, then developed recommendations on how to implement RLHS in various provincial jurisdictions, maintaining provincial/program identity (e.g., in selecting indicators, assessments) while initiating a shared culture of continuous learning and improvement.

Discussion: This initiative in standards development supports provincial and federal decision-making on healthcare monitoring, system integration, communities of practice, and multicenter research while, crucially, ensuring better operationalization of the RLHS in EIS. The work accomplished at this CDC and new knowledge may inform similar international initiatives to bridge evidence-practice gaps in EIS for psychosis globally.

T136. THE PSYCHS: POSITIVE SYMPTOMS AND DIAGNOSTIC CRITERIA FOR THE CAARMS HARMONIZED WITH THE SIPS: A RESEARCH INSTRUMENT FOR THERAPEUTICS DEVELOPMENT IN CLINICAL HIGH RISK FOR PSYCHOSIS PSYCHOMETRIC EVALUATIONS OF THE PSYCHS INTERVIEW

Catalina Mourgues-Codern^{*1}, Paolo Fusar-Poli², Jai Shah³, Scott Woods¹

¹*Yale University*, ²*King College of London*, ³*McGill University*

Background: The PSYCHS (Positive SYmptoms and diagnostic criteria for the CAARMS Harmonized with the SIPS) is a new semi-structured clinical diagnostic interview and set of rating scales intended to ascertain clinical high risk for psychosis (CHR-P) and measure the severity of attenuated positive psychotic symptoms over time. It has been constructed carefully harmonizing the Comprehensive Assessment of At-Risk Mental States (CAARMS 2015) and Structured Interview for Psychosis-risk Syndromes (SIPS, version 5.6.1). Both of these existing instruments have well-established validity and reliability. Psychometric properties of the PSYCHS, however, should be established independently.

Methods: Two ongoing projects are being conducted to investigate criterion validity of the PSYCHS against two gold-standard interviews. One project is being undertaken against the SIPS at ten different sites, while the other is being conducted against the CAARMS at another ten. The study population consists of individuals between the ages of 12 and 35, with an expected female/male ratio of 1:1. Participants with medical, substance abuse, or communication disorders that could interfere with accurate patient evaluation are excluded from the study. Each participant undergoes two interviews conducted by two separate certified interviewers, not more than two weeks apart. In the SIPS-PSYCHS project, one interviewer conducts a SIPS interview while the other conducts a PSYCHS interview. In the CAARMS-PSYCHS project, one interviewer conducts a CAARMS, while the other conducts a PSYCHS. Interviewers remain blinded to each other's findings. The order of interviews for each project is randomly assigned within each site. The main analysis will determine raters' agreement between PSYCHS-SIPS and PSYCHS-CAARMS considering three diagnostic groups: psychosis (20%), CHR-P (40%), and neither (40%) as quantified by intraclass kappa coefficient. The proportion for each group was selected to represent the expected proportion of patients in a typical referred sample. An estimated sample size of 100 participants for each project was calculated by the kappaSize (V1.2) to yield 95% confidence to obtain agreement between two raters that is at least very good (lower bound of kappa=0.60 and target kappa=0.79). SIPS and CAARMS interrater reliability will be obtained to ensure consistency within gold standard assessment. For validity of symptom ratings against the gold standard, intraclass correlations will be used to assess agreement. The proposed samples will be

sufficient to yield 95% confidence (two-tailed) to obtain an agreement between two raters that is at least moderate (ICC GREATER THAN .74) with a power of .80. Convergent and divergent validity of the PSYCHS will be investigated using measures internal to the Accelerating Medicines Partnership® -Schizophrenia (AMP® SCZ) data collection. A third project will be conducted with another group of 10 sites and 100 participants to assess test-retest reliability for the PSYCHS. The sample size was estimated using the same specifications as the validation study. The percentage of agreement and kappa coefficient is expected to be at least very good (95% confidence to exceed kappa=0.60) for both validity projects and the test-retest project. Symptom agreement is expected to be at least moderate (ICC GREATER THAN .74). Group differences and correlations between the PSYCHS and other measures will show differences and associations in the expected direction for convergent and divergent validity.

Results: Eight participants have been studied (CHR-P = 5, Psychotic = 1, neither = 2) to date as part of Study 1. The absolute agreement for ascertainment between PSYCHS and SIPS was 100%. Additional available psychometric data will be presented.

Discussion: Early returns from criterion validation study 1 suggest that SIPS CHR ascertainment as determined by the PSYCHS is similar to SIPS CHR ascertainment as determined by the SIPS, supporting use of the PSYCHS to derive SIPS criteria for clinical trials entry and for other studies when indicated. Additional available psychometric data will be presented.

T137. BLINDED REMOTE RATINGS OF SITE BASED PANSS INTERVIEWS ADDRESS FUNCTIONAL UNBLINDING IN A STUDY OF ACUTE EXACERBATION OF PSYCHOSIS IN SCHIZOPHRENIA

Steven Targum^{*1}, William P Horan², Sharon Sawchak², Inder Kaul², Stephen K Brannan², Steven M Paul²

¹*Signant Health*, ²*Karuna Therapeutics*

Background: KarXT (xanomeline and trospium chloride) is an oral M1/M4-preferring muscarinic agonist in development for the treatment of psychiatric disorders. Trospium blocks the peripheral cholinergic effects associated with xanomeline (e.g., nausea, vomiting, diarrhea, sweating) but permits its central effects to persist. The possibility that cholinergic-related treatment emergent adverse events (TEAEs) might occur during KarXT treatment and allow functional unblinding was investigated in 2 previously reported studies of KarXT in acutely psychotic people with schizophrenia (EMERGENT-1 and -2). In both studies, remote raters blinded to TEAEs replicated the significant site-based PANSS scores favoring KarXT-assigned participants over placebo and obviated concerns about functional unblinding. EMERGENT-3 was the third study of KarXT in schizophrenia to compare scoring differences between live interviews and remote ratings derived from audio recordings of site-based interviews.

Methods: EMERGENT-3 was a phase 3 efficacy and safety study of KarXT in acutely psychotic hospitalized adults with DSM-5 schizophrenia experiencing an acute exacerbation of psychosis (NCT04738123). Eligible participants had total PANSS scores between 80-120, scores 4 on at least 2 key positive symptom items, and a CGI-S score 4 at screening and baseline. Enrolled participants were randomized to oral KarXT or placebo (1:1 ratio) for 5 weeks and flexibly titrated to a maximum dose of xanomeline 125 mg/trospium 30 mg BID based on tolerance. Site-based raters administered PANSS interviews at every study visit and remote raters scored audio-digital recordings of these interviews. We compared paired total

PANSS scores and subscales including the Marder negative symptom factor (NSF). No data points were imputed in these analyses. Treatment response was defined as $\geq 30\%$ total PANSS score improvement from baseline using available pairs from the baseline and endpoint visits. Statistical analysis included ANOVA, paired t tests, and chi square analyses.

Results: Paired PANSS scores across all study visits (n=982) were highly correlated ($r=0.915$). 210 paired PANSS scores were available at the baseline and endpoint visits. KarXT-assigned participants had significantly greater improvement than placebo on both site-based and paired remote ratings for total PANSS scores ($p=0.0005$ and 0.0017 respectively) and the positive subscale (both $p < 0.0001$); site-based scores were significant on the negative subscale and Marder NSF whereas remote ratings yielded non-significant trends. Both site-based and remote ratings yielded significantly more KarXT treatment responders than placebo ($p < 0.004$ and < 0.04 respectively) with a total predictive value of 89.5%. A bi-directional pattern of scoring deviations was observed for the total PANSS and all subscales such that site-based scores were significantly higher than remote scores when site-based scores were symptomatically high but significantly lower when scores were low.

Discussion: Remote ratings of audio-recorded PANSS interviews replicated site-based ratings and confirmed for the third time (EMERGENT -1, -2, and -3) that remote raters with no knowledge of TEAEs can replicate the significant therapeutic benefit of KarXT over placebo for participants with schizophrenia. The findings obviate concerns that site-based raters were functionally unblinded by knowledge of TEAEs. Remote raters matched the significant findings of KarXT over placebo on the total PANSS and PSS and yielded non-significant trends favoring KarXT for negative symptoms. Lacking visual observation, the audio-recording method may limit remote raters' ability to fully assess negative symptoms.

T138. UNDERSTANDING THE INFLUENCE OF CHILDHOOD ADVERSITY ON PATHWAYS TO CARE DURING FIRST EPISODE PSYCHOSIS

Sheri Oduola*¹

¹*University of East Anglia*

Background: The link between childhood adversity (physical, sexual abuse, neglect, parental separation trauma) and the incidence of psychosis is established. However, there is limited research on the influence of childhood adversity (CA) on help-seeking and pathways to care (PtC) during first episode psychosis (FEP). In this study, we addressed two aims: (a) the associations between PtC characteristics, sociodemographic characteristics and reports of childhood adversity, and (b) the associations between the number of childhood adversities and PtC characteristics in a FEP sample.

Methods: We used data from the Clinical Record Interactive Search-First Episode Psychosis (CRIS-FEP) study. The study was conducted at the South London and Maudsley NHS Trust between 2010 and 2012. Descriptive statistical tests were used to determine associations between sociodemographic, PtC and childhood adversity. We performed multivariable logistic regression to assess the associations between a report of CA and PtC characteristics. We used multivariable negative binomial regression to examine the relationships between the number of CAs and PtC characteristics. In both regression analyses, we controlled for a priori confounders (age and gender).

Results: We identified 558 FEP patients. Of these, 218 (38.3%) patients had experienced childhood adversity, of whom 34.8% had at least two CA recorded. Patients were more likely to have experienced CA if they were female, younger, had an insidious onset of psychosis,

had a longer duration of untreated psychosis (DUP) and had used services before the onset of FEP. Among the patients that experienced CA, there was substantial evidence that they were more likely to be women (adj. OR=1.56; 95% CI=1.17 – 2.26) and had a longer DUP (adj. OR= 1.21; 95% CI=1.02 – 1.40). In terms of the relationships between the number of CA and PtC characteristics, we found evidence that patients with a long DUP (adj. IRR= 1.10; 95% CI 1.03 – 1.16), insidious onset of psychosis (adj. IRR= 1.65; 95% CI 1.21 – 2.25), and those with previous service use history (adj. IRR=1.29; 95% CI 1.02 -1.64) were more likely to experience multiple CA. Conversely, we observed that patients with family involvement in their help-seeking were less likely to report multiple CA (adj. IRR= 0.79; 95% CI 0.63 - 1.00).

Discussion: Our findings provide evidence of a link between childhood adversity and pathways to care during the first episode of psychosis. Experiences of CA are associated with longer DUP and are more prevalent in young people and women being female. There was strong evidence that patients with longer DUP, insidious onset of psychosis and previous service use are more likely to report multiple CA. Our findings are relevant to policymakers, clinicians, patients and carers.

T139. COURSE OF PSYCHOTIC DISORDERS AND CANNABIS USE: RESULTS FROM A 5-YEAR LONGITUDINAL STUDY

Giuseppe D'Andrea*¹, Amal Abdel-Baki²

¹Bologna University, ²Centre hospitalier de l'Université de Montréal

Background: Since their introduction, early-intervention services for psychosis (EIS) have proven to be more effective than standard care in reducing the long-term burden. Nevertheless, the course of psychotic disorders is highly heterogeneous and some individuals will not recover. Cannabis use, which is strongly associated with psychosis onset, might also be a key contributor to poorer outcomes.

Methods: We used a group-based dual trajectory modelling approach on a sample of first-episode psychosis (FEP) referred to two EIS located in the urban centre of Montreal to identify distinct trajectories of psychotic disorders and cannabis use and assess their relationship over a 5-years period. Both severity of psychosis and cannabis use were assessed yearly using, respectively, the Clinical Global Impression scale and the Drug Use Scale. The associations between the identified trajectories and baseline socio-demographic and clinical variables of interest were tested using multinomial logistic regression.

Results: A total of 392 individuals were included. We identified four trajectories of cannabis use: non-users (40.6%), quitters (11.6%), decreaseers (20.0%), and chronic users (27.8%). We also found four distinct trajectories of psychosis: early remission (11.5%), late remission (5.2%), partial remission (51.4%), and persistence (31.9%). Chronic cannabis users had 61% of probability to be in the group with persistent symptoms. However, non-users still had 23% of probability of non-remitting. Male sex and lower education were associated with non-remission of psychosis, whereas second-generation migrants were more likely to achieve symptoms remission compared with non-migrants. Lower social occupational functioning and diagnosis (non-affective v. affective) at baseline predicted worse long-term outcomes. Similar associations were found between predictors and cannabis use trajectories. Male sex and lower education were associated with chronic use of cannabis. Migrants were also more likely to be non-users. Lower social occupational functioning was associated with chronic use while there was no evidence of a relationship with the clinical diagnosis.

Discussion: Cannabis use persistence is associated with poorer outcomes even in EIS settings and needs appropriate intervention. Further research is needed to better identify the factors associated with persistence of cannabis use in order to reduce the burden of psychotic disorders.

T140. LINGUISTIC CORRELATES OF SUICIDAL BEHAVIOR IN INDIVIDUALS ON PSYCHOSIS SPECTRUM

Alessia McGowan^{*1}, Matthew Dobbs², Francesca Serio³, Matthew Cotter², Sophia Shuster¹, Alexandria Selloni², Cansu Sarac⁴, Zarina Bilgrami⁵, Shaynna Herrera¹, Guillermo A. Cecchi⁶, Marianne Goodman¹, Cheryl Corcoran⁷, Agrima Srivastava²

¹*Icahn School of Medicine at Mount Sinai*, ²*Icahn School of Medicine At Mount Sinai*, ³*Department of Psychiatry, Icahn School of Medicine at Mount Sinai, New York, NY 10029, USA*, ⁴*Department of Health Sciences, University of Milan, Milan, MI 20122, Italy*, ⁵*Icahn School of Medicine at Mount Sinai and Long Island University*, ⁶*IBM, Thomas J. Watson Research Center*, ⁷*Icahn School of Medicine At Mount Sinai, James J. Peters VA Medical Center*

Background: Suicidal ideation and behavior are prevalent among individuals at clinical high-risk for psychosis (CHR) and individuals with psychosis. Natural Language Processing (NLP) provides an efficient method to identify linguistic markers of suicidality in these individuals. Our prior work has demonstrated that decreased use of modals (e.g., “could”, “should”) and increased use of words with semantic similarity to “anger” are correlated with suicidal ideation in CHR individuals. This study is the first to use NLP analyses of spoken language to identify linguistic correlates of prior suicidal behavior (SB) among individuals on the psychosis spectrum. We hypothesize that individuals on the psychosis spectrum with a history of SB will use language related to impulsivity at higher rates than those who have not. Further, we test whether semantic similarity to anger or modal use may also differentiate individuals on the psychosis spectrum with and without suicidal behavior.

Methods: The sample includes 62 individuals on the psychosis spectrum without SB, 19 CHR with SB, and 29 healthy controls. SB was measured using the Columbia-Suicide Severity Rating Scale. NLP methods include part-of-speech (POS) tagging, a GoEmotions-trained BERT (Bidirectional Encoder Representations from Transformers) Model, and Zero-Shot Text Classification. Impulsivity was modeled by iteratively comparing the semantic similarity of sentences from open-ended speech samples to items on the Barratt Impulsiveness Scale (BIS) using a BERT-based model. All analyses were done with adjustment for demographics.

Results: Individuals with psychotic symptoms with a history of SB used more words related to “anger” compared to those without SB ($s=0.05$; $p < 0.001$) and healthy controls ($s=0.09$; $p < 0.001$). Modal use was not significantly different between the groups. However, individuals on the psychosis spectrum, both with SB ($s=0.43$; $p < 0.01$) and without SB ($s=0.42$; $p < 0.01$) used more words related to the sentence “I act on impulse” compared to healthy controls. There was no significant difference between individuals on the psychosis spectrum with and without SB. The same pattern of results was found for “I do things without thinking”, “I make my mind up quickly”, “I have racing thoughts”, “I don’t pay attention”, and “I say things without thinking”. Thus, for impulsivity, there were no significant differences between those with and without a history of suicidal behavior, only between each of these groups and the healthy controls.

Discussion: As anger is not characteristic of psychosis or psychosis-risk, and anger in language relates to both SI and SB, findings have implications for the consideration of subthreshold anger in suicide risk assessment. However, increased spontaneous use of impulsivity-related speech does not separate individuals with and without histories of SB in this cohort, unlike other cohorts without psychotic symptoms. These findings are similar to what we found previously for use of 1st person pronouns, which typically differentiates individuals with and without SI, but did not do so in a cohort of individuals on the psychosis spectrum. Likely, this is because these individuals already have increased impulsivity and focus on self, as compared with healthy individuals. As NLP is scalable, these language markers may improve suicide screening and prediction.

T141. EMPLOYING SERVICE USER DATA TO IMPROVE EARLY PSYCHOSIS CARE: EPI-CAL'S REAL WORLD IMPLEMENTATION OF DATA DRIVEN CARE

Sabrina Ereshefsky^{*1}, Mark Savill¹, Kathleen E. Nye¹, Regina Gemignani¹, Valerie L. Tryon¹, Madison J. Miles¹, Chelyah Miller¹, Katherine Pierce¹, Merissa Kado-Walton², Amanda P. McNamara², Khanh Linh H. Nguyen¹, Nitasha Sharma¹, Briana Sepulveda¹, Maliha Safder², Lindsay M. Banks¹, Yi Zhang¹, Laura M. Tully¹, Rachel Loewy³, Christopher Hakusui¹, Viviana Padilla¹, Stephania L. Hayes¹, Daniel J. Shapiro¹, Karina Muro¹, Khalima A. Bolden-Thompson¹, Renata M. Botello¹, Rebecca Grattan¹, Andrew Padovani¹, Adam B. Wilcox⁴, Joy Melnikow¹, Daniel Tancredi², Bonnie Hotz¹, Donald Addington⁵, Sonya Gabrielian⁶, Steven R. Lopez⁷, Lisa Dixon⁸, Cameron S. Carter¹, Tara A. Niendam¹

¹University of California, Davis, ²University of California, San Diego, ³University of California, San Francisco, ⁴Washington University St. Louis, ⁵University of Calgary, ⁶University of California, Los Angeles, ⁷University of Southern California, ⁸New York State Psychiatric Institute

Background: Research supports the benefits of collecting service user (SU) outcomes data to longitudinally track treatment progress and symptom fluctuations in a range of medical and psychopathology conditions, including psychosis-spectrum disorders. The field could still benefit from greater understanding on how to translate this data into clinical practice. More information about clinicians' decision-making using SU data and the subsequent impact to SU outcomes, particularly in early psychosis (EP) spaces, is needed.

Methods: Data-driven decision-making is a core goal of Beehive, EPI-CAL's (<https://epical.ucdavis.edu>) data collection and visualization platform for SU, primary support person, and clinic data. Beehive was designed with community partners for California EP programs participating in a learning healthcare network/EPI-NET. EP staff participate in a 3-part Beehive training series, which includes multiple sessions on how to view data and use it in care. Providers use of data in care is captured in multiple ways: 1) SU's assigned clinician views of the individual's data are tracked – each 10 visits the clinician receives a popup, “How was this data used as part of care?” and clinicians “select all that apply” of potential actions they took; 2) Providers are responsible for resolving “urgent clinical notifications” when SU responses to key survey questions indicate risk to self (RTS) or others (RTO), being unhoused, and plans to stop taking medications by indicating their response in the “action list”; and 3) Beehive tracks SU lead clinician's views of any data. To better understand successes and challenges with implementation, and specific questions of using data in care, qualitative “barriers and facilitators” interviews were conducted with clinic staff/providers.

Results: 18 California EP community and university clinics who have been actively implementing Beehive for at least 6 months were included (2021-2023). SU participation varied between 0 and 60 months. 67 responses were received to the data use in care item, and 326 urgent clinical alerts were triggered. The top 3 actions clinicians took after viewing their client's data included "did not change current plan" (19%), provided psychoeducation (16%), and illustrated progress towards specific goal (12%). Approximately 97% of urgent clinical issues were resolved, with a median response time of 2 days. A majority of alerts were for RTS (~58%) and the most frequent RTS/RTO action was "conducted risk assessment" (67%). Compared to the extremely high clinician actions to urgent clinical alerts, for SUs with at least 2 time points (~100), only around 50% of their lead clinicians viewed any data, which is lower than anticipated. There were no effects of clinician viewing behavior on longitudinal SU data outcomes: symptoms (MCSI), process of recovery (QPR), life satisfaction (PWI), shared decision-making, and treatment satisfaction. Around 30 barriers and facilitators interviews with staff/providers suggest several benefits to Beehive — increased opportunity to discuss treatment goals, visualize data, and pull information helpful for reports — as well as challenges — additional training needed, acuity of clients, and collecting the data in general as initial barriers.

Discussion: Innovative approaches to collecting and using data in EP care has shown implementation successes as well as challenges. There are still several challenges to true measurement-based care implementation efficacy, as higher adoption is needed and it is difficult to view outcomes when use is so low. Clinician behavior change is also a significant potential moderator, as data-driven care may be new for many of our community-based clinicians. Together, these data suggest clinicians are responsive with external prompts (such as emails or pop-ups), find these features useful, and collect important information related to interventions with EP service users. However, when the impetus is on the clinician, we have more work to do.

T142. OPEN BOARD

T143. WHY DO SOME PEOPLE WITH PSYCHOSIS RISK SYMPTOMS SEEK PROFESSIONAL HELP AND OTHERS DO NOT?

Tecelli Dominguez^{*1}, Daniel Pech Puebla², Tamara Sheinbaum¹, Lourdes Nieto¹, Ana Fresán¹, Rebeca Robles¹, Steven. R López³, Neus Barrantes-Vidal⁴, César Celada¹, Mauricio Rosel¹, Ricardo Saracco¹, Maria del Carmen Lara⁵, Camilo de la Fuente-Sandoval⁶, Karina Franco-Paredes⁷, Felipe Díaz-Reséndiz⁷

¹*Instituto Nacional de Psiquiatría "Ramón de la Fuente Muñiz"*, ²*Comisión Nacional de Salud Mental y Adicciones*, ³*University of Southern California*, ⁴*Universitat Autònoma de Barcelona*, ⁵*Benemérita Universidad Autónoma de Puebla*, ⁶*Instituto Nacional de Neurología y Neurocirugía*, ⁷*Universidad de Guadalajara*

Background: Despite early detection and intervention efforts, many individuals with the first signs of psychosis still spend between one and two years without seeking adequate treatment. Help-seeking barriers differ according to the cultural context and country-specific mental healthcare systems. Research in this field has been mostly conducted in Western developed countries, where pathways toward care, availability, and accessibility of mental health resources differ from those of low and middle-income countries (LAMIC). Understanding

barriers to help-seeking in LAMIC, where early psychosis programs are still scarce, is important for improving strategies focused on reducing the duration of untreated psychosis. The current study aimed to explore differences in help-seeking barriers, perceived social support, and clinical and functional characteristics between two groups of Mexican young adults reporting psychosis risk symptoms, one currently receiving mental health treatment and the other not (MHT and without MHT). Furthermore, we explore predictors of using mental health services.

Methods: The sample comprised 481 Mexicans (mean age=27.2 years) reporting psychosis risk symptoms (according to the PQ-B cut-off), of which 53% (n=255) were not receiving mental health treatment. Participants responded to self-reported questionnaires through an online survey between March 2022 and October 2023. All participants provided informed consent.

Results: Findings of comparisons between groups showed that those without MHT reported higher barriers of self-reliance ($t(452)=5.2$, p LESS THAN 0.001), lack of time ($t(452)=5.8$, p LESS THAN 0.001) and money ($t(452)=3.4$, p LESS THAN 0.001), embarrassment ($t(452)=4.9$, p LESS THAN 0.001), concern about the family finding out ($t(452)=3.8$, p LESS THAN 0.001), and lack of clinician confidentiality ($t(452)=3.6$, p LESS THAN 0.001). The group receiving MHT showed significantly higher perceived social support and higher severity in all the clinical (except for depression) and functional variables than the group without MHT. The factors associated with an increased probability of using mental health services were: older age (OR=1.0, IC 95%: 1.02-1.07; p LESS THAN 0.001), a higher education level (OR=1.3, IC 95%: 1.1-1.5; p LESS THAN 0.01), higher socioeconomic status (OR=1.8, IC 95%: 1.2-2.6; p LESS THAN 0.01), greater distress associated with psychosis risk symptoms (OR=1.02, IC 95%: 1.01-1.03; p LESS THAN 0.01), higher severity of personality disorder (OR=1.0, IC 95%: 1.0-1.1; p LESS THAN 0.05) and anxiety symptoms (OR=1.2, IC 95%: 1.1-1.5; p LESS THAN 0.01), poor social functioning (OR=1.1, IC 95%: 1.0-1.1; p LESS THAN 0.0001), greater perceived cognitive impairment (OR=1.03, IC 95%: 1.01-1.05; p LESS THAN 0.01), fewer help-seeking barriers (OR=0.94, IC 95%: 0.9-1.0; p LESS THAN 0.001), self-reported mental health problems (OR=13.1, IC 95%: 8.5-20.4; p LESS THAN 0.001) and higher perceived social support (OR=1.02, IC 95%: 1.0-1.02; p LESS THAN 0.05).

Discussion: As far as we know, this is the first study exploring barriers to help-seeking in Mexican young adults with psychosis risk symptoms. Findings support previous studies indicating that stigma toward psychosis constitutes a major problem for contact with health services that may delay early identification and increase the duration of untreated psychosis. Regarding the Mexican context, the lack of preventive programs and community public services makes accessibility difficult and increases barriers for those with fewer economic resources. Findings provide relevant information that may help us understand why some of the Mexicans at-risk for psychosis are not using mental health services, which is useful for designing more effective strategies to improve help-seeking, early identification, and timely treatment delivery in Mexico.

T144. EXPLORING PATIENT PERSPECTIVES ON ANTIPSYCHOTIC MANAGEMENT FOLLOWING REMITTED FIRST EPISODE PSYCHOSIS: A QUALITATIVE STUDY

Laurent Bechard*¹, Elizabeth Anderson², Charles Massé³, Mina Gabriel-Courval³, Charles Desmeules³, Maxime Huot-Lavoie³, Olivier Corbeil⁴, Sébastien Brodeur³, Marc-André Roy³, Sophie Lauzier⁴, Marie-France Demers⁴

¹University Laval, ²School of Psychology, Université Laval, ³Université Laval Faculty of Medicine, ⁴Pharmacy Faculty, Laval University

Background: The management of antipsychotic treatment post-remission of a first-episode psychosis (FEP) remains contentious, with concerns about adverse effects and recovery outcomes. Guidelines advise using shared decision-making (SDM), yet its implementation is still limited. Patient perspectives on the treatment decision-making process are underexplored. Understanding these perspectives is crucial for optimizing SDM in clinical practice. We aim to describe the perception of service users on pros/cons of antipsychotic discontinuation after post remission of FEP.

Methods: This qualitative descriptive study involved semi-structured interviews with service users with remitted FEP at two early intervention clinics in the province of Québec, Canada. Data were thematically analyzed to discern user perspectives on the continuation or discontinuation of antipsychotic medication.

Results: Twelve service users (average age 26; 7 males, 5 females) participated, with a median follow-up of 30 months. Of these, 7 chose to continue antipsychotics, 2 were in the process of stopping, 2 intended to discuss cessation, and 1 had already stopped. Perceived advantages reported by the participants for long term antipsychotic maintenance were well-being, reduced psychotic symptoms, improved social functioning, and a reduced risk of relapse. All participants associated potential discontinuation with a heightened risk of relapse, none stated the specific percentage risk of relapse, nor the known efficacy of long-term antipsychotic use in preventing relapse in FEP as evidenced by current research. Some participants also viewed positively the fact that antipsychotic intake increased appetite, improved performance in hobbies, and gave emotional stability. However, continued long-term use was not without its perceived cons; notably, side effects were the most frequently cited concern, highlighted by half of the participants. Financial burden, dependency, and potential long-term health implications were also mentioned. Misconceptions about long-term medication risks, such as liver damage with lithium or renal damage with antipsychotics, were reported. Conversely, the choice of potentially stopping medication was seen as a way to improve well-being, reduce adverse effects, and a regain sense of self. Opinions on medication's role in achieving well-being or normalcy varied significantly; some viewed ongoing treatment as essential for stability, while others saw discontinuation as key to regaining autonomy.

Discussion: This study highlights the deeply personal and complex nature of decision-making regarding long-term antipsychotic management following FEP. Information reported by participants on the disadvantages of continued medication seemed to stem more from personal experiences rather than clinical counseling, which may reveal information needs. Although the risk of relapse is well recognized, the significance of such relapse varied extensively, with few service users reflecting on its potential impact on their lives. This underscores the need for clinicians to engage with service users more comprehensively, balancing the discussion of benefits and potential adverse effects, as experienced and perceived by the patient. Such engagement should aim to align treatment plans with each patient's values and preferences. Additionally, the complexity observed in these decision-making processes highlights the need for a decision aid tool, specifically designed to assist stakeholders in deciding whether to continue or not antipsychotic. This tool could significantly enhance the SDM process by providing personalized, evidence-based information tailored to individual needs.

T145. CANNABIS AND ALCOHOL MISUSE IN A COHORT OF PATIENTS WITH FIRST-EPISODE PSYCHOSIS: DIFFERENT TRAJECTORIES OF SUBSTANCE ABUSE AND IMPACT ON CLINICAL OUTCOMES

Carolina Spanevello*¹, Luis Alameda², Alessandra Solida³, Philippe Golay¹, Philippe Conus⁴

¹*Service of General Psychiatry, Department of Psychiatry, Lausanne University Hospital, Switzerland,* ²*Center for Psychiatric Neuroscience, Department of Psychiatry, Lausanne University Hospital, Switzerland - Service of General Psychiatry, Department of Psychiatry, Lausanne University Hospital, Switzerland,* ³*Department of Psychiatry- Lausanne University Hospital (CHUV)- CH,* ⁴*Service of General Psychiatry, Department of Psychiatry, Centre Hospitalier Universitaire Vaudois (CHUV) and University of Lausanne (UNIL), Lausanne, Switzerland*

Background: Substance use disorder (SUD) is common in first-episode psychosis (FEP) and linked to poorer clinical and functional outcomes. Previous studies on the subject were mostly cross-sectional or had short-term follow-ups, leaving clinical impact of SUD course still unclear. Our main aim in this study was to (A) group patients on the base of different trajectories of SUD course along a 3-year follow-up period and to (B) explore any consistent association with baseline characteristics and clinical outcomes.

Methods: A total of 457 FEP subjects were included from our early-intervention program. First, we performed a latent class analysis on substance abuse indicators (alcohol and cannabis) during the 3-years program and defined groups based on different trajectories of SUD course. Thereafter, we adjusted for confounding factors and compared these groups for sociodemographic, clinical and outcome data through a series of logistic regressions.

Results: First we observed that cannabis and alcohol users formed two quite distinct groups of patients with few overlapping subjects, thus outlining different consumer profiles. As a supporting evidence, latent class analysis showed that SUD evolution was different in these groups, with lack of decreased consumers in the alcohol one (abuse, abstinent or light) and three profiles for cannabis (abstinent or light, decreased and persistent). Furthermore, logistic regression showed significantly better outcomes in patients who were abstinent compared to the persistent ones. Subjects decreasing cannabis use had better functional outcomes, but less clinical improvement than expected.

Discussion: Findings in this first-episode cohort support previous evidence that substance abuse has negative impact on clinical outcomes and functioning. Comparing to previous studies, decreased SUD was less significantly associated with clinical improvement.

T146. LITERATURE REVIEW ON THE IMPACT OF PHARMACISTS IN PSYCHOTIC AND BIPOLAR DISORDERS: A SCOPING REVIEW

Nadia Akliouat*¹, Elizabeth Anderson², Charles Desmeules³, Laurent Bécharde¹, Olivier Corbeil¹, Frédéric Bergeron⁴, Marc-André Roy⁵, Marie-France Demers¹

¹*Pharmacy Faculty, Laval University,* ²*School of Psychology, Laval University,* ³*Faculty of Medicine, Laval University,* ⁴*University Laval,* ⁵*Université Laval Faculty of Medicine*

Background: Previous studies have shown pharmacists in mental health. No studies have been conducted to describe the role of pharmacists in the early intervention of psychotic or

bipolar disorders. This population is more prone to side effects from the treatments they receive. Lower adherence to antipsychotic medications is a challenge in treating patients with these disorders. A low adherence is linked to a greater risk of hospitalizations.

Methods: The study aims to conduct a scoping review of the literature on the impact of pharmacists on individuals with psychotic or bipolar disorders in the literature. The searched database includes Ovid MEDLINE, EMBASE, Cochrane Database of Systematic Reviews, PsycINFO, Web of Science without any date limitation. Data were extracted according to population, study design, country, impact of the pharmacist in the study, and study results. We included articles discussing psychotic and bipolar disorders. The articles must present the impact of clinical pharmacists. We also included retrospective cohort studies, longitudinal and observational studies, and quality improvement projects.

Results: 1676 studies were identified, and 1399 articles have been screened. The results of the study are going to be presented. A preliminary overview of the studies evaluated underlines the possible contribution of pharmacists on adherence, tolerability issues and care coordination. The pharmacist helps improve the efficacy of treatments and reduce polypharmacy.

Discussion: Pharmacists play a significant role in the care given to people with psychotic and bipolar disorders. The findings contribute to a deeper understanding of the current state of knowledge surrounding the implication of pharmacists in severe mental illnesses and help define opportunities on how to improve patients' access to the best possible care. This study also sheds light on the nuanced impact of pharmacists in optimizing outcomes for individuals with psychotic and bipolar disorders, signaling a call for further research and strategic interventions in early intervention.

T147. GLOBAL DISRUPTIONS IN WHITE MATTER INTEGRITY IN PATIENTS WITH FIRST EPISODE OF PSYCHOSIS

CIBERSAM. Universidad de Sevilla, IBiS, Sevilla, ⁹University of Copenhagen Center for Neuropsychiatric Schizophrenia Research, ¹⁰University of Edinburgh, ¹¹National University of Ireland, Galway, ¹²University of Heidelberg, ¹³Maastricht university, ¹⁴Hospital General Universitario Gregorio Marañón, ¹⁵Philipps-University Marburg, Department of Psychiatry, ¹⁶Orygen Youth Health Research Centre, ¹⁷University of Campania Luigi Vanvitelli, ¹⁸Universidade Federal de Sao Paulo - UNIFESP, ¹⁹Seoul National University College of Medicine, ²⁰Sheba Medical Center At Tel Hashomer, ²¹McGill University, ²²Department of Psychiatry and Psychotherapy, Medical University of Vienna,

Vienna, Austria, ²³University of Zurich, ²⁴The PSYSCAN Consortium, ²⁵University Medical Center Utrecht, ²⁶Department of Psychosis Studies, IoPPN, King's College London, UK

Background: Disruptions in white matter integrity have been reported across all stages of psychosis. However, findings have not been consistent, and it remains unclear whether these abnormalities precede disease onset or whether they occur downstream of disease progression. A major limiting factor of previous research has been the use of modest sample sizes. This study aims to overcome this limitation by involving multiple centres and to investigate white matter integrity at an early stage of the disease.

Methods: As part of the large-scale multi-centre PSYSCAN project, 207 (aged 25.64 ± 5.43 years; 134 male) participants with first-episode psychosis (FEP) and 113 (aged 23.67 ± 4.48 years; 66 male) age and sex-matched healthy controls (HC) completed the baseline assessment. T1-weighted and diffusion-weighted images were acquired using 3T scanners at all 18 scanning sites. Tract-Based Spatial Statistics was used to analyse fractional anisotropy. Participants also completed further scans and tests at baseline and additional time points.

Results: Relative to the HC participants, fractional anisotropy was significantly lower ($p < .05$) in FEP in multiple major white matter tracts, including the forceps minor, corticospinal tract, anterior thalamic radiation, inferior and superior longitudinal fasciculus, inferior fronto-occipital fasciculus, and hippocampus. FEP subjects displayed no brain areas of significantly increased fractional anisotropy in comparison with HC.

Discussion: This study provides empirical support that white matter integrity is disrupted during the early stages of psychosis. This disruption is not exclusive to one region but affects the brain globally. Heterogeneity in the neuropathology of psychosis, neurodevelopmental abnormalities, and factors affecting the white matter microstructure such as inflammation may contribute to the observed widespread disruption. Future research focused on underlying mechanisms is needed.

T148. LATENT TRAJECTORIES OF FUNCTIONAL AND CLINICAL OUTCOMES FOLLOWING EARLY INTERVENTION SERVICES FOR FIRST EPISODE PSYCHOSIS

Olivier Percie du Sert^{*1}, Joshua Unrau², Ridha Joobar², Ashok Malla², Delphine Raucher-Ch  n  ², Martin Lepage²

¹Douglas Mental Health University Institute, ²McGill University

Background: From the very first episode, the course of psychosis is marked by substantial heterogeneity. This heterogeneity poses significant challenges in accurately diagnosing individuals, predicting treatment response, as well as prognosticating outcomes. While systematic and meta-analytical reviews have demonstrated the effectiveness of early interventions services (EIS) for first-episode psychosis (FEP), not all individuals derive equal benefits. The heterogeneity of functional and clinical trajectories within the context of EIS remains poorly understood. This study aimed to identify latent trajectories of functional, and clinical outcomes in a representative sample of FEP individuals undergoing EIS during the critical period. Additionally, we examined the inter-relationship between trajectories and investigated the association of trajectory membership with baseline characteristics and distal outcomes.

Methods: The Prevention and Early Intervention Program for Psychoses (PEPP-Montreal) is a 2-year, high-fidelity, catchment area-based, EIS for FEP. Between 2003 and 2018, PEPP-Montreal provided services to 689 drug-na  ve individuals aged 14-35 years old, with

schizophrenia or another psychotic disorders. A comprehensive longitudinal assessment conducted at baseline, 1, 2, 3, 6, 12, 18 and 24 months yielded a detailed characterization of participants on multiple dimensions including sociodemographic, cognition, psychopathology, and functioning. Longitudinal latent growth modelling was used to identify trajectories of functioning, positive and negative symptoms. Covariates were investigated following a manual three-step approach. Multinomial logistic regressions were performed to identify predictors of latent class membership among baseline characteristics. Wald chi-square tests were used to test for differences in distal outcomes.

Results: Two trajectories of social-occupational functioning were identified: serious to slight impairment (57%) and major to serious impairment (43%). Positive symptoms exhibited two trajectories: high and decreasing (68%) and low and decreasing (32%). Negative symptoms displayed three trajectories: persisting (44%), decreasing (41%) and fluctuating (15%). Trajectories may differ in terms of the initial level of outcome and the rate of change over time. Individuals with lower symptom trajectories tended to follow a more favorable trajectory of functioning, while those with higher symptom trajectories were more likely to have an impaired trajectory of functioning. Additionally, early treatment response consistently and strongly predicted membership in better trajectories (OR = [4-14], while significant differences in clinical remission and functional recovery were found between trajectories at the end of EIS.

Discussion: While individual trajectories were heterogeneous and highly variable, these results confirm the existence of identifiable patterns and distinct courses of outcomes. Although precision psychiatry is still an emerging concept, our findings offer insights into clinically meaningful subgroups of individuals that could inform the development of individually tailored EIS and prognosis models for individuals experiencing FEP. Ultimately, the early identification of individuals who could benefit from more intensive and targeted care becomes crucial in optimizing treatment efficacy.

T149. SOCIAL ANHEDONIA IN CLINICAL HIGH RISK FOR PSYCHOSIS AND FIRST EPISODE PSYCHOSIS: ASSOCIATIONS WITH SOCIAL COGNITION AND DEPRESSIVE SYMPTOMS

Nahrie S Kim¹, Tae Young Lee¹, Aram Im¹, Diane Gooding*²

¹*Pusan National University Yangsan Hospital*, ²*University of Wisconsin-Madison*

Background: Characterization of social anhedonia in individuals at risk for, or in the early phases of, psychosis is essential in terms of better understanding clinical needs and enhancing precision medicine. Prior work has suggested the association between elevated levels of social anhedonia and poorer clinical outcomes. The high comorbidity of major depressive disorder in some individuals at clinical high risk for psychosis (CHR-P) further complicates the presentation. Because impairments in social cognition may lead to disruptions in reward processing, one study goal was to examine the association between social cognitive task performance and self-reported levels of social anhedonia. We also sought to investigate further the relationships between social anhedonia, depression, and other psychopathological features.

Methods: The participants included 51 CHR-P individuals, 29 first-episode psychosis (FEP) patients, and 92 matched healthy controls (HC). We administered the Anticipatory and Consummatory Interpersonal Pleasure Scale (ACIPS) to measure social anhedonia, the Reading the Mind in the Eyes Test (RMET), and the Mayer-Salovey-Caruso Emotional Intelligence Test-Managing Emotions (MSCEIT-ME) to assess social cognition, and the

Montgomery-Asberg Depression Rating Scale (MADRS) to evaluate depressive symptom severity. Group comparisons and correlation analyses examined the relationship between the ACIPS and the RMET, MSCEIT-ME, and MADRS.

Results: Both the CHR-P and FEP groups demonstrated significantly lower ACIPS scores, indicating greater social anhedonia, than the HC group ($p < .001$). Within the CHR-P group, 21 individuals had comorbid major depressive disorder. The ACIPS scores of the CHR-P group with comorbid depression were significantly lower than those without comorbid depression ($p < .05$). The MADRS score in the CHR-P group was correlated with ACIPS scores at a trend level. The ACIPS scores of FEP patients were significantly correlated with MSCEIT-ME scores but not with RMET accuracy. In contrast, neither the CHR-P nor HC groups exhibited any correlation between the ACIPS and either social cognitive task (MSCEIT-ME or RMET).

Discussion: These data converge with earlier studies indicating that CHR-P individuals exhibit pronounced social anhedonia before psychosis onset. The findings extend the literature by suggesting potential variations in the mechanisms underlying the manifestation of social anhedonia within the psychosis spectrum. The significant association of social anhedonia with concurrent depression observed within a subgroup of CHR-P individuals may indicate a particularly at-risk group or may be predictive of a distinct diagnostic trajectory within the CHR group. Further investigation from a transdiagnostic perspective should be conducted on CHR-P individuals. These additional characterizations may help inform early identification and treatment efforts.

T150. INTRODUCING A VALUABLE RESEARCH TOOL: THE HEALTHCARE-INTEGRATED RESEARCH DATABANK

Anne-Marie Essiambre^{*1}, Chantale Thériault¹, Maxime Huot-Lavoie², Colombe Claveau³, Olivier Corbeil⁴, Laurent Béchar⁴, Sophie Chabot¹, Elizabeth Anderson⁵, Marie-France Demers⁴, Roy Marc-André⁶

¹CERVO Brain Research Centre, ²Faculty of Medicine, Laval University, ³Psychology School, Laval University, ⁴Pharmacy Faculty, Laval University, ⁵School of Psychology, Université Laval, ⁶Department of Psychiatry, Laval University

Background: Clinique Notre-Dame-des-Victoires is a first episode psychosis (FEP) clinic, based in Québec, Canada. The clinic provides clinical support for youth who have undergone a FEP, featuring a diverse team of clinicians from various health fields dedicated to enhancing their long-term recovery. Complementing the clinical team, the clinic also houses healthcare-integrated research team, the Équipe de recherche RAPPsoDIS (Recherche Axée sur la Personne et le Psychose: Démarche Intégrée aux Soins, i.e. the Person-Centered Research and Psychosis: Integrated Approach to Care). A databank has been developed to address identified clinical needs and research questions posed by graduate students or researchers, aiming to enhance knowledge in the field of FEP. More specifically, the primary objectives include: 1) enhancing comprehension of FEP patients' experiences; 2) identifying mental and physical comorbidities and their correlations with various FEP aspects; 3) defining the relationship between psychosis-associated factors and functional levels; 4) evaluating the impact of diverse treatments; 5) measuring the influence of overall health on functioning; 6) documenting treatment response and contributing factors; and, 7) advancing understanding of the evolution of FEP.

Methods: Ethical approval has been obtained before establishing the healthcare-integrated research databank. The platform employed for the databank is RedCap (Research Electronic Data Capture), a secure web software designed for constructing and overseeing projects, including databases and surveys. Access to a patient's clinical data requires written consent. Following this, a research team member collects and inputs data into the databank. Consequently, the databank's population aligns with admission criteria for the FEP clinic: patients must exhibit symptoms or a diagnosis of a psychotic disorder, be aged between 18-35, and either have not been treated for psychosis or have received treatment for less than 12 months.

Results: The structure of the databank was inspired by the clinical monitoring of patients admitted to the FEP clinic. Observation spans from admission to the clinic and recurs every six months until the end of follow-up. Diverse databank forms capture metabolic, demographic, pharmacological, and clinical data. For instance, blood tests measure health indicators such as blood sugar, prolactin, cholesterol levels, and metabolic syndrome risk. Sociodemographic details include socio-professional status, marital status, education, legal status, diagnoses, comorbidities, family history (mental and physical), psychological trauma history, and psychiatric hospitalization. Ongoing records of psychotropic medications encompass type, dosage, and treatment duration. Additionally, data from various clinical scales widely used in the FEP field is collected.

Discussion: The continual advancement of technologies, including secure web software, presents a significant advantage for mental and physical health research. It offers compelling options to enhance understanding in FEP. Utilizing a databank such as the Healthcare-integrated Research Databank is one of these valuable options. The great variety of data in this databank renders it exceptionally unique and holds promise for addressing research questions and clinical needs. In the near future, we aim to enhance data management through the implementation of artificial intelligence. This approach has the potential to streamline databank management, benefiting various research projects. Looking ahead, clinicians and patients may also reap the rewards of these advancements.

T151. UNDERSTANDING CAFFEINE IMPACT ON SUSTAINED ATTENTION IN EARLY PHASE PSYCHOSIS: UNVEILING COGNITIVE INSIGHTS THROUGH THE USE OF EEG

Ashley Francis^{*1}, T-Jay Anderson², Katie McKearney³, Philip Tibbo⁴, Derek Fisher⁵

¹*Dalhousie University Faculty of Medicine*, ²*Department of Psychology, Dalhousie University*, ³*Department of Psychology, Mount Saint Vincent University*, ⁴*Dalhousie University, Faculty of Medicine*, ⁵*Department of Psychology, Mount Saint Vincent*

Background: Caffeine is commonly consumed for its purported positive effects on alertness, mood, and cognition. Cognitive impairment, including the domain of attention, stands out as a notable feature of schizophrenia (SZ). Those diagnosed with SZ often consume high levels of caffeine, commonly exceeding 550 mg daily, but how caffeine influences cognition in individuals with SZ, especially in the early stages of the illness, remains understudied. Electroencephalography (EEG)-derived event-related potentials (ERPs) provide a means to explore these cognitive effects at the neural level. This study aimed to investigate how acute caffeine intake affects individuals with SZ using a double-blind, placebo-controlled design.

Methods: Our study involved individuals from the Nova Scotia Early Psychosis unit who were within the first five years of their SZ diagnosis (n = 11) and healthy controls (n = 14), all between the ages of 20 – 38 (HC: M = 22.5, SZ: M:28.18), participants significantly

differed in age with individuals with SZ being significantly older than HCs. There were no other differences between groups on any other demographic information.

Results: Our findings revealed that, regardless of the drug condition, individuals with SZ consistently showed smaller P300 amplitudes than HCs throughout AX-continuous performance task (AX-CPT). Individuals with SZ also tended to have faster P300 latencies, possibly indicating incomplete processing within this group. There were no main effects found for the behavioural findings, however, some interesting interactions were found. One interesting interaction revealed that there was a relationship between the accuracy of responses, drug condition and group, such that HCs ($M = 93.96$, $SE = 1.66$) in the caffeine condition were outperforming individuals with SZ ($M = 87.79$, $SE = 2.19$; $p = .05$). We also found the expected results, which suggested that the caffeine significantly improved the performance of HCs on the behavioural findings. Interestingly, our study suggested that the relationship between caffeine and SZ might be influenced by symptom profiles. Specifically, higher negative symptoms were linked to longer latencies while amplitude appeared to be more influenced by positive symptoms, suggesting an increase in positive symptoms correlated with a decrease in P300 amplitude, however, this was only true when caffeine was present.

Discussion: Our research suggests that acute caffeine intake did not enhance sustained attention in individuals with early-phase schizophrenia, at either the neural or behavioural level. Future studies should consider using caffeine doses equivalent to or higher than participants reported daily intake as we found that compared to previous reports the usage reported by our participants was abnormally low. The relatively low caffeine use in our SZ sample could serve as a limitation to the study and may be a distinct feature of an early-phase sample, however, this relationship would need to be further explored.

T152. EARLY PSYCHOSIS PROGRAM SERVICE USER SELF-REPORTED EDUCATION, EMPLOYMENT, AND SOCIAL ACTIVITIES AND THE RELATIONSHIP TO OVERALL LIFE SATISFACTION: PRELIMINARY DATA FROM THE CALIFORNIA EPI-CAL PROJECT

Valerie Tryon^{*1}, Kathleen E. Nye², Nev Jones³, Leigh Smith⁴, Mark Savill⁵, Sabrina Ereshefsky⁶, Daniel Shapiro⁷, Katherine M. Pierce⁵, Chelyah Miller⁸, Madison J. Miles², Amanda P. Psychiatry and Behavioral Sciences; Early Psychosis Programs, ⁸Department of Psychiatry and Behavioral Sciences, University of California-Davis, Sacramento, CA, ⁹University of California at San Diego, ¹⁰Herbert Wertheim School of Public Health and Human Longevity Science, University of California San Diego, ¹¹University of California, San Diego, ¹²Department of Psychiatry, Weill Institute for Neurosciences, University of California - San Francisco, ¹³Department of Psychiatry and Behavioral Sciences, University of California,

Davis, School of Medicine, Sacramento, CA 95820, USA, ¹⁴Center for Healthcare Policy and Research, University of California-Davis, Sacramento, CA, ¹⁵Washington University in St. Louis, ¹⁶Department of Pediatrics, University of California Davis, ¹⁷Department of Psychiatry, University of Calgary, ¹⁸Department of Psychiatry and Biobehavioral Sciences, David Geffen School of Medicine, University of California Los Angeles, ¹⁹Department of Psychology, University of Southern California, ²⁰NYSPI/Columbia University Medical Center

Background: California's EPI-CAL project (<https://epical.ucdavis.edu>) joined several university- and community-based early psychosis (EP) programs to create a learning health care network and contribute to the NIMH EPINET database. People receiving EP care consistently identify obtaining occupational success and high-quality social relationships as important goals. Satisfaction with vocational roles and social relationships can contribute to overall quality of life. The objective of the current study was to summarize education and employment-related activities for services users in EPI-CAL, to examine if they are satisfied with their current occupational and educational roles in life and their relationships, and whether this was related to overall satisfaction with life as whole.

Methods: Service users across EPI-CAL clinics completed self-report surveys about outcomes related to their life and mental health treatment. Surveys are administered at enrollment in the EP program and every 6 months thereafter. Descriptive analyses summarize the demographic and outcomes data collected related to service users' self-reported functioning, including survey responses regarding life outlook, social relationships, employment, and education. Chi-square analysis was used to examine age group differences between education and employment activities. A linear regression was run to examine the effect of role satisfaction and social relationships on overall life satisfaction as measured by the Personal Wellbeing Index (PWI).

Results: To date, 287 service users across 20 EPI-CAL clinics have completed surveys on life outlook, education, employment and related activities, and social relationships. Services users received diagnoses associated with a first episode psychosis (FEP; $n = 208$, 72%), clinical high risk (CHR; $n = 65$, 23%), or FEP/CHR status not confirmed ($n = 14$, 5%). Ages ranged from 11 to 36 ($M = 20.01$ years, $SD = 4.7$). School and work attendance was examined across age groups with 137 individuals (48%) reporting school attendance only (part-time or full-time), 49 individuals (17%) in work only, 34 individuals (12%) in both school and work, and 49 individuals (17%) engaged in neither school nor work. As expected, there was a significant effect of age on the type of activities that individuals were engaged in ($\chi^2(9)=127.75$, $p < 0.001$), with younger people proportionally participating in only school to a higher degree than other roles and older adults (26+ years) were engaged in only work or neither work nor school to a higher degree than other age groups. When asked whether they were engaged in as much work, volunteering, or school as they wanted, 115 (40%) service users either agreed or strongly agreed and 101 (35%) disagreed or strongly disagreed. Social relationships (belonging to a group of people that share attitudes and beliefs), role satisfaction (feels that current role will help them reach their long-term goals), and participation in education and/or employment activities significantly predicted overall satisfaction with life as a whole (R^2 for overall model 23.1%; $F(5, 238) = 14.27$, $p < 0.001$).

Discussion: In the current study, work and school engagement varies widely across service users in EP programs as the individuals in these programs represent a diverse group that are at different developmental stages in their life. Self-reported social relationship satisfaction, role satisfaction, and work and/or school engagement were significantly related to overall life satisfaction. Therefore, EP service providers must focus on occupational, educational, and

social relationship satisfaction as recovery goals for individuals receiving early intervention services.

T153. EVALUATING AN EARLY-STAGE PSYCHOSIS TRAINING PROGRAM FOR INTERDISCIPLINARY MENTAL HEALTH TRAINEES: A MIXED-METHODS PILOT STUDY

Joseph DeLuca^{*1}, Julie Berrett-Abebe¹, Michelle Pagnotta¹, Reese Ranno¹, Lennart Mierow¹, Margaret McClure¹

¹*Fairfield University*

Background: Early-stage psychosis (EP) refers to youth at clinical high risk for psychosis (CHR) or those experiencing first-episode psychosis (FEP). Early identification is critical, since a longer duration of untreated psychosis (DUP) is consistently associated with poorer recovery outcomes. However, many mental health (MH) providers do not receive training in EP screening/referral and few studies have focused on training MH trainees – a critical population of future leaders in the field who are very likely to work with young people experiencing psychosis during their training. The aim of this study was to pilot test an EP training program for interdisciplinary MH trainees.

Methods: We conducted this ~75-minute in-person training in December 2023 with interdisciplinary MH trainees (graduate and undergraduate) at a US university. A mixed-methods approach was used, with a pre-test (N=33) and immediate-post-test (N=37). The presentation was co-developed and co-presented by an EP expert (licensed clinical psychologist) and two experts in interdisciplinary healthcare (licensed social worker and licensed counselor). The interactive presentation included ~15 minutes of foundational content on interdisciplinary healthcare best practices, followed by ~60 minutes of EP content (e.g., prevalence and spectrum of psychosis, CHR v. FEP, case study and video, stigma, screening/referral, Q and A). Primary outcome variables included clinical comfort in treating someone with psychosis; intended clinical behavior regarding screening, seeking supervision/consultation, and speaking with caregivers about psychosis; clinical self-efficacy regarding knowledge and skills; public stigma (social distance, negative stereotypes); psychosis knowledge and perceived barriers to implementing knowledge/skills (open-ended questions); and feasibility/acceptability (satisfaction).

Results: Matched participant data were analyzed (N=21). This matched sample was primarily white (81%), graduate students (76%), female (67%), and aged 18-34 (81%). There was a relatively even distribution of trainees from psychology, social work, counseling, psychiatric nursing, and marriage/family therapy. Paired-samples t-tests revealed significant pre/post changes in all outcome domains: clinical comfort ($p=.021$), intended clinical behavior (likelihood of screening [$p=.005$] and speaking with caregivers [$p=.002$]; seeking supervision/supervision [$p=.340$]), clinical self-efficacy (knowledge [$p \text{ LESS THAN } .001$] and skills [$p \text{ LESS THAN } .002$]), public stigma (social distance [$p \text{ LESS THAN } .001$] and negative stereotypes [$p=.002$]), and feasibility/acceptability (satisfaction $M=9.2/10.0$, $SD=1.3$, and GREATER THAN 95% agreed the training was useful and could be incorporated into their clinical work). One-third of participants reported limited psychosis knowledge at pre-test, and preliminary qualitative analyses suggested improvements in psychosis knowledge at post-test. Barriers to implementing knowledge from the training into clinical practice included structural barriers (e.g., too many screeners at intake, reimbursement) and lack of confidence due to limited clinical experience.

Discussion: This brief, interdisciplinary training program on EP demonstrated acceptability, feasibility, and initial effectiveness. Interdisciplinary MH trainees reported improvements in their clinical development, reductions in stigma, and high satisfaction with the training. Participants also identified perceived barriers to using new knowledge and skills. Future research will further explore barriers and facilitators, as well as survey participants longitudinally to explore trainees' retention and use of training skills.

T154. EARLY PSYCHOSIS INFORMATICS INTO CARE [EPICARE]: A CO-DESIGNED FRAMEWORK FOR IMPLEMENTING AND EVALUATING A NATIONAL INTEGRATED DIGITAL REGISTRY AND CLINICAL DECISION SUPPORT SYSTEM WITHIN EARLY INTERVENTION IN PSYCHOSIS SERVICES

Sian Lowri Griffiths^{*1}, Graham Murray², Sophie, M Allan³, Sonia Johnson⁴, Richard Drake⁵, Sarah Sullivan⁶, Megan Pope¹, John Ainsworth⁵, Pauline Wheelan⁵, Ben Green⁵, Mohammad Zia Katshu⁷, Yanakan Logeswaran⁸, Matt Machin⁹, Justin Waring¹, Rachel Upthegrove¹, James Kirkbride⁸

¹University of Birmingham, ²Department of Psychiatry, ³University of East Anglia, ⁴University College London, ⁵University of Manchester, ⁶University of Bristol, ⁷Nottingham University, ⁸UCL, ⁹University of Manchester

Background: Early Intervention in Psychosis (EIP) services in England are mandated to provide multidisciplinary care to people experiencing First Episode Psychosis (FEP). Despite UK National Health Service (NHS) investment in EIP, people from historically underserved populations may have unequal access to high quality services, and only 30-40% achieve full recovery. In other disease areas, including stroke and dementia, national digital registries coupled with clinical decision support systems have revolutionised delivery of equitable, evidence-based interventions to transform patient outcomes and reduce population-level disparities in care and prognosis. Given psychosis is ranked the third most burdensome mental health condition by the World Health Organization, it is essential that we achieve the same parity of health improvements. We have co-designed an evidence-based, stakeholder-informed framework for the build, implementation, and evaluation of a national integrated digital registry and clinical decision support system for psychosis, known as EPICare (Early Psychosis Informatics for Care).

Methods: Using a participatory co-design framework, we engaged key stakeholders (N~40-50) across four meetings to establish the parameters and essential features of EPICare and identify factors likely to influence adoption and implementation into routine practice. Stakeholders consisted of organisational, clinical, academic, and patient and public contributors. In collaboration with National Health Service (NHS) informatics teams, we identified how to retrieve key data items from Electronic Health Records and subsequently design the software architecture and data model to create an infrastructure plan for future implementation.

Results: Guided by Normalisation Process Theory, data synthesised from observations of stakeholder meetings and individual interviews (n=10) were subject to interpretative qualitative analysis. A co-designed set of guides were produced to allow for the build, implementation, and evaluation of EPICare in a larger, future study. The results of which will be presented in this talk, along with the next steps for the future deployment and evaluation of EPICare within EIP in the UK.

Discussion: With the enormous pressures facing our health systems, leveraging data from routine practice, to learn and provide real-time actionable insights, will be vital to improve real-world outcomes, identify and prevent inequalities in care, and ensure individuals receive the most appropriate treatments at the right time to promote recovery and maximise life chances.

T155. PITUITARY VOLUME AND STRESSFUL LIFE EVENTS IN ADOLESCENTS AT CLINICAL HIGH RISK FOR PSYCHOSIS

Mireia Solerdelcoll*¹, Adriana Fortea², Daniel Ilzarbe³, Elena de la Serna⁴, Emma Muñoz⁵, Inmaculada Baeza⁶, Gisela Sugranyes⁶

¹Institute of Neuroscience, Hospital Clínic de Barcelona, ²Department of Psychiatry and Psychology, Institute of Neuroscience, Hospital Clínic of Barcelona, Spain, ³Department of Child and Adolescent Psychiatry and Psychology, Institute of Neuroscience, Hospital Clinic of Barcelona, Barcelona, Spain, ⁴Department of Child and Adolescent Psychiatry and Psychology, Institute of Neuroscience, Hospital Clinic of Barcelona, Barcelona, Spain. Centro de Investigación Biomédica en Red de Salud Mental (CIBERSAM), Barcelona, Spain, ⁵Magnetic Resonance Image Core Facility, Institut d'Investigacions Biomèdiques Agustí Pi i Sunyer (IDIBAPS), Barcelona, Spain, ⁶Department of Child and Adolescent Psychiatry and Psychology, Institute of Neuroscience, Hospital Clinic of Barcelona, Barcelona, Spain. Centro de Investigación Biomédica en Red de Salud Mental (CIBERSAM), Barcelona, Spain. Institut d'Investigacions Biomèdiques Agustí Pi i Sunyer (IDIBAPS), Barcelona, Spain.

Background: Identifying biomarkers of transition to psychosis in individuals at clinical high risk for psychosis (CHR-P) is essential to understanding the mechanisms underlying the disease. Pituitary volume (PV) abnormalities, which are thought to index hypothalamic-pituitary-adrenal (HPA) axis dysregulation, have been observed in the early stages of psychosis. PV enlargements have been identified in CHR-P samples and are more pronounced among those who later develop psychosis. Adolescence is an important period for understanding brain changes associated with the onset of psychosis and coincides with developmental maturation of the HPA axis, however, no studies so far have examined PV changes in adolescents at CHR-P. We aimed to compare PV in adolescents at CHR-P and healthy controls at baseline.

Methods: A longitudinal study (CAPRIS) was performed in adolescents (aged 10-17 years) at CHR-P and healthy controls (HC). At baseline, socio-demographic data were collected, and a comprehensive clinical assessment was performed on all participants, including the Structured Interview for Prodromal Symptoms, and the Scale of Prodromal Symptoms (SIPS/SOPS) and the Stressful Life Events Schedule (SLES). Structural images were acquired at baseline. Images were processed with FreeSurfer. Between-group differences in PV were examined.

Results: A total of 67 scans (30 CHR-P and 37 HC) were included in the analysis. There were no significant differences in sex, age, or cannabis use between groups, but there were differences in the use of pharmacological treatment ($p < .001$). A higher number of Stressful Life Events (SLE) in the CHR-P compared with HC was found ($p < .001$). CHR-P individuals had significantly larger PV relative to healthy controls ($823,9 \pm 132,9$ vs. $757,1 \pm 135,8$ mm³, $p = 0,047$), however, between-group differences after controlling for the use of antipsychotics, were not maintained ($p = 0.223$). There was a strong,

positive correlation between PV and psychosocial stress, $r = .82$, $p < .001$, with a greater number of SLE associated with larger PV.

Discussion: The phase before the onset of psychosis in a sample composed of exclusively children and adolescents is associated with a larger PV, possibly reflecting stress-related HPA axis hyperactivity. We propose that PV together with a combination of criteria that focus on complementary aspects of the clinical features, such as the role of stress and hormonal stress response can increase our ability to predict the occurrence of a first episode of psychosis, thus allowing specific and targeted preventive strategies. Preventing or reducing the stress response in the prodromal phase could potentially alter the trajectory to psychosis.

T156. SEX DIFFERENCES IN WORKING MEMORY IN EARLY PSYCHOSIS: A TRANSLATIONAL STUDY IN RATS AND HUMANS

Itziar Montalvo¹, Antonio Armario², Joan Visa², Silvia Fuentes², Roser Nadal², Meritxell Tost¹, Francesc Estrada¹, Ángel Cabezas³, Elisabet Vilella³, Javier Labad^{*4}

¹*Department of Mental Health. Parc Tauli University Hospital. Institut d'Investigació i Innovació Parc Taulí (I3PT). CIBERSAM. Sabadell, Barcelona. Spain,* ²*Institut de Neurociències, Universitat Autònoma de Barcelona, Spain.,* ³*Hospital Universitari Institut Pere Mata, IISPV, Universitat Rovira i Virgili. Reus, Spain.,* ⁴*Consorci Sanitari del Maresme, Mataró*

Background: Working memory deficits in schizophrenia are present as impairments in the temporary storage and manipulation of information, significantly impacting cognitive functions and overall daily functioning. These cognitive deficits occur at early stages of the disease, even before the onset of psychotic symptoms. Previous research in both humans and rats (using the maternal immune activation [MIA] model of schizophrenia) suggest that there are sex differences in working memory deficits. In general, most human studies suggest a better performance in working memory in males, although other studies point to a poorer working memory in women with a history of childhood trauma. Some animal studies report poorer working memory in males. The main aim of our study was to test whether there were sex differences in working memory in rats and humans.

Methods: The animal study used a MIA model with the viral mimic polyinosinic-polycytidylic acid (poly IC). Long-Evans male and female rats from Janvier (France) were used. On days GD15 and GD17 pregnant rats were given vehicle (saline) or received 5 mg/kg (1 ml/kg) poly I:C in saline through the tail vein, while gently restrained. The influence of prenatal treatment in pups on working memory was evaluated in adulthood with the T-maze (working memory, 5 days including habituation and pretraining). Pre-pulse inhibition of the startle response (PPI, a single day, as a measure of sensorimotor gating) was also measured. The human study included 44 patients with clinical-high-risk for psychosis (CHR), 113 first-episode psychosis (FEP) and 49 healthy controls. Childhood trauma was assessed with the Childhood Trauma Questionnaire (CTQ). The Weschler Memory Scale-III-Edition Spatial Span (WMS-III-SS) was used to assess visual working memory with a translational approach (compared to the T-maze). Statistical analyses were conducted with SPSS v. 25.0 (IBM Corp, USA). General mixed models were used in rats to compare the effects of treatment (Poly IC vs saline) and sex on working memory. Multiple linear regression analyses were used in humans to explore the relationship between sex, diagnoses and childhood trauma on working memory, adjusting for age and education status, and testing potential interactions (sex by

diagnosis, sex by childhood trauma). Only significant interactions were found in the final equation. Significance was set as $p < 0.05$.

Results: Poly IC did not exert a statistically significant effect in the T-maze working memory test, but tended to induce opposite effects in males (decreasing) vs females (increasing). In addition, control females showed a reduced PPI and lower number of correct responses in the T-maze, in comparison to control males. In humans, CHR diagnosis (Beta= -0.220, $p = 0.015$) but not FEP diagnosis was associated with poorer working memory. Sex and childhood trauma were not associated with cognitive performance, nor significant interactions between sex and diagnoses or childhood trauma were found.

Discussion: While the MIA model with poly I:C in rats suggests opposite effects by sex—decreasing in males and increasing in females—the clinical implications of these findings remain uncertain. In humans, the association between clinical high-risk for psychosis (CHR) diagnosis and poorer working memory highlights the presence of cognitive impairments in people at risk of psychosis and the need for early intervention. However, the absence of significant influences related to sex or interactions with diagnoses and childhood trauma in humans suggests the need to explore other contributing factors. Our results emphasize the importance of conducting comprehensive investigations into sex-specific cognitive vulnerabilities in schizophrenia.

T157. WEIGHT CHANGES AT 12 WEEKS IN DRUG-NAIVE, FIRST-EPIISODE PSYCHOSIS PATIENTS ATTENDED IN A REAL-WORLD SETTING

Paula Suárez-Pinilla^{*1}, M^a Carmen Flor-Gómez², Clementina González-Rubial³, Susana Viota-Mañanes⁴, Rocio Perez-Iglesias⁵, Jose Antonio Cortés-Fernández², Guillermo Isidro-García², Jorge Romay-González⁵, Beatriz Voces-Gutierrez², Javier Vazquez-Bourgon⁶

¹University Hospital Maqués de Valdecilla, Santander, ²Hospital Universitario Marqués de Valdecilla, ³Hospital Comarcal de Laredo, ⁴Hospital Comarcal Sierrallana, Spain, ⁵University Hospital Marques de Valdecilla, ⁶Department of Psychiatry, University Hospital Marqués de Valdecilla, Institute of Biomedical Research Valdecilla (IDIVAL), Santander, Spain. CIBERSAM

Background: Second-generation antipsychotics often leads to weight gain even in first-episode psychosis patients, showing a rapid and continuous weight gain in the first few weeks. This study examined the weight changes induced by antipsychotic treatment in a cohort of first-episode drug-naive subjects.

Methods: We audited all the patients consecutively admitted to the Early Intervention (EI) Clinical Program for Psychosis (ITP-Can-Santander), in Spain, from January 2020 to July 2023. Inclusion criteria were: aged from 17 to 65, and being affected by a drug-naïve FEP (affective or non-affective). Exclusion criteria were: suffering from a severe neurological disease or traumatic brain injury, severe intellectual disability or/and psychosis directly induced by illicit substances. Participants were treated with very low dose of antipsychotic medication in monotherapy, CBT, and physical health interventions, which started within the first two weeks of contact with services. For this study, we investigated changes at 12 weeks in body weight.

Results: A total of 163 patients were included. Fifty-five percents were female ($n=89$). The mean age was 37 years old. Fifty three percent of the cohort ($n=87$) had more than 35 years at first contact with services, particularly women (64,1%). The mean daily dose of antipsychotics (in chlorpromazine equivalents) was 195.04 (SD=97.16) mg. The mean

baseline weigh was 65.9 (SD=14.3) kg, although the mean ‘usual’ weigh was 67.8 (SD=14.9) kg. This could mean a weight loss of 1.9 kg with respect the ‘usual’ weight at the onset of psychosis.

At week 12, 148 patients were evaluated (91% adherent to EI program). The average weight at endpoint was 71.2 (SD=13.6) Kg, meaning a weight gain of 4.9 (SD=5.6) Kg with respect the baseline mean weigh, but only 2.6 (SD=8.6) Kg when considering the mean ‘usual’ weigh. Outcomes associated with significant weight gain after 12 weeks were: tobacco consumption, cannabis use, being male and being under 35 years-old (all $p \geq 0.025$). Interestingly, being inpatient at baseline resulted in higher weight gain after 12 weeks compared to those subjects treated in the outpatient setting since onset, although this difference was not statistically significant ($t=1.89$; $p=0.061$). Finally, there were not a significant correlation between antipsychotic doses (in chlorpromazine equivalents) and weight increase after 12 weeks (Pearson’s coefficient=-.099; $p=0.316$).

Discussion: Weight gain is common in drug-naïve patients after the first 12 weeks of treatment, even with very low doses of atypical antipsychotics. However, a plausible previous weight loss before psychosis onset may be considered when quantifying the ulterior weight gain. Periodical assessments of weight along with interventions promoting physical exercise and healthy lifestyle should be part of the clinical management in EI real-world settings.

T158. STRATIFICATION OF INDIVIDUALS IN SOCIAL COGNITIVE TRAININGS: INVESTIGATING DIFFERENCES ACROSS DATA-DRIVEN BRAIN SUBGROUPS IN RECENT ONSET PSYCHOSIS

Julian Wenzel^{*1}, Öznur Bastürk¹, Dominic Dwyer², Shalaila Haas³, Paolo Brambilla⁴, Stephen J. Wood², Rachel Upthegrove⁵, Stefan Borgwardt⁶, Rebekka Lencer⁷, Eva Meisenzahl⁸, Raimo K. R. Salokangas⁹, Christos Pantelis¹⁰, Alessandro Bertolino¹¹, Nikolaos Koutsouleris¹², Joseph Kambeitz¹, Lana Kambeitz-Ilankovic¹

¹University of Cologne, Faculty of Medicine and University Hospital Cologne, Clinic for Psychiatry and Psychotherapy, ²Orygen, Melbourne, Australia, ³Icahn School of Medicine at Mount Sinai, New York, USA, ⁴University of Milan, Milan Italy, ⁵University of Birmingham, Birmingham, United Kingdom, ⁶University of Luebeck, Luebeck, Germany, ⁷University of Muenster, Muenster, Germany, ⁸Heinrich-Heine University Duesseldorf, Duesseldorf, Germany, ⁹University of Turku, Turku, Finland, ¹⁰University of Melbourne and Melbourne Health, Melbourne, Australia, ¹¹University of Bari, Bari, Italy, ¹²Ludwig-Maximilian-University, Munich, Germany

Background: Cognitive abilities critically affect real-life social and professional functioning [1] and are frequently impaired in psychiatric conditions including psychosis [2]. Social cognitive training (SCT) has shown small to medium effect sizes on cognition and real-world functioning within the psychosis spectrum [3]. Despite a large proportion of patients benefitting from the training, considerable heterogeneity in SCT response is present [4]. SCT effectivity might depend on individual differences in the brain’s susceptibility to neuroplastic changes and therefore stratification of individuals based on their brain structural characteristics might offer opportunities for personalization of SCT.

Methods: 97 individuals (age in years [sd] = 27.4 [6.49], female in % = 40.2) with recent-onset psychosis (ROP) from a multi-site cohort were randomized to either 10h of SCT or treatment as usual (TAU). We split individuals into relatively impaired and relatively

preserved brain subgroups which were derived from their individual brain structural characteristics using a data-driven clustering approach published previously [5]. Cognitive performance including social cognition, attention, verbal learning, speed of processing, working memory and global cognition as well as social and role functioning scales were assessed pre- and post-intervention to evaluate SCT effects.

Results: We found a significant improvement in Global Functioning (GF) role scores for the SCT as compared to the TAU group ($F(1,89) = 4.9, p = .03$). Among individuals of the SCT arm, individuals in the relatively preserved brain subgroup showed a significantly increased performance in the (untrained) domain of attention at the cognitive assessment post-intervention, whereas individuals assigned to the relatively impaired brain subgroup showed a decline in performance in this domain ($F(1,92)=1.7, p = .017$). Unfortunately, both effects did not survive false discovery rate correction.

Discussion: SCT has shown effectivity in improving cognitive and real-world functioning in psychosis. However, our findings show a trend that taking into account individual characteristics on the neurobiological level one might be able to identify individuals who are particularly profiting from SCT. Future studies should pinpoint more specific neurostructural and -functional targets for stratification in order to nurture this potential avenue for personalization of SCT.

T159. RISK OF RELAPSE ASSOCIATED WITH SPECIFIC ANTIPSYCHOTICS IN PERSONS WITH FIRST-EPISODE PSYCHOSIS AND CO-OCCURRING CANNABIS USE DISORDER

Heidi Taipale^{*1}, Alexander Denissoff², Jari Tiihonen³, Marta Di Forti⁴, Ellenor Mittendorfer-Rutz³, Antti Tanskanen³, Antti Mustonen⁵, Solja Niemelä²

¹Niuvanniemi Hospital, University of Eastern Finland, ²University of Turku, ³Karolinska Institutet, ⁴King's College London, ⁵Tampere University

Background: Cannabis use is associated with an increased relapse rate in persons with psychosis and in general, antipsychotic medications are effective in reducing relapses in psychosis. There is a lack of research on the effectiveness of antipsychotics regarding patients with concomitant cannabis use and psychosis, and regarding comparative effectiveness of specific antipsychotics. We studied real-world effectiveness of antipsychotics for preventing psychosis relapses among persons with first-episode psychosis and co-occurring cannabis use disorder.

Methods: Swedish nationwide registers were utilized to identify persons with first-episode psychosis and co-occurring cannabis use disorder (first-time diagnosis of psychosis as ICD-10 F20-F29, with concomitant recording of F12) during the years 2006-2021. Association between use of specific antipsychotics (oral vs. long-acting injectable, LAI, forms) and risk of hospitalization due to psychosis relapse was investigated in within-individual design where each person acts as his/her own control to minimize selection bias, analyzed with stratified Cox models.

Results: The cohort included 1820 patients (85% men, mean age 26.8, SD 8.3). Of them, 81.9% used antipsychotics during the follow-up and 63.6% were re-recorded with a cannabis use-related diagnosis, indicating persistent use. During the follow-up, 61% (N=1111) of the cohort experienced psychosis relapse. Compared with non-use, use of any antipsychotic was associated with a 33% decreased risk of relapse (aHR 0.67, 95%CI 0.60-0.72). The lowest risk of relapse was found for risperidone-LAI (0.40, 0.22-0.71), aripiprazole-LAI (0.42, 0.27-0.65), clozapine (0.43, 0.29-0.64), paliperidone-LAI (0.46, 0.30-0.69) and antipsychotic

polytherapy (0.60, 0.51-0.70). Of oral non-clozapine antipsychotics, aripiprazole was associated with the lowest risk of relapse (0.61, 0.45-0.83). Relatively similar results were observed regarding the risk of any psychiatric hospitalization and substance use-related admissions.

Discussion: Antipsychotics are effective in relapse prevention in patients with first-episode psychosis and co-occurring cannabis use disorder. These findings support the use of long-acting injectable formulations of second-generation antipsychotics in relapse prevention in these patients.

T160. FIRST-EPISODE PSYCHOSIS AND GAMING DISORDER: IMPROVING SCREENING AND PATIENT'S EVOLUTION

Maxime Huot-Lavoie^{*1}, Olivier Corbeil², Laurent Béchard³, Sébastien Brodeur⁴, Charles Desmeules¹, Chantale Thériault⁵, Anne-Marie Essiambre⁵, Colombe Claveau⁶, Lauryann Bachand⁷, Joelle Rodrique¹, Amélie M Achim⁸, Amal Abdel-Baki⁹, Isabelle Giroux¹⁰, Yasser Khazaal¹¹, Marie-France Demers¹², Marc-André Roy¹³

¹Université Laval Faculty of Medicine, ²Faculty of Pharmacy, Université Laval, ³Pharmacy Faculty, Laval University, ⁴Faculty of Medicine, Laval University; IUSMQ, CIUSSS-CN, ⁵CERVO Brain Research Centre, ⁶Psychology School, Laval University, ⁷School of Psychology, Université Laval, ⁸Département de psychiatrie et de neurosciences Université Laval; VITAM - Centre de recherche en santé durable; Centre de recherche CERVO, ⁹Centre hospitalier de l'Université de Montréal, ¹⁰School of psychology, Laval University, ¹¹Université de Lausanne, ¹²Faculté de pharmacie de l'Université Laval, Institut Universitaire en Santé Mentale de Québec, Centre de Recherche de l'Institut Universitaire en Santé Mentale de Québec, ¹³Faculté de médecine de l'Université Laval, Institut Universitaire en Santé Mentale de Québec, Centre de Recherche de l'Institut Universitaire en Santé Mentale de Québec

Background: With the recent addition of gaming disorder (GD) in the 11th international classification of disease (ICD-11), there has been a growing interest in understanding the impact of video games among people with severe mental illnesses. Although clinicians widely recognize the frequent comorbidity of GD and psychotic disorders (PD), little is known about the consequences of this addiction in such vulnerable populations.

Considering the significant impact of addictions such as substance abuse on patients' recovery, there is an impetus to better comprehend the association between PD and GD, particularly in young adults suffering from first-episode psychosis (FEP) given their increased use of video games. To this end, our research program aims to: 1) summarize the available knowledge on the comorbidity between GD and PD, including FEP; 2) determine the prevalence of GD in patients with FEP; 3) identify the consequences of GD on these patients' outcomes.

Methods: First, we realized a scoping review to summarize the depth and breadth of the literature regarding comorbid PD with GD and to identify knowledge gaps. Secondly, we conducted a prospective cohort study including all patients admitted to an adult early intervention program for FEP between November 1st, 2019, and October 31st, 2022. All patients were systematically screened for GD using the Nine-Item Internet Gaming Disorder scale (IGDS9-SF) at admission and every 6 months thereafter for up to 3 years. Diagnosis of GD was confirmed by the treating psychiatrist based on the ICD-11 criteria. The severity of

the patients' psychopathology and their functioning were rated by the treating psychiatrist using the Positive and Negative Symptom Scale (PANSS) and the Social and Occupational Functioning Assessment Scale (SOFAS), respectively, at admission and every 6 months for the duration of the follow-up.

Results: Literature concerning comorbid PD with GD is limited to only a few case reports. Little evidence suggests that excessive video game play or abrupt gaming disruption may trigger psychosis. However, there have been no empirical study conducted to support these hypotheses. Among 285 patients treated at the FEP program during the 3-year study period, 31 (10.9%) displayed an excessive gaming behaviour. Among those patients, 14 were diagnosed with GD based on the ICD-11 criteria, for a prevalence of 4.9%. Main preferences for video game types were massively multiplayer online role-playing games (MMORPGs), strategy games, solo-role playing, action-adventure games, and sports games. Trajectory analysis showed a significant association between GD and patients' symptomatology and functioning, as measured by the PANSS (chi-square = 0.035) and the SOFAS (chi-square = 0.007), respectively.

Discussion: There is a paucity of data regarding GD and comorbid PD; it is plausible that psychotic symptoms may lead or exacerbate video gaming behaviours, and the other way around, but this remains to be further explored. The preliminary results of our cohort study highlight an increased prevalence of GD in FEP patients compared to the general population. Most importantly, these findings suggest that GD may significantly interfere with patients' recovery, which underscores the need for greater clinical and research attention to this comorbidity.

T161. SUPPORTING EDUCATION IN YOUNG PEOPLE FACING A FIRST EPISODE PSYCHOSIS: THE EXPERIENCE OF A RECOVERY-ORIENTED SUMMER SCHOOL

Amelie Pavard^{*1}, Tasneem Pichori², Anne-Laure Krikorian³, Benjamin Garnier⁴, Malgozarta Pousthomis⁴, Mathilde Rozet⁴, Louis Volle⁴, Marjorie Coquery⁴, Romain Tabone⁴, Annabelle Boudou⁴, Nathalie Perez⁴, Quentin Litaudon⁴, Frederic Haesebaert⁵

¹CH Le Vinatier, Lyon, ²Abt Brain, Lyon (France), ³Université Claude Bernard, Lyon (France), ⁴CH Le Vinatier, Lyon (France), ⁵PSYR2 Team, INSERM U1028, CNRS UMR5292, Lyon Neuroscience Research Center, Université Claude Bernard Lyon 1, Lyon, France, Lyon, France.

Background: Students represent a vulnerable population: nearly 75% of mental health disorders begin before age 24 (Kessler et al., 2007). Young adults are bound to face an important amount of changes in different areas of their lives (corporal, emotional, hormonal, environmental, and economical dependance), and even more so as students (geographical distance from family, cognitive mobilization, examination stress...). Despite this high level of vulnerability that requires greater mental health care, we observe less resources and less healthcare seeking in this population (Morvan and Frajerma, 2021).

Due to cognitive impairment and residual symptoms, students experiencing a first psychotic episode (FEP) are particularly at risk of dropping out. The literature shows that accessing cognitive remediation therapy and transferring the acquired knowledge into daily life (bridging) is difficult for FEP users. To improve cognitive abilities and bridging, several studies highlight the need to develop integrative and ecological approaches that promote

active experimentation strengthening self-determination (Versace et al., 2021; Masson, 2022; Haesebaert, 2023). Supporting FEP students in an integrative way in and with their environment, therefore represents a challenge.

Methods: According to Romainville (2000), three main important factors can promote adaptation to higher education: personal factors (motivation, self-esteem, coping skills, learning strategies, self-construction, managing daily-life, lifestyle and physical activity, self-determination), pedagogic factors (self-documentation and teaching methods), and environmental factors (familial dimension and resource people at school).

Based on these factors, we co-built a 4-days “summer school” with healthcare professionals and academics (physical activity educator, occupational therapist, neuropsychologist, case managers, psychologist, psychiatrists and peer helpers).

The objectives were to provide a daily rhythm, information about school arrangements, concrete and simple tools to integrate into students’ daily lives (e.g. stress regulation tools, cognitive management...), and to help identify resource people available during the school-year to avoid dropouts. Everyday included mindfulness practises, physical activity, as well as a psychoeducation sessions and active experimentation on a target topic.

Results: We carried out two sessions in summers 2023 (S1) and 2024 (S2). We observed good user attendance: 67% (S1) and 80% (S2) participants attended the entire summer school. Participants indicated that the summer school was useful (78%), and that they felt comfortable contacting one of the speakers in the future (76%). Post-summer schools, users were significantly more confident about their studies ($p=.05$) and the balance between studies, leisure, and social life ($p=.05$), compared to pre-summer schools. Six months post-summer schools, 57% (S1) and 87% (S2) of the students were still in school. We plan to organise a 2-day-boosting session in February 2024 after the exams, to support the students’ motivation. This short session will also rely on the student adaptation questionnaire to university (QAEU, Carayon and Gilles, 2005), as a complementary measure of effectiveness.

Discussion: The summer school offers an integrative and ecological approach in school university environment, and promotes active experimentation to strengthen self-esteem and motivation. It appears to be an interesting way of promoting social functional recovery and reducing school dropouts for FEP students.

T162. ROLE OF CLINICAL INSIGHT AT FIRST MONTH IN PREDICTING RELAPSE AT THE YEAR IN FIRST EPISODE OF PSYCHOSIS (FEP) PATIENTS

Mirjana Selakovic*¹, Ilias Vlahos², Irene Ralli², Alexandros Hatzimanolis², Lida- Alkisti Xenaki², Stefanos Dimitrakopoulos², Rigas- Filippou Soldatos², Stefania Foteli², Nikos Nianiakos², Ioannis Kosteletos², Pedagogiotissa Stefanatou², Ageliki- Aikaterini Ntigridaki², Theoni- Fani Triantafyllou², Marina Voulgaraki², Vassiliki Ermilou², Leonidas Mantonakis², Konstantinos Kollias², Nikos C. Stefanis²

¹*GH Sismanogleio*, ²*1st Department of Psychiatry, National and Kapodistrian University of Athens, Eginition Hospital*,

Background: Clinical insight constitutes a useful marker of the progress and outcome of First Episode of Psychosis (FEP) and lack of insight has been associated with more severe psychopathology, treatment non-adherence and re-hospitalization/relapse. In this study, we aimed to further investigate the possible role of insight as predictor of relapse, its relation to

diagnosis (non-affective vs affective psychosis) and to other parameters of positive psychotic symptomatology namely delusions, hallucinations and suspiciousness.

Methods: 88 patients of the Athens FEP study were examined at three different time points (baseline, month, year). Their scores in the relevant items of the Positive and Negative Syndrome Scale (PANSS) were compared (G12 for insight; P1 for delusions, P3 for hallucinations, P6 for suspiciousness) and were further associated to diagnosis (non-affective vs affective psychosis) and outcome of the year (remission/relapse).

Results: According to G12, 16.1% of the participants had insight at baseline, 69% at one month and 86.9% at one year. Subjects with absence of insight at one month and one year according to G12 had significantly greater P1, P3 and P6 at one month and one year, respectively. Patients with relapse at one year had greater score on G12 at one month and one year, while the median change of G12 from baseline to one year was lower in those with relapse. At one month, P1 and P6 were significantly higher in patients diagnosed with non-affective psychosis compared to those diagnosed with affective psychosis ($p < .001$).

Discussion: Lack of insight based on G12 at one month may serve as predictor of relapse at one year. Delusions and suspiciousness (based on P1, P6) at one month relate to the diagnosis of non-affective psychosis.

T163. COMPARING FUNCTIONAL OUTCOMES BETWEEN TWO COORDINATED SPECIALTY CARE AT 6- AND 12-MONTHS: THE ROLE OF DUP

Hadar Hazan*¹, Bin Zhou², Fangyong Li³, Maria Ferrara⁴, John Cahill⁵, Emily Kline⁶, Toni Gibbs-Dean⁷, Silvia Corbera Lopez⁸, Sneha Karmani⁷, Sarah Riley⁹, Sumeyra Tayfur⁷, Cenk Tek⁷, Matcheri Keshavan¹⁰, Vinod Srihari¹¹

¹Yale Medical School, ²Yale university, ³Yale centre for analytical sciences, ⁴Institute of Psychiatry, University of Ferrara, Italy, ⁵Department of Psychiatry, Yale University School of Medicine, New Haven, Connecticut, ⁶Boston University School of Medicine, ⁷Yale University School of Medicine, ⁸central Connecticut state university, ⁹Yale university medical school, ¹⁰Harvard University, ¹¹Yale Department of Psychiatry, New Haven, CT

Background: Aim: This study aimed to investigate whether patient outcomes differ between Coordinated Specialty Care (CSC) clinics and determine how the Duration of Untreated Psychosis (DUP) explains these differences.

Methods: A quasi-experimental design compared functional outcomes from two CSC clinics: one implementing early detection (ED) strategies (STEP, $n = 147$) and the other using standard detection methods (PREP, $n = 75$). Linear regression assessed associations between DUP (total, demand, supply) and outcome measures (global, occupational, and social functioning and quality of life) at baseline, 6, and 12 months. Analysis of Variance (ANOVA) compared outcomes between sites, and Sobel's test assessed DUP's mediation role.

Results: Patients at STEP showed more significant improvement in overall functioning (measured by GAF- Δ) at both 6 and 12 months compared to those at the PREP clinic. DUP-total, and specifically the DUP-supply when considering QoL, accounted for some of the differences in overall functioning (GAF- Δ) and QoL scores between the two sites at 6 months. DUP did not explain the differences at the 12-month mark.

Discussion: Conclusions: DUP reduction may improve functional outcomes in the early stages of CSC treatment. However, long-term effects are less clear, and other service

elements at each clinic may also influence outcomes. Future research should explore underlying mechanisms and compare different CSC models.

T164. BASELINE ANTIPSYCHOTIC PRESCRIPTION AND SHORT-TERM OUTCOME INDICATORS IN INDIVIDUALS AT CLINICAL HIGH-RISK FOR PSYCHOSIS: RESULTS FROM A 1-YEAR FOLLOW-UP INVESTIGATION IN A REAL-WORLD CARE SETTING.

Lorenzo Pelizza*¹, Alessandro Di Lisi¹, Emanuela Leuci², Emanuela Quattrone², Marco Menchetti¹

¹Bologna University, ²AUSL di Parma

Background: The prognostic prediction of outcomes in individuals at clinical high-risk for psychosis (CHR-P) is still a significant clinical challenge. Among multiple baseline variables of risk calculator models, the role of ongoing pharmacological medications has been partially neglected, despite meta-analytical evidence of higher risk of psychosis transition associated with baseline prescription exposure to antipsychotics (AP) in CHR-P individuals. The main aim of the current study was to test the hypothesis that ongoing AP need at baseline indexes a subgroup of CHR-P individuals with more severe psychopathology and worse prognostic trajectories along a 1-year follow-up period.

Methods: This research was settled within the ‘Parma At-Risk Mental States’ program. Baseline and 1-year follow-up assessment included the Positive And Negative Syndrome Scale (PANSS) and the Global Assessment of Functioning (GAF). CHR-P individuals who were taking AP medications at entry were included in the CHR-P-AP+ subgroup. The remaining participants were grouped as CHR-P-AP-. In between-group comparisons, categorical variables were examined using the Chi-square test, while the Mann–Whitney U test was used to compare continuous parameters. Logistic regression analyses with dichotomized 1-year outcome parameters (previously showing statistically significant differences in inter-group comparisons) as dependent measures and sociodemographic and clinical characteristics as independent variables were also performed.

Results: Hundred and seventy-eight CHR-P individuals (aged 12–25 years) were enrolled (91 CHR-P-AP+, 87 CHR-P-AP-). Compared to CHR-P AP-, CHR-P AP+ individuals had older age, greater baseline PANSS ‘Positive Symptoms’ and ‘Negative Symptoms’ factor subscores and a lower GAF score. At the end of our follow-up, CHR-P-AP+ subjects showed higher rates of psychosis transition, new hospitalizations and urgent/non-planned visits compared to CHR-P- AP- individuals.

Discussion: In agreement with increasing empirical evidence, also the results of the current study suggest that AP need is a significant prognostic variable in cohorts of CHR-P individuals and should be included in risk calculators. In particular, AP prescription at presentation can be considered as an indicator of poorer short-term outcome (such as psychosis transition, new hospital admission, and urgent/non-planned visits).

T165. RETROSPECTIVE STUDY OF PHARMACOGENETIC ANALYSES OF A COHORT OF PATIENTS WITH ULTRA-TREATMENT RESISTANT SCHIZOPHRENIA

Alexandre Carpentier*¹, SPR Team², Noémie Roudil³, Mickaël Naassila⁴, Marie-Cécile Bralet⁵

¹Clermont de l'Oise Psychiatric Hospital, ²Pôle PRERPS-Centre Hospitalier Isarien-EPSM Oise, ³Service Pathologies Résistantes (SPR), Clermont de l'Oise Psychiatric Hospital, ⁴GRAP INSERM UMR 1247, ⁵CRISALID CHI Clermont de l'Oise/institut de Psychiatrie/GRAP INSERM UMR 1247/ UPJV Amiens/CESP INSERM UMR 1018 Paris

Background: Antipsychotic medications serve as the primary treatment for schizophrenia. There exists considerable variation among individuals in how they respond to antipsychotics, encompassing both the effectiveness of the treatment and the occurrence of adverse effects. Although the exact source of this interindividual variability in antipsychotic response remains incompletely understood particularly in case of treatment resistant schizophrenia or ultra-treatment resistant schizophrenia, genetics emerges as a significant contributing factor. The ongoing research effort to identify pharmacogenetic markers that can predict both the efficacy and adverse reactions to antipsychotics is a rapidly advancing field. This research has the potential to replace the current trial-and-error approach to selecting schizophrenia treatments with a personalized medicine approach.

Furthermore, in instances of ultra-treatment-resistant schizophrenia, each successive intervention may exacerbate poor tolerance attributed to the frequent utilization of antipsychotic polypharmacy. The objective of our study was to conduct a retrospective analysis of pharmacogenetic assessments within a cohort of patient with ultra-treatment-resistant schizophrenia. The goal was to identify any pharmacogenetic specificities that could substantiate the hypothesis of a distinct phenotype associated with ultra-treatment-resistant schizophrenia.

Methods: A retrospective analysis was conducted to investigate the pharmacogenetic profiles of a cohort of 8 patients with ultra-treatment-resistant schizophrenia. The study spanned a specified time frame, examining historical data and pharmacogenetic information from patient records. Additional analyses conducted after October 2023 will be included in results presented on the poster.

Results: Analyses focused on the following cytochromes: CYP2D6, CYP1A2, CYP2C9, CYP2C19, CYP3A4 and CYP2B6. One patient underwent a pharmacogenetic exome sequencing after the discovery of two rare variant of the CYP2B6. All patients demonstrated hypermetabolism of CYP1A2, and 50% of them displaying hypermetabolism of CYP2C19. Conversely, 50% of the patients demonstrated complete or partial hypometabolism of CYP2D6 and/or CYP2B6. Two highly rare variants in the LRP1B and GNB3 genes were identified during exome analysis but could not be interpreted."

Discussion: These preliminary results will be further supplemented for the poster presentation, but they already reveal specificities related to some cytochromes. Additionally, discovery of rare variants is noteworthy, further exposing a patient to antipsychotic side effects and a poor response to clozapine.

T166. THE SHARED GENETIC BASIS OF CANNABIS USE AND PSYCHOSIS: A CROSS-POPULATION GENETIC PATHWAY ANALYSIS

Isabelle Austin-Zimmerman*¹, Emma Johnson², Giulia Trotta³, Edoardo Spinazzola³, Zhikun Li³, Diego Quattrone⁴, Robin Murray⁵, Pak Sham⁶, Evangelos Vassos⁴, Marta Di Forti⁵

¹King's College London, ²Washington University School of Medicine, ³Institute of Psychiatry, Psychology and Neuroscience, King's College London, ⁴Institute of Psychiatry, Psychology and Neuroscience, King's College London, ⁵Institute of Psychiatry, Psychology and Neuroscience, King's College London, UK, ⁶The University of Hong Kong

Background: The causal direction of the correlation between cannabis use and psychosis has been a subject of ongoing interest across fields of psychiatric medicine, epidemiology, addiction science, and genetics. This paper presents an in-depth genetic analysis aiming to elucidate the causal associations and underlying mechanisms explaining the observed association between cannabis use and psychosis.

Here, we build upon the existing literature by meta-analysing recent schizophrenia and bipolar disorder GWAS to create a broad psychosis phenotype. We combine this with recent data from the largest GWAS of cannabis use disorder (CUD) to conduct local genetic correlation analysis and pathway analyses to identify the specific regions and pathways across the genome that may explain the shared genetic liability for the two traits. Previous work in this field has focused almost solely on data from participants of European (EUR) ancestry. In this study we utilise data from African (AFR) ancestry participants in the Genomic Psychiatry Cohort (GPC) to facilitate cross-population analyses, enhancing the generalisability of our findings.

Methods: We used METAL to conduct a cross-disorder fixed effect meta-analysis using data from the recent GWAS of schizophrenia and bipolar disorder. Given the aim of capturing the full breadth of genomic associations with both psychotic disorders, we did not filter out variants that were only present in one of the input studies. We used Linkage Disequilibrium Score Regression (LDSC) to calculate a SNP-based heritability and establish the genome-wide genetic correlation between our psychosis phenotype and CUD. We also investigated the local genetic correlation using Supergnova, to identify the specific regions driving this genome-wide correlation. We used multiple methods, including PASCAL and MAGMA, to identify significantly enriched genetic pathways that are either trait-specific or overlapping. Finally, we used Mendelian Randomisation (MR) analyses to identify putatively causal associations between these pathways and cannabis-associated psychosis.

Results: We identify 517 genome-wide significant loci for psychosis in EUR subjects. We calculate a SNP-based heritability estimate for this broad psychosis phenotype of 0.14 (0.004, $p=6.3 \times 10^{-251}$). The genetic correlation between psychosis and CUD is 0.35 ($p=2.53 \times 10^{-67}$). We identify three regions of significant local genetic correlation on chromosomes 1, 2, and 12. Genes within these regions play a role in intracellular signalling, neuronal development, and have been linked to a range of neuropsychiatric and cardiometabolic traits in previous genomic studies.

We identify 75 traits significantly associated with CUD, and 196 pathways significantly associated with psychosis. Of these, 32 are common between the two traits, which is greater than the overlap expected by chance ($p=2.2 \times 10^{-7}$). These overlapping pathways have a range of biological functions, including signal transduction, platelet production and activation, opioid signalling, neurotransmission, insulin secretion, GABAergic activation and signalling.

Discussion: The identified pathways provide insights into the potential biological mechanisms linking cannabis use and psychosis and highlights several areas of key future research. This is one of very few studies in this field to include to AFR data. Additional studies with increased diversity remain essential across the field of psychiatric genetics to ensure findings are offering value to the full patient population.

T167. ANALYSIS OF THE INFLUENCE OF GENETIC LOAD FOR SCHIZOPHRENIA RESILIENCE ON SUBCLINICAL DISORDER-RELATED TRAITS IN THE GENERAL POPULATION

Patricia Mas-Bermejo^{*1}, Sergi Papiol², Pilar Torrecilla³, Valeria Lavín³, Jackie Nonweiler³, Monika Budde², Thomas R. Kwapil⁴, Urs Heilbronner², Neus Barrantes-Vidal³, Thomas G. Schulze², Araceli Rosa⁵

¹*Secció de Zoologia i Antropologia Biològica, Universitat de Barcelona; Institut de Biomedicina de la Universitat de Barcelona,* ²*Institute of Psychiatric Phenomics and Genomics, Ludwig Maximilian University,* ³*Universitat Autònoma de Barcelona,* ⁴*University of Illinois at Urbana-Champaign,* ⁵*Universitat de Barcelona*

Background: Most people at elevated risk for a mental disorder will never develop it. This has led to the investigation of plausible protective mechanisms in these individuals that would help them remain healthy despite their genetic burden. Recently, a genome-wide association study (GWAS) for schizophrenia resilience was developed capturing the protective effect of common genetic variants that presumably reduce the penetrance of risk loci for schizophrenia. Here, we aimed to leverage this GWAS to study the effect of such genetic resilience for schizophrenia in the context of subclinical disorder-related traits expressed as a continuum in the general population.

Methods: The samples analyzed in this study included two cohorts comprising 228 and 941 nonclinical college students from the Barcelona Longitudinal Investigation of Schizotypy studies (BLISS-1 and BLISS-2, respectively) and a cohort comprising 389 subjects from the general population in Germany (PsyCourse). Psychotic-like experiences were assessed in the three samples with the Community Assessment of Psychic Experiences (CAPE). Schizotypy was assessed with the Wisconsin Schizotypy Scales in BLISS-1 and the Multidimensional Schizotypy Scales in BLISS-2. These variables were dichotomized using a median split approach to define high versus low scores. Polygenic scores for schizophrenia resilience (resilience-PGS) were computed for each participant using the PRS-CS method based on the recent schizophrenia resilience GWAS. Associations between resilience-PGS and the psychometric variables were tested with logistic regressions and the obtained results were meta-analyzed applying an inverse variance method with random effects models.

Results: The meta-analyses of the associations between resilience-PGS and the positive, negative and depressive dimensions of psychotic-like experiences revealed no significant results. However, a trend towards an association was observed for the CAPE depressive dimension, where subjects with higher resilience-PGS scored lower on this variable (OR = 0.84; 95%-CI = 0.69 - 1.03; P = 0.09). Regarding schizotypy, the meta-analyzed results showed no significant associations between resilience-PGS and neither the positive nor the negative dimension of schizotypy.

Discussion: Our results suggest that although this resilience-PGS has been previously used successfully to discern between affected and unaffected individuals with similar schizophrenia genetic load, it might not be able to capture with such precision the subtle differences in subclinical traits at the nonclinical end of the continuum. Nevertheless, considering the trend towards significance found, it could be possible that our analyses still lack some statistical power to capture its effects. In any case, further investigations in this area should be carried out to gain more knowledge on how resilience variants keep us from developing a disorder. Understanding these mechanisms would represent a sound step toward more effective early interventions.

T168. GENETICS OF SCHIZOTYPY: REVIEW OF CURRENT LITERATURE AND NOVEL INSIGHTS FROM DEEP PHENOTYPING

Tina Meller^{*1}, Clara Lundberg¹, Carlo Maj¹, Andreas Forstner², Igor Nenadic³

¹*Philipps University Marburg*, ²*University of Bonn*, ³*Philipps-Universität Marburg / UKGM*

Background: Schizotypy, a multifaceted personality construct, is a stable phenotypic indicator of psychosis proneness and an established dimensional marker of psychosis risk, while psychotic-like experiences (PLE), describe more state-like occurrences of (prodromal) symptoms. Still, the genetics of subclinical psychosis remain less clear: Initial studies indicated an involvement of single schizophrenia risk variants in schizotypy, but findings on associations with polygenic risk scores (PRS) are inconsistent.

In the current study, we combine deep phenotyping with multiple schizotypy instruments as well as psychotic-like experiences (as state markers, considering both frequency and related distress) to test their associations with polygenetic schizophrenia risk and a novel polygenic score of resilience to schizophrenia. In addition to direct associations, we also test interactions of schizotypy facets with each other and PLE, as recent behavioral and brain imaging studies indicate the relevance of relative dimension patterns rather than levels of single facets. We contrast our findings with those of our recently published analysis of two large nonclinical samples.

Methods: In N=367 healthy young adults (mean age=23.85, SD=3.79), we assessed prodromal symptoms and related distress (PQ-16) and three complementary schizotypy inventories (SPQ-B, OLIFE, MSS) that were aggregated into facet-level composite scores for positive, negative, and disorganized schizotypy. In our previously published analysis, we tested associations between schizotypy (SPQ-B) and a schizophrenia PRS in N=623 (231 male, mean age=32.62, SD=12.47) psychiatrically healthy adults and N=1133 (516 male, mean age=44.63, SD=12.85) blood donors.

DNA was extracted from whole blood samples and genotyped using standard quality control procedures. PRS for schizophrenia and resilience to schizophrenia were calculated based on GWAS summary statistics. Cryptic relatives ($\pi\text{-hat} \geq 0.125$) and outliers in ancestry components (distance from the mean of GREATER THAN 6SD) were excluded. We tested bivariate associations (Spearman's rho) and linear regression models with interaction terms in R, including sex and ancestry components as covariates in all analyses and applying false discovery rate (FDR) correction to control for multiple comparisons.

Results: We found positive associations between the schizophrenia PRS and PQ-16 symptom number ($\rho=0.16$, $p=0.003$, $p_{\text{corr}}=0.018$) and level of distress ($\rho=0.14$, $p=0.009$, $p_{\text{corr}}=0.027$) as well as a nominally significant association with the positive schizotypy score that did not remain after FDR-correction ($\rho=0.11$, $p=0.041$, $p_{\text{corr}}=0.082$). While none of the interactions between schizotypy scores were associated to either of the two PRS, we found a significant interaction between schizophrenia PRS and the disorganized schizotypy score on PQ-16 distress ($b=-0.10$, $p=0.004$, $p_{\text{corr}}=0.048$), with a positive relationship between PRS and distress under low disorganized schizotypy and a negative relationship between the two under high disorganized schizotypy.

Our previous analysis did not find significant correlations between the polygenic score for schizophrenia and schizotypy dimensions in either of the two cohorts. This was confirmed by meta-analysing the p-values of each sample.

Discussion: Our study is the first to provide an analysis of both trait-level (schizotypy) and state-level (PLE) indicators of psychosis risk and their association to polygenic markers of both risk for and resilience to schizophrenia.

We confirm polygenic risk for schizophrenia to be associated with both frequency of and subjective distress to PLE in non-clinical subjects, but only find a nominally significant association with positive schizotypy. Concurrent with recent studies, our results thus indicate a greater overlap between polygenic schizophrenia risk and prodromal symptoms and PLE as well as the distress related to those symptoms. While our results - concurrent with our own and other previous analyses - do not support a direct association between polygenic schizophrenia risk and schizotypy, we show that schizotypy modulates how polygenic risk is expressed and experienced in state-level psychotic phenomena. Importantly, this also highlights the divide between frequency versus distress markers of PLE, which is in line with recent imaging studies implicating different regional brain structural effects, depending on whether prodromal symptoms or PLE are just frequent or subjectively distressing.

Our findings also shed a light on the apparent paradoxical phenomenon that schizotypy (an established risk phenotype) can also act protectively and lead to decreased subjective distress, especially in cases where only a single schizotypy facet is elevated. These findings help extend our understanding of the genetics of schizophrenia by including full spectra (such as subclinical phenomena) and multi-dimensional variation across different facets (positive, negative, and disorganised). Our interpretation of the current findings as well as our own recent meta-analytical analysis allow us to sketch a model of how schizophrenia risk genes might operate across the non-clinical and clinical spectrum as well as across diagnostic categories.

T169. PREVALENCE, CORRELATES AND CLINICAL RELEVANCE OF PSYCHOTIC EXPERIENCES IN THE DUTCH GENERAL POPULATION

Wim Veling^{*1}, Vera Brink¹, Catheline van Driel¹, Stynke Castelein², Hannah Jongsma³

¹University Medical Center Groningen, ²Lentis Research of Lentis Psychiatric Institute and Rob Giel Research Center of University Medical Center Groningen, ³Center for Transcultural Psychiatry 'Veldzicht'

Background: In people with mental health problems, psychotic experiences (PEs) may represent the milder end of the psychosis continuum. In such samples, PEs have been associated with an increased risk for developing psychotic disorder, and with more severe psychopathology in general. The meaning and clinical relevance of PEs in the general population is less clear. As PEs occur infrequently, studies predominantly investigated lifetime prevalence, and could explore only a limited set of potential correlates. Large population-based studies are needed to study prevalence of more recent PEs and test a broad range of potential correlates of PEs in the general population.

Methods: This study used cross-sectional Lifelines data, a large longitudinal cohort study that includes over 167,000 participants (10%) from the northern population of the Netherlands. 48,652 adults participated in the third wave, that included the Psychosis Screening Questionnaire (PSQ), assessing PEs in the past year. For the current study, participants aged GREATER THAN 18 were included if they had complete data on the screening question of all five PSQ items. 12-month prevalence of PEs was calculated. A broad range of potential sociodemographic, behavioral, environmental, premorbid, family,

health related, functioning and cognitive correlates of PEs was tested in logistic regression analyses.

Results: 48,286 people (99.2% of the eligible Lifelines sample) had complete data on the 12-month PSQ items. One third endorsed at least one of the five screening items, 10 percent two items, 4.3 percent three or more items. The prevalence of thought interference in the past year was 13.2%, paranoid ideations were reported by 10.2%, hallucinations by 3.2%. The regression analyses are ongoing.

Discussion: Psychotic experiences in the past year are not uncommon in the adult general Dutch population, with four percent reporting at least three PEs. The proportions of PEs are similar to those in some other countries. Discussion of correlates and interpretation of the meaning and clinical relevance of PEs in the general population will be presented at the conference.

T170. PERINATAL VARIATION IN ENVIRONMENTAL LIGHT ASSOCIATED WITH INCREASED RISK FOR SCHIZOPHRENIA - AN EXPLORATORY ANALYSIS OF COMBINED SAMPLES

Digby Qusted*¹, Ayse Kurtulmus², Aynur Gormez³, Rashmi Patel⁴, Akeem Sule⁵, Srivasan Thirumalai⁶, Andrew McQuillin⁷, Michaela Otis⁸

¹Oxford Health NHS Foundation Trust, ²Istanbul Medeniyet University Goztepe research and training Hospital, Department of Psychiatry, Istanbul, Turkey., ³Istanbul Medeniyet University, Department of Psychiatry, Istanbul, Turkey, ⁴Department of Psychosis Studies, IoPPN, King's College London, UK, ⁵Essex Partnership University NHS foundation Trust; Dept. of Psychiatry, Cambridge University, UK (Hon), ⁶Marlborough House MSU, Milton Keynes Oxford Health NHSFT, ⁷Molecular Psychiatry Laboratory, Division of Psychiatry, Faculty of Brain Sciences, University College, London, ⁸Multimorbidity and Mental Health Theme; Department of Primary Care and Public Health, Imperial College, London, United Kingdom

Background: Studies have shown associations between perinatal light variability with case register incidence rates and of vitamin D deficiency in schizophrenia suggesting the possible relevance of peri-natal sunshine to schizophrenia genesis. Early post-natal solar insolation level has also been positively associated with age of onset in bipolar disorder ((Bauer et al; 2015; J. of Psychiatric Research; 64; 1-8). We investigated further an original hypothesis (Qusted DJ. 1996 - Med. Hypotheses. Mar;46(3):233-8) that perinatal variation in environmental light (EL) exposure could be associated with the condition, in a model incorporating familial risk and gender, and present here the outcome of the exploratory analysis of data from two combined samples.

Methods: In study (1) Schizophrenic patients (n=89) were diagnosed according to SADS-L while a healthy control (HC) version was used for the comparator group (n=174). Fields included place and date of birth, family psychiatric history (FPH) with pedigree information as well as personal history. In Study (2) a primary care self-report dataset was used where those with a personal history of mental illness were excluded. Measures of variation of perinatal environmental light (EL) exposure were divided into 9 pre-and 6 post-natal trimesters. Sunshine EL exposure for each individual was calculated from MET Office UK data in sunshine hours per day by month and then grouped into trimesters, as a difference from the historic means for England and Wales, or Scotland, with these monthly sunshine means subtracted from the individual's data. The historic means used were a 63 year set for

Study (1) and 50 years for Study (2). Logistic regression was used to estimate the effect of EL variation on schizophrenia risk by fitting a two way interaction term with EL and FPH, adjusting for gender.

Results: In the combined dataset including 89 (60 M; 29 F) schizophrenic patients and a total of 449 (171 M; 278 F) healthy controls, mean daily sunshine variations in the three month trimester groupings showed a significant effect of low EL on the risk of schizophrenia in the post-natal (OR=3.49, 95%CI=1.72-7.09, P=0.001) and mid-foetal trimesters (OR=3.09, 95%CI: 1.50-6.35, P=0.002) as an interaction effect with positive FPH in first degree relatives and adjustment for gender. Above average levels of sunshine were protective, even with a positive FPH for the first post-natal trimester but not in the mid-foetal trimester. In a stratification cohort using only those with FPH an interaction effect with low EL was seen for both genders in the post-natal trimester but an effect in males in the mid-foetal trimester was non-significant.

Discussion: The above findings show an association between the EL variable and risk for schizophrenia analysed as an interaction with family history in a combined dataset where the number of healthy controls was substantially enlarged by the inclusion of a self-report primary care sample. This finding therefore suggests that if peri-natal sunshine variation is relevant to schizophrenia then a factor linked with development is being influenced by a fluctuation in the number of sunshine hours per day as a difference from the historic monthly means. However, in a previous analysis of the schizophrenia sample in study (1) findings also suggested that the mean total of daily sunshine hours per month is associated with schizophrenia risk. The present finding continues to be limited by the schizophrenia patient number, although the HC group was substantially increased in this combined exploratory analysis. A further limitation is the assumption that geographical relocation did not occur during the analysed phases of gestational and post-natal development. The previously analysed variability in total daily sunshine hours by trimester will therefore need to be investigated in further studies with larger sample sizes, including both healthy controls and schizophrenic patients with well characterised family histories and the inclusion of an aetiopathogenetic mechanism.

T171. DIAGNOSIS AND MANAGEMENT OF COGNITIVE IMPAIRMENT IN SCHIZOPHRENIA: REAL-WORLD EVIDENCE FROM A CROSS-SECTIONAL SURVEY OF PSYCHIATRISTS

Theresa Cassidy*¹, Artak Khachatryan², Stephanie Read²

¹Boehringer Ingelheim Pharmaceuticals, Inc., ²Evidence and Access, Certara, London, UK

Background: Cognitive impairment (CI) associated with schizophrenia is a core feature of the disorder and is associated with reductions in quality of life and independent living. Current treatments for schizophrenia, such as antipsychotics, are effective at reducing positive symptoms, but do not improve cognitive outcomes. Despite the established negative impact of CI in schizophrenia, it is unclear to what extent practicing physicians recognise, diagnose, treat and manage the condition. This study aimed to understand and characterise physician attitudes and practice regarding how schizophrenia patients with CI are assessed, monitored and treated in routine clinical care.

Methods: A bespoke online survey was developed and administered to 121 psychiatrists across the United States (US), United Kingdom (UK) and Germany in December 2022. Psychiatrists were identified via a third-party panel and were eligible for inclusion if they had

been practicing for ≥ 36 months (including ≥ 12 months in the US, UK or Germany) and treated ≥ 5 patients with schizophrenia annually.

Results: 121 psychiatrists completed the online survey (US: n=41; UK: n=40; Germany: n=40). This sample of experienced psychiatrists (45.5% had ≥ 15 years practice) estimated a mean (standard deviation [SD]) of 51.0% (28.0%) of schizophrenia patients exhibit signs of CI; of these patients, psychiatrists diagnosed CI in a mean (SD) of 34.8% (29.7%). The most common instruments to assess CI were the Montreal Cognitive Assessment and the Mini-Mental State Examination, with 62.0% and 81.8% of psychiatrists respectively reporting their use. When assessing CI in patients, psychiatrists ranked deficits in executive function (38.0%), reduced attention (19.0%) and deficits in reasoning/ problem solving (16.5%) as the most important signs of impairment. Psychiatrists ranked working/studying (48.8%), managing finances (16.5%) and taking prescribed medications (11.6%) as the most disrupted activities of daily living for patients with CI. If patients exhibited CI, 91.7% of psychiatrists recorded it in the patients' medical charts, with terms such as cognitive impairment (81.0%), attention deficit (47.1%) and communication deficit (43.8%) most commonly noted. For treatment of CI, psychiatrists reported implementing a watch-and-wait strategy for 46.5% of patients. Almost half of psychiatrists (48.8%) reported that CI increased the frequency of patient follow-up visits. A large proportion (59.5%) of psychiatrists did not administer medications, however, 52.9% prescribed cognitive behavioural therapy to manage CI. There was no consensus on the effect of anti-psychotic treatments, with 52.9% of psychiatrists indicating improvement and 46.3% of psychiatrists indicating a negative impact on the severity of CI symptoms.

Discussion: These data contribute to the understanding of physicians' attitudes and practices towards CI in schizophrenia. Considering the large proportion of schizophrenia patients affected by CI, the considerable variation in diagnosis, treatment and management practices reported by psychiatrists highlights the need for clearer guidance in the management of CI to improve treatment outcomes and quality of life for patients.

T172. OBJECTIVE BURDEN AMONG PRIMARY AND SECONDARY CAREGIVERS FROM COGNITIVE IMPAIRMENT SYMPTOMS OF PATIENTS WITH SCHIZOPHRENIA

Corey Reuteman-Fowler¹, Sebastien Tulliez², Matthew Ridley³, Katja Rudell³, Alessandra Girardi³, Christoph Correll^{*4}, Richard Keefe⁵, Abraham Goldring⁶

¹Boehringer Ingelheim Pharmaceuticals, Inc., ²Boehringer Ingelheim International GmbH, ³PAREXEL International Corp., ⁴, ⁵Duke University Medical Center, Professor of Psychiatry and Behavioral Sciences, ⁶Clinical Trial Media

Background: Cognitive impairment associated with schizophrenia (CIAS) is highly burdensome and the severity of such symptoms can impact the burden of care. The chronic nature of schizophrenia incurs substantial burden to the caregiver - whether family or professional (social workers, case manager etc) - from the shift of burden of care from inpatient hospital services, with four main areas of burden being identified in the literature: daily "hassles", and financial, emotional, and physical burden. Recent guidance/standards, including clinical, Health Technology Assessment (HTA e.g., NICE), are beginning to recognize the value of evidence demonstrating the alleviation of carer provision for patients with a medical condition (e.g., for decision making), particularly those with neurological and psychiatric conditions that arguably impose the greatest burden on caregivers. However, existing research focuses mostly on primary (i.e., family) caregivers as opposed to secondary

caregivers (i.e., professionally trained). The present study therefore aimed to provide a preliminary overview of objective caregiver burden experiences (defined in the literature as the effects on the caregiver in respect of daily tasks) from CIAS symptoms among both primary (family, informal) and secondary (professional, formal) caregivers.

Methods: In a COA content validation interview study, a question asking about the caregivers' experiences of the cognitive functioning issues they had observed in the patient, elicited spontaneous data pertaining caregiver's experience of burden. Subsequently, a secondary, qualitative, inductive thematic analysis was conducted on this burden-focused data.

Results: Findings revealed two overarching themes: 1. Caregiver difficulty (Subthemes: Hard to continue care, Hard to improve their quality of life, Constant additional and extra work[load], Hard to teach/unable to learn, Difficult to communicate with patient, and Blame [in the firing line]), and 2. Caregiver necessity (Subthemes: 'Without my care they wouldn't get things done', and Financial budgeting – reminders and remedials). Our analysis demonstrates both caregiving difficulty and necessity to be high across the dataset and irrespective of whether a primary or secondary caregiver was interviewed.

Discussion: Consistent with the literature, the requirement for the assumption of extra work and role responsibilities was central to the high level of caregiving difficulty and necessity found among both primary and secondary caregivers of patients with schizophrenia. Financial impacts were described as a necessity. Experience of frustration was mentioned by one caregiver and no further evidence emerged regarding the emotional, or the physical aspects of caregiving. To be able to present adequate evidence in accordance with the contemporary HTA guidance, further work is warranted inclusive of subjective caregiver burden experiences (defined in the literature as the extent to which the caregivers perceive the burden of care) associated with CIAS. Moreover, due to the multidimensional nature of caregiver burden, additional facets need to be incorporated in future studies, including incidence of financial costs, depression, time of work, shame, embarrassment, guilt, self-blame, gender, ethnicity, and culture. A noted limitation is the secondary analysis nature of this study, conducted on data acquired from a study with a different objective. Nevertheless, this research highlights the importance of incorporating caregiver burden experiences in schizophrenia, and the need for further work to acquire richer caregiver burden data.

T173. OUTCOMES OF SCHIZOPHRENIA PATIENTS RECEIVING COMMUNITY MANAGEMENT SERVICE IN URBAN CHINA

Jiali Wang*¹, Jinghua Su², Xiaohua Sun³, Xiaofei Hou⁴, Haidong Song³, Guangming Xu⁴, Liang Zhou²

¹The University of Chicago, ²Affiliated Brain Hospital of Guangzhou Medical University, Guangzhou, China, ³Affiliated Mental Health Center Zhejiang University school of Medicine, Hangzhou Seventh People's Hospital, Hangzhou, China, ⁴Mental Health Center of Tianjin Medical University, Tianjin Anding Hospital, Tianjin, China

Background: To provide integrated community-based mental health care for patients with serious mental illness, China launched the Community-based Program of Management and Treatment for Serious Mental Illness in 2004, known as the Community Management Service. Patients receive telephone or face-to-face follow-up management delivered by community mental health professionals. Over 70% of service recipients are schizophrenic patients. Although Community Management Service has been implemented for nearly two

decades and has covered the whole mainland China, the efficacy of the Community Management Service on patient-level outcomes remains unknown. The study aimed to estimate potential effects of the Community Management Service on patient-level outcomes, including symptoms, social function, outpatient service utilization, and medication compliance.

Methods: We conducted a single-blind, multi-centered cohort study. The exposed group was patients receiving management. We matched unmanaged patients with two patients receiving management according to city, gender, and age due to the limited number of unmanaged patients. Baseline data were from patients' medical records in 2019. Sociodemographics, age of onset, DUP, and outcomes were collected via face-to-face interviews from March 2022 to January 2023. The primary outcome was symptom assessed with PANSS. Multivariate regression models were used to estimate the potential effects. Propensity score matching and adjustment were performed as sensitivity analysis. Analyses were conducted using Stata 17.0, with statistical significance set at 0.05.

Results: A total of 259 patients were included in the cohort study, including 93 unmanaged patients and 166 patients receiving management. Mean age was 38.5 (12.3), and 59.5% were female. PANSS score in patients receiving management was significantly higher (58.0 (45.0, 70.0) vs. 49.5 (38.5, 64.0), $P=0.004$). The multivariate linear regression showed no statistically significant difference in PANSS between patients receiving management or not ($b=0.015$, 95%CI=-0.076, 0.106). Results of sensitivity analysis were consistent with main analysis. However, we found significant interactions between continuous education and management status ($P=0.010$). Among patients with primary school or below educational level, those receiving management were observed to have fewer symptoms ($b=-0.401$, 95%CI=-0.710, -0.092). Patients receiving management had more outpatient visits (IRR=1.140, 95%CI=1.005, 1.293), and higher odds of regular outpatient visits (OR=1.972, 95%CI=1.096, 3.551). Social function deficits were higher in patients receiving management ($b=1.234$, 95%CI=0.001, 2.466). But among patients with lower educational level, those receiving management tended to have better social function ($P=0.011$). There were no significant associations between Management and medication compliance.

Discussion: Although the Program has established China's first community-based mental health system, our findings suggested limited improvement in patient-level outcomes. Therefore, in the future, intensive intervention services, such as psychosocial intervention and intervention targeting medication adherence, should be considered based on existing services. Besides, given the limited resources of community mental health services, future research should further identify patients who are more sensitive to the services to promote the rational allocation and utilization of resources and to optimize the Program. Finally, more comprehensive evaluations are needed.

T174. EFFECT OF PUBLIC SMOKING RESTRICTION PRECAUTIONS ON THE SCHIZOPHRENIA PATIENTS' SMOKING PREVALANCE AND AMOUNT OF SMOKING CONSUMPTION

Eldem Güvercin*¹, Bilge Targıtay Öztürk², Tolga Binbay², Berna Binnur Akdede³, Köksal Alptekin³

¹Dokuz Eylul University, Faculty of Medicine, Izmir, ²Dokuz Eylul University, School of Medicine, Department of Psychiatry, Izmir, Turkey, ³Dokuz Eylul University Department of Neuroscience, Dokuz Eylül University, School of Medicine, Department of Psychiatry, Izmir

Background: In 2008, Türkiye has introduced a law for preventing smoking and its harmful effects. It has brought serious restrictions on advertisements and sponsorships encouraging smoking, and smoking was banned in common public areas, public offices and all kinds of public transportation vehicles. These restrictions taken throughout the country generally yielded results, and in the first 5 years of legal regulations, smoking prevalence decreased by 13.4% across Türkiye. Smoking is more common among patients with schizophrenia than in general population. It has been reported that tobacco smoking is 1.5 times more frequent in patients with schizophrenia, compared to general population. Reducing smoking in patients with schizophrenia may contribute to reducing morbidity and mortality in these individuals.

Methods: In this retrospective study, we evaluated 435 individuals diagnosed with schizophrenia who applied to the outpatient clinic at the Dokuz Eylül University Hospital, İzmir, Türkiye. Participants divided into two groups: First group (n=236) consist of the patients, applied to the outpatient clinic before the endorsement of smoking restriction laws (at the year of 2008 and before). Second group (n=199) including the patients, who have applied the outpatient clinic after the year of 2008. Their smoking habits and cigarettes consuming per day were analyzed with independent samples T-test.

Results: Both the cigarette consumption frequency (t (433): -2.05; p LESS THAN 0.05) and the number of cigarettes smoked per day (mean: 11.23; SD: 14.48 vs mean: 13.45; SD: 17.33; p LESS THAN 0.05) were found to be significantly lower in individuals who were followed up at the outpatient clinic after 2008 compared to individuals who were evaluated before 2008.

Discussion: The current legal restrictions for smoking have significant effects in patients with schizophrenia, both the smoking habit and the average number of cigarettes consuming per day have decreased in these patients. Reducing smoking in patients with schizophrenia is a realistic and desirable goal and it is important to ensure the continuity of the precautions. We hope that the encouraging decrease in the prevalence and amount of smoking in patients with schizophrenia under the influence of legal regulations, will provide additional measures and public health policies to additional smoking reduction in patients with schizophrenia.

T175. CONTENT CONFIRMATION OF THE SCHIZOPHRENIA COGNITION RATING SCALE (SCORS): A QUALITATIVE STUDY WITH PRIMARY AND SECONDARY CAREGIVERS

Corey Reuteman-Fowler¹, Sebastien Tulliez^{*2}, Maggie Heinrich³, Katja Rudell³, Alessandra Girardi³, Christoph Correll⁴, Richard Keefe⁵, Abraham Goldring⁶

¹Boehringer Ingelheim Pharmaceuticals, Inc., ²Boehringer Ingelheim International GmbH, ³PAREXEL International Corp., ⁴The Zucker Hillside Hospital; Donald and Barbara Zucker School of Medicine at Hofstra/Northwell; Charité - Universitätsmedizin Berlin, ⁵Duke University Medical Center, ⁶Clinical Trial Media

Background: Cognitive impairments associated with schizophrenia are burdensome with detrimental effects on patients' everyday life. The Schizophrenia Cognition Rating Scale (SCoRS) is a 20-item interview-based clinical reported outcomes assessment of cognition-related functioning in patients with schizophrenia. The assessment requires input from patients, caregivers, or clinicians. Although the SCoRS demonstrated good psychometric properties in several publications, further confirmation of its content with the informant population, in particular, primary caregivers who spend more time with the patient during the day is needed. This study sought to assess the content confirmation of the instrument and its

understanding and clarity with caregivers who cared for a patient with a diagnosis of schizophrenia.

Methods: A qualitative cross-sectional non-interventional study was conducted in the United States. Interviews were conducted with primary caregivers (PC; unpaid), and secondary caregivers (SC; professionally trained). Two discussion guides were developed: one for the primary informants, and one for the secondary informants. Interviews lasted approximately 90 minutes and included three parts: 1) caregiver and patient characteristics; 2) concept elicitation; and 3) cognitive debriefing.

Results: Altogether, 40 caregivers were interviewed, n=20 in each group. The majority of caregivers were females (PC: 85%; SC:60%). The mean age at the time of interviews was 51 years (range=28-82) for PCs and 41 years (range 22-60) for SCs. Half of the PCs were parents of the patient with schizophrenia, 40% relatives and 10% partners. The SC group included 25% therapists, 15% clinical research coordinators, 10% sub-investigator psychometric raters, 5% registered nurse and 5% director of non-profit organization. Most caregivers accurately interpreted questions, items and response options (70%-100%). Ease of response selection across items appeared overall slightly lower for primary caregivers, typically due to the clinical profile of some patients (e.g., rare or no social relationships, no change of routine) or the uncertainty concerning what the patient is really thinking/understanding (e.g., no overt manifestations), rather than the scale properties. Most items were endorsed by the majority of informants in both groups. However, they did not observe much language difficulties in two items: leading to conversational confusion and attention in conversation (n items = 2, endorsed by LESS THAN 30% of caregivers). Nevertheless, these two items were well understood by most caregivers in both groups, response options were easy to select and the examples provided were considered useful. Additionally, all domains were endorsed by at least 50% of caregivers in both groups. Certain concepts were seen to be highly relevant to patients with schizophrenia. Particularly Attention and Problem-solving were endorsed by 95% of caregivers living with the patients. Memory and Working Memory were endorsed by all SCs.

Discussion: The content and usability of the SCoRS were confirmed with both informal and professionally trained caregivers. However, caregivers did not observe patients' conversations in group settings or with new individuals and therefore could not assess these activities. This data further highlights that cognitive issues are frequently present in patients with schizophrenia, and thus need addressing to improve the patients' quality of life.

T176. GLOBAL DISTRIBUTION OF ENVIRONMENTAL RISK STUDIES FOR SCHIZOPHRENIA

Evangelos Vassos*¹, Sarah Tosato²

¹King's College London, ²Section of Psychiatry, Department of Neurological, Biomedical and Movement Sciences, University of Verona, Italy

Background: There is a substantial body of literature on genetic and environmental risk factors associated with schizophrenia. Genetic research has largely been conducted in Europe and North America, with little representation of the rest of the world. Indeed, previous reviews of twin and genome-wide association studies show that European ancestry populations are over-represented, with middle- and low-income countries having little or no participation in the current body of genetic research. Concerns have been raised that this

preferential representation of Europeans may exacerbate health disparities between different ethnic/ancestral groups. However, there is no systematic evaluation of similar disparities of studies focusing on environmental exposures. For this reason, we performed a systematic review of studies evaluating environmental risk factors for schizophrenia, recording where they were conducted and then by linking our findings with publicly available data, we tried to identify correlates with the uneven global distribution.

Methods: Using Pubmed and PsycINFO electronic databases, we performed a systematic review of studies reporting on exposure to established environmental risk for schizophrenia (e.g. migration, urbanicity, childhood trauma, cannabis etc) and subsequent onset of incident schizophrenia spectrum disorders. We plotted the number of studies and of recruited cases by the country where studies were conducted. Then we downloaded publicly available data on population size, measures of wealth (e.g. GDP), measures of medical provisions (number of doctors), measures of research investment (R and D spending, number of researchers), and of quality research outputs (number of papers published, number of Nobel laureates in science) per country. We performed univariable and multivariable regression analyses of each predictor with the number of studies and recruited cases per country identified through our literature search.

Results: In total we identified 308 publications of 342 studies fulfilling our inclusion criteria, including 445,000 cases with schizophrenia spectrum disorders. The majority were conducted in northern Europe (most studies from the UK; N=53) and North America. Very few studies were conducted in South America, South Africa and East Asia, with large parts of the world totally unrepresented. In the associations between the number of environmental risk studies for schizophrenia with potential predictors, we found that neither population nor wealth or research investment of countries were strong predictors of research outputs in the field. Interestingly, the stronger correlations were found for number of researchers per population and for indicators of high-quality research, such as number of Nobel laureates per country.

Discussion: Our results demonstrate a gap of knowledge due to the under-representation of environmental risk studies of incident schizophrenia in large parts of the world. This has implications in the generalisability of any findings from studies conducted in the Northern hemisphere but also in our ability to progress in efforts to make causal inferences about biological pathways to schizophrenia. As an example, if migration or urbanicity, which are considered as ‘proxy’ for unmeasured underlying risk factors, act only in industrialised communities and not in low-income countries, we should invest in research on differences between these environments, which could shed a light on the actual causal pathways to schizophrenia.

Our conclusion is that emphasis needs to be given to enabling and expanding schizophrenia research to parts of the world currently under-represented. This will enable generalisation and a more equitable utilisation of research findings but will also progress research on causal pathways to schizophrenia.

T177. A PRELIMINARY STUDY ON THE FACTORS AFFECTING THE RECOVERY OF INPATIENTS IN PSYCHIATRIC HOSPITALS-FOCUSING ON RECOVERY PRACTICES IN WHO QUALITY RIGHTS

Narae Jeong¹, Yu Sang Lee^{*2}

¹Department of Clinical Psychology, Yongin Mental Hospital, Yongin, Republic of Korea,

²*Yongin Mental Hospital*

Background: Recovery-based practice has been gradually receiving attention in the Korean psychiatric settings, but there is still a lack of research on factors and applications related to recovery. World Health Organization QualityRights(WHO, 2019) is a comprehensive package of educational and instructional materials based on a human rights based approach and recovery, starting with efforts to ensure mental health and well-being. Based on this direction, Korean psychiatric settings need to actively devise ways to promote recovery-oriented practical activities. Therefore, this study aimed to systematically identify the factors influencing the attitude towards recovery targeting those receiving inpatient treatment in a psychiatric hospital.

Methods: A total of 100 inpatients at Yongin Mental Hospital in Korea completed self-report questionnaires assessing demographic characteristics, illness duration and history, social support, stigma, and attitudes towards recovery and human rights sensitivity. All data were converted into continuous and categorical variables and analyzed through hierarchical regression analysis.

Results: Based on the analysis of 80 responses, excluding data with numerous missing values and insincere answers, it was observed that the duration of illness and the number of hospitalizations significantly influenced attitudes toward recovery. Additionally, self-perceived social support emerged as a potential factor influencing recovery attitudes. Social support was found to moderate the relationship between disease duration and recovery.

Discussion: The study suggests that the duration of illness and the number of hospitalizations impact the attitudes toward recovery among psychiatric inpatients, with higher perceived social support associated with more positive recovery attitudes. In other words, as the psychiatric problem becomes chronic, the attitude to recover decreases, but social support and interest seem to be able to buffer their relationship. There is a need to gradually expand recovery-centered approaches in Korean psychiatric settings, and it is necessary to prepare specific measures to support this. Finally, the significance and limitations of the studies were discussed.

WHO QualityRights; Psychiatric inpatients; Social Support; Recovery oriented approach.

T178. A VAGAL INFLUENCE ON SCHIZOPHRENIA? RESULTS OF TWO SWEDISH NATIONWIDE RETROSPECTIVE COHORTS

Cornelia Richter^{*1}, Skibicka Karolina², Urs Meyer¹, Sabine Rohrmann³, Jean-Philippe Krieger⁴

¹University of Zurich, Institute of Veterinary Pharmacology and Toxicology, ²Pennsylvania State University, Department of Nutritional Sciences; University of Gothenburg, Institute of Neuroscience and Physiology, ³University of Zurich, Epidemiology Biostatistics and Prevention Institute, ⁴University of Zurich, Institute of Veterinary Pharmacology and Toxicology; University of Gothenburg, Institute of Neuroscience and Physiology

Background: The vagus nerve is a major bidirectional route of communication between the brain and the body. Several lines of evidence suggest that impaired vagal communication may be a potential risk factor for the development of schizophrenia. First, meta analyses indicated that heart rate variability, a proxy measurement for vagal activity, is consistently lower in patients with schizophrenia compared to healthy controls and mirrors the progression of psychotic symptoms. Second, preclinical studies in rats demonstrated that the lesion of subdiaphragmatic vagal afferents is sufficient to induce a schizophrenia-like behavior. Longitudinal evidence in humans is, however, lacking. Hence, the objective of this

study was to test whether disrupted vagal communication impacts the subsequent risk to develop schizophrenia in humans. For this, we studied individuals with vagotomy, the surgical resection of the vagus nerve once commonly performed to treat peptic ulcers.

Methods: We applied a retrospective cohort approach using nationwide data from the Swedish National Patient Registry from the period 1970-2010. First, we compared the risk to develop schizophrenia between vagotomized patients (n = 16 231) and non-vagotomized individuals matched for age and sex randomly sampled from the registry (n= 162 310; “general population cohort”). In a second analysis, we took into account that peptic ulcer was the main indication for vagotomy and therefore compared vagotomized patients (n= 7 625) with individuals matched for age, sex, and history of peptic ulcer disease (n= 38 125; “ulcer cohort”). For both cohorts, the association between vagotomy and schizophrenia was investigated using Cox proportional hazards models, including death as competing risk.

Results: Both analyses found no significant change in the risk to develop schizophrenia following vagotomy overall (hazard ratio [HR] = 1.25 [95% confidence interval [CI] 0.78, 2.01] in the “general population cohort” and HR = 0.90 [0.27, 3.15] in the “ulcer cohort”). These results however, hide a disparity between different vagotomy surgeries: truncal vagotomy was associated with an 8.6-fold increase in the risk to develop schizophrenia in the “general population cohort” (HR: 8.56 [4.82, 15.20]), whereas selective vagotomy showed no significant effect (HR: 0.54 [0.27, 1.11]). The number of schizophrenia cases was too small to analyse vagotomy subtypes in the “ulcer cohort”.

Discussion: Our results partly support the idea that impaired vagal function can precipitate the development of schizophrenia. Notably, the finding that truncal but not selective vagotomy is associated with an increased risk of schizophrenia raises the possibility that the activity of non-gastric vagal branches may be of particular relevance for the development of schizophrenia. Future studies should aim at increasing the number of included patients to obtain better estimates, for example by combining registries from different nations.

T179. AN EXAMINATION OF FACTORS ASSOCIATED WITH POLICE STIGMA AND VIOLENCE TOWARDS BLACK INDIVIDUALS SUFFERING FROM MENTAL ILLNESS

Amy Weisman de Mamani^{*1}, Merranda McLaughlin², Salman Ahmad¹, Genesis Saenz-Escalante¹, Denise Chung-Zou¹

¹*U. of Miami*, ²*University of Washington*

Background: High-profile, police-induced deaths have disproportionately involved individuals with serious mental illness (SMI), particularly Black men (Dempsey et al., 2020; Frankham, 2018; Edwards et al. 2018). As such many black people with SMI report a hesitancy to call the police even when they are in dire need of police assistance (Altamirano and Weisman de Mamani, 2023). As prejudice and stigma are often precursors to aggression (Gilbert and Bushman, 2017), it is critical to identify factors associated with police stigma towards individuals with serious mental illness (SMI). In line with the frustration aggression hypothesis (Gilbert and ushman, 2017) which purports that that one’s own frustration and distress are often linked to prejudice and aggression towards others, we hypothesized that officers who experience more psychological distress and greater suicidal ideation would report holding more stigma towards individuals with schizophrenia. Qualitative data from police officers was also examined to help pinpoint ways to improve police officer interactions with individuals with SMI.

Methods: A mixed method design was used to conduct assessments with 107 police officers recruited through Qualtrics' online panels. The Depression Anxiety and Stress Scale-21 (DASS-21), The Suicidal Behavior Questionnaire, and the Modified Day's Mental Illness Scale were used to measure psychological distress, suicidal ideation and behaviors, and mental illness stigma respectively. Qualitative data from police officers was also derived from analogue studies using hypothetical vignettes of an encounter between a police officer and a black man with schizophrenia.

Results: As hypothesized, we found that officers who had poor mental health, assessed through both the DASS-21 ($r = .380$; $p < .001$) and the Suicidal Behavior Questionnaire ($r = .353$, $p < .001$), were more likely to hold stigmatizing attitudes toward people with SMI. Many interesting themes also emerged with respect to our qualitative data. For example, in one scenario officers were asked to describe their response to a hypothetical vignette depicting an interaction between a Black man with schizophrenia and a police officer that resulted in the officer shooting and killing the man. While some officers criticized the use of lethal force, the large majority of responses were in defense of the officers' actions (etc., "officers must do whatever it takes to effect an arrest", "...force is sometimes necessary.")

Discussion: Stigma toward others is a form of non-physical aggression that can be highly correlated with physical aggression (Vincent, Peterson and Parrot, 2016). Thus, our finding that police officer's own distress is linked to greater stigma towards individuals with SMI may offer indirect support for the frustration aggression hypothesis (Gilbert and Bushman, 2017). These findings suggest that efforts to bolster officers' own mental health may be one indirect way to reduce stigma and aggression toward people with SMI. Given that the most frequent theme to emerge for the escalation scenario was a defense of the officer's actions, our data suggest that police officers may be less willing to acknowledge the shortcomings of their role, because they feel laypeople/onlookers do not understand the full context of these situations (e.g., high stress, poor pay, newly trained officers put in high crime areas). Thus, future work that attempts to improve communication and understanding between police officers and the communities they serve (particularly the Black community), may assist in decreasing the likelihood of violent outcomes when these groups interact.

T180. GENETIC AND ENVIRONMENTAL INDUCED REDOX DYSREGULATION DURING EARLY DEVELOPMENT AFFECTS NEURONAL MATURATION/DIFFERENTIATION AND NKCC1/KCC2 SWITCH IN IPSC-DERIVED NEURONS OF EARLY PSYCHOSIS PATIENTS

Basilio Giangreco*¹, Daniella Dwir², Luca Bartesaghi³, Omar Alijevic⁴, Aline Monin², Ha Nam Nguyen⁵, Philipp S. Baumann⁶, Raoul Jenni², Martine Cleusix⁶, Michel Cuénod², Paul Klauser⁷, Philippe Conus⁶, Stephan Kellenberger⁴, Hongjun Song⁸, Roman Chrast³, Kim Q. Do², Nicolas Toni²

Psychiatric Neuroscience and Service of Child and Adolescent Psychiatry, Department of Psychiatry, Lausanne University Hospital, Lausanne, Switzerland, ⁸Department of Neuroscience and Mahoney Institute for Neurosciences, Perelman School of Medicine, University of Pennsylvania, Philadelphia, Pennsylvania, USA

Background: Excitatory/inhibitory (E/I) imbalance is a hallmark of schizophrenia (SZ) and may play a crucial role in the manifestation of the cognitive symptoms. These alterations may arise from abnormal maturation of the inhibitory system during early brain development, involving the NKCC1/KCC2 switch. This mechanism encompasses the switch of the GABAergic neurotransmission from excitatory to inhibitory, induced by a decrease in NKCC1 expression in parallel with an increase in KCC2 expression. The NKCC1/KCC2 switch was found to be involved in the maturation of the E/I balance but also in the proliferation and differentiation of neural progenitors during brain development. Moreover, some postmortem studies suggest impairments in NKCC1 and KCC2 expression in SZ. Based on the major role of oxidative stress (OxS) in the pathophysiology of SZ, we hypothesized that NKCC1/KCC2 alterations may be induced by a redox dysregulation, originating from the interaction between genetic and environmental risk factors. More specifically, we investigated, in both an animal model and in early psychosis (EP) patients, whether a redox dysregulation during early neuronal development affects the NKCC1/KCC2 switch, leading to neuronal maturation/differentiation impairments.

Methods: The animal study was conducted on a transgenic mouse model of GSH deficit (Gclm-KO), which has a SZ related phenotype. The Gclm-KO mice display increased OxS and decreased parvalbumin-expressing interneurons (PVI) in the ventral (VH) but not dorsal (DH) hippocampus. Proliferation of neural progenitors in the dentate gyrus (DG) of the VH and DH was quantified with BrdU injection followed by immunohistochemistry (IH) on WT and KO mice (N=5). NKCC1/KCC2 were evaluated by western blot on the microdissected DG.

For the human study, iPSC were induced from fibroblasts of EP patients (EPP) and healthy controls (HC), bearing or not a genetic polymorphism for OxS vulnerability, and enrolled in a multi-levels characterized cohorts. iPSC were differentiated into neural precursors cells (NPC, N=3-5) and followed during their differentiation into neurons (N=1).

Results: We found abnormal proliferation/survival of neural progenitors and altered NKCC1/KCC2 protein levels in the DG of the Gclm-KO as compared to the WT. This proliferation/maturation imbalance was further found in iPSC-induced NPC and neurons from EPP, as compared to HC, with increased Ki67 and decreased DCX levels by IH. Neurons from EPP exhibited an immature phenotype, characterized by a reduction in dendritic complexity (MAP2/Tuj1). The NKCC1/KCC2 switch was also altered during the differentiation of patient NPC into neurons. Moreover, EPP NPC had higher levels of Nrf2 during the early phase of differentiation, as compared to HC and were also more sensitive to a pro-oxidant environment, by increasing their antioxidant defenses (nrf2, gclc, gclm, gpx and gred gene expression). Interestingly, a pro-oxidant environment during the very early phase of maturation increased NKCC1 in both HC and EPP NPC, leading to a delay in the NKCC1/KCC2 switch. An additional OxS challenge in a pro-oxidant environment induced a long-term effect in the HC NPC, with decreased KCC2 expression.

Discussion: Altogether, our results suggest that redox dysregulation, induced by a genetic predisposition and/or a pro-oxidant environment, affects the NKCC1/KCC2 switch, which may lead to abnormal maturation of neurons. While these findings are preliminary and require additional confirmation, they remain highly significant for advancing our comprehension of the developmental changes in NKCC1/KCC2 during brain maturation, which could explain the cognitive symptoms associated with SZ.

T181. NAVIGATING DIVERSITY IN MATERNAL IMMUNE ACTIVATION PROTOCOLS: A COMPREHENSIVE REVIEW OF MAMMALIAN MODELS

Ali Shahbazi¹, Maral Khodaparast*¹, Dina Vagharimehr²

¹*Iran University of Medical Sciences*, ²*University of Pavia*

Background: After the historic realization of the impact of infectious disease outbreaks on next generation's psychiatric health, many different maternal immune activation (MIA) protocols have been designed in order to replicate some aspects of human psychiatric disorders in different animals extending from mice to non-human primates. These models make it possible to examine aspects of the pathomechanism of schizophrenia, autism and depression that were not accessible through any preceding replications of these disorders. MIA models have also become a useful medium to study the effect of a variety of interventions on prevention and reversal of psychiatric disease-related phenotypes. However, the variation of MIA protocols makes confusion when choosing the right model for a given objective and raises questions about method standardization and comparability of the widely available manuscripts that have used these protocols. The aim of this review is to help with designing maternal immune activation methodologies for a given research question.

Methods: The data presented in this review are derived from articles retrieved from PubMed and Scholar spanning 1990-2023, utilizing the following keywords: Prenatal Immune Activation, Maternal Immune Activation, Gestational Immune Activation, Schizophrenia, Autism, Depression, LPS, Poly I:C and MAM. Human, ex vivo and in vitro studies and animal neurodevelopmental studies that have used non-immune stimulating agents have not been included in this review.

Results: The data extracted from selected papers has been organized into comprehensive tables, encompassing details on experimental animals, MIA induction protocols, validation techniques, secondary interventions, and corresponding behavioral and molecular assessments.

In the analysis of diverse MIA protocols, studies were primarily categorized based on the experimental animals including rodents and primates, studies were then subcategorized using the immune mimetic agent (Poly I:C, LPS, direct use of virus, bacteria) and gestational stages of immune activation (early, mid, or late gestation). The administration details including: dosage ranges, routes, and durations, model validation (selected cytokines), study outcomes including: molecular assessments and behavioral evaluations and secondary interventions (both pharmacologic and nonpharmacologic) were then presented meticulously in separate tables.

Discussion: The comprehensive exploration of maternal immune activation (MIA) has provided valuable insights into the complex interplay of neurodevelopment and environmental factors contributing to neuropsychiatric disorders and also helped in developing relevant tools for preclinical drug research. However, the absence of uniformity in research methodologies makes it hard to design a study using these animal models. Recently a detailed guideline has been proposed for reporting MIA studies, which is an important aid in increasing the quality of the future research.

This review takes a step back and aims to help design MIA research methodologies. The data regarding protocol variations have been presented for each step of the experiment and help selecting proper MIA protocol for experiments via substantial summarization and classification of the available literature. We aim to facilitate standardization in experimental

design and interpretation, fostering a more cohesive understanding of MIA's impact on psychiatric disorders in animal models and addressing the gaps and future direction for studies in this field.

T182. NEUROPATHOLOGY OF COGNITIVE IMPAIRMENT IN CHRONIC SCHIZOPHRENIA

Naomi Futhey*¹, Elizabeth Gregory¹, Belen Arranz², Josep Maria Haro³, Fidel Vila-Rodriguez¹, Mark S. Cembrowski¹, Veronica Hirsch-Reinshagen¹

¹*The University of British Columbia*, ²*Hospital Parc Sanitari Sant Joan de Déu*, ³*Parc Sanitari Sant Joan de Déu, CIBERSAM, Universitat de Barcelona, Barcelona, Spain*

Background: Cognitive impairment is a core tenant of chronic schizophrenia and can be as disabling as that experienced by patients with Alzheimer Disease (AD). Research shows impairment may present prior to the onset of positive symptoms and be exacerbated by aging, but a mechanism has never been elucidated. In AD, accumulation of abnormal proteins leads to chronic neurodegeneration and a characteristic neuropathological signature. Our pilot data, however, shows that cognitive impairment in chronic schizophrenia is only partially explained by neurodegeneration, suggesting the presence of a different neuropathological process specific to schizophrenia.

Methods: We have obtained clinical and demographic data for 55 patients with chronic schizophrenia that underwent autopsy in compliance with standard European ethical requirements. Clinical data includes psychiatric diagnoses, Global Assessment of Functioning (GAF) score, Clinical Global Impressions (CGI) measurement, pharmacological treatment history, and cause of death. A subset of 34 subjects has additional neuropsychological evaluations including Positive and Negative Syndrome Scale (PANSS) scores, Mini-Mental Status Examination (MMSE), Frontal Assessment Battery (FAB), Calgary Depression Scale for Schizophrenia (CDSS), and CERAD scores. Standard evaluation of neurodegenerative diseases was performed in all subjects using 15 tissue blocks per subject, including all lobes, white matter, limbic system, deep grey nuclei (basal ganglia and thalamus), brainstem, and cerebellum. Initial exploratory data analyses was performed to ascertain central tendency, dispersion, and data distribution, as well as whole group correlations between severity of neurodegenerative pathology with clinical and neuropsychological score scales.

Results: The mean (SD) age of death in our cohort was 78.2 (9.4), and the mean disease duration 53.9 (10.6) years. 14 patients (32.6%) had completed primary school or more, and 42 (81.1%) were heavy smokers. 37 (74.0%) were on antipsychotics, the mean GAF score was 30.7 (12.0) and mean CGI 4.4 (0.9). Mean total PANSS score was 100.3 (30.0), mean positive symptom score was 22.2 (9.2) and the mean negative score was 28.5 (9.8). The mean MMSE was 17.4 (8.3), CDSS was 1.9 (2.5) and FAB 7.6 (4.5). On autopsy, 25 patients out of 54 (47%) had neurodegenerative or cerebrovascular neuropathological findings of enough severity to explain cognitive impairment in non-schizophrenia patients. These included 17 (32%) cases with moderate or severe AD pathology, 5 (9%) with significant cerebrovascular disease, and 3 (6%) cases with severe non-AD neurodegenerative pathology. One patient had remote history of a lobectomy. However, neurocognitive test scores did not correlate with severity of neuropathological changes.

Discussion: This cohort represents a group of elderly patients with chronic schizophrenia with relatively low mean education level, high smoking rate, marked impairment in global

functioning and significant cognitive impairment. The latter two are not entirely explained by neuropathological changes typically associated with dementia.

T183. ALTERED RETINAL MICROSTRUCTURES AND ELECTROPHYSIOLOGY AND THEIR ASSOCIATION WITH CLINICAL PARAMETERS AND VISUAL BRAIN REGIONS IN SCHIZOPHRENIA SPECTRUM DISORDERS

Florian Raabe*¹, Emanuel Boudriot², David Popovic¹

¹Max-Planck Institute of Psychiatry, ²Department of Psychiatry, LMU Munich Germany

Background: Optical coherence tomography (OCT) and electroretinography (ERG) studies have revealed both structural and functional retinal alterations in patients with schizophrenia spectrum disorders (SSD). However, it remains unclear which retinal layers are affected in SSD and how retina, brain, and clinical symptomatology are interconnected.

Methods: OCT, ERG, and brain magnetic resonance imaging (MRI) were applied to comprehensively investigate the visual system in a cohort of 103 patients with SSD and 130 healthy control individuals. A sparse partial least squares algorithm was used to identify multivariate associations between phenotypic and biological data. To assess specific differences between the groups, covariate-adjusted case-control comparisons of OCT and ERG parameters were subsequently performed with generalized estimation equations. Additional post hoc analyses were conducted to explore the relationship between retinal parameters, clinical disease features, and MRI volumes in patients.

Results: The sparse partial least squares analysis yielded a phenotype-eye-brain signature of SSD in which greater disease severity and impaired cognition were associated with electrophysiological and structural retinal impairment ($p < 0.001$). In case-control comparisons, patients with SSD had lower macular thickness, thinner retinal nerve fiber and inner plexiform layers, less negative a-wave amplitude, and lower b-wave amplitude. In patients, post hoc analyses linked retinal features to clinical parameters, such as duration of illness, duration of untreated psychosis, and cognition.

Discussion: This study demonstrates microstructural and electrophysiological retinal alterations in individuals with SSD that are associated with clinically relevant outcome parameters. Assessment of retinal parameters might help for future stratification of patients and could support the way towards personalized treatment strategies.

T184. STATE-DEPENDENT MODULATION OF STRIATAL AND HIPPOCAMPAL GLUTAMATE FUNCTION BY TAAR1 AGONIST ULOTARONT

Nina Dedic*¹, Sung Min Yang¹, Ayan Ghoshal¹, Jeffrey Hubbard², Florian Gackière², Romain Teyssié², Stuart A Neale³, Seth C Hopkins¹, Kenneth S Koblan¹, Linda J Bristow¹

¹Sumitomo Pharma America, ²Neuroservices Alliance, ³Neurexpert Limited

Background: Aberrant dopaminergic and glutamatergic function, particularly within the striatum and hippocampus, has repeatedly been associated with the pathophysiology of schizophrenia. Supported by preclinical and recent clinical data, trace amine-associated receptor 1 (TAAR1) agonism has emerged as a potential new treatment approach for schizophrenia. While current evidence implicates TAAR1-mediated regulation of dopaminergic tone (i.e. presynaptic dopamine syntheses capacity and/or release) as the

primary circuit mechanism, little is known about the effects of TAAR1 agonists on the glutamatergic system and excitation-inhibition balance. Here we assessed the impact of ulotaront (SEP-363856), a TAAR1 agonist in Phase III clinical development for schizophrenia, on glutamate function in the mouse striatum and hippocampus.

Methods: Acute brain slices were obtained from *Drd1a*-tdTomato and C57Bl6/J mice for striatal and hippocampal experiments, respectively. Whole-cell patch-clamp (voltage-clamp mode) recordings in the dorsal striatum were performed to investigate the effects of TAAR1 agonists ulotaront and RO5166017 on synaptic transmission. Striatal medium spiny neurons (MSNs) were identified based on their electrophysiological properties, and classified as D1 (i.e. tdTomato+) or putative D2 (i.e. tdTomato-) MSNs. Extracellular recordings in the hippocampal CA1 region were performed to assess firing activity and synaptic transmission (either via a multielectrode array or glass micropipette).

Results: Ulotaront reduced spontaneous glutamatergic synaptic transmission and neuronal firing in striatal and hippocampal brain slices, respectively. Interestingly, ulotaront potentiated electrically-evoked excitatory synaptic transmission in both brain regions, with the striatal effect being specific to a subpopulation of D2 MSNs. Similar striatal effects were also observed with the TAAR1 agonist, RO5166017. Furthermore, ulotaront exhibited a significant effect on excitatory but not the inhibitory synaptic activity of MSNs, which suggests a modulatory effect on striatal excitation-inhibition balance.

Discussion: The ability of ulotaront to selectively potentiate evoked synaptic responses, while reducing spontaneous activity suggests state-dependent modulation of glutamatergic tone and the potential to enhance the signal-to-noise ratio. These findings expand the mechanistic circuit hypothesis of TAAR1 agonists, which may be uniquely positioned to normalize both, the excessive dopaminergic tone and regulate abnormal glutamatergic function associated with schizophrenia.

T185. A DIFFUSION TENSOR IMAGING STUDY COMPARING WHITE MATTER INTEGRITY IN FAMILIAL HIGH-RISK INDIVIDUALS FOR BIPOLAR DISORDER AND PSYCHOSIS WITH HEALTHY CONTROLS

Muhammed Demir*¹, Cemal Demirlek², Burcu Verim², Berna Yalincetin³, Berna Akdede⁴, Burak Baykara⁵, Nabi Zorlu⁶, Emre Bora⁷

¹*Institute of Health Sciences, Department of Neuroscience, Dokuz Eylul University,*
²*Department of Neurosciences, Institute of Health Sciences, Dokuz Eylul University, Izmir, Turkey,* ³*Department of Neuroscience, Dokuz Eylul University, Izmir, Turkey,* ⁴*Dokuz Eylul University, Faculty of Medicine, Department of Psychiatry, Izmir, Turkey,* ⁵*Department of Child and Adolescent Psychiatry, Dokuz Eylul University Medical School, Izmir, Turkey,* ⁶*Department of Psychiatry, Katip Celebi University, Ataturk Education and Research Hospital, Izmir, Turkey,* ⁷*Dokuz Eylul University Department of Neuroscience, Dokuz Eylul University, School of Medicine, Department of Psychiatry*

Background: Within familial high-risk studies for bipolar disorder (FHR-BD) and psychosis (FHR-P), Diffusion Tensor Imaging (DTI) has become pivotal in exploring the intricacies of white matter microstructure in the human brain. By investigating individuals at familial high risk, this study aims to unveil subtle changes in white matter integrity that may precede clinical manifestations. Utilizing Tract-Based Spatial Statistics (TBSS) and the randomise tool in FSL, our analysis focuses on key DTI metrics—Fractional Anisotropy (FA), Radial Diffusivity (RD), and Axial Diffusivity (AD). The objective is to pinpoint specific white

matter irregularities associated with familial risk, offering valuable insights into early neurobiological indicators. These findings may pave the way for tailored interventions and preventative measures for individuals predisposed to bipolar disorder and psychosis.

Methods: In this study, we recruited a total of 56 participants, comprising 18 individuals at familial high risk for psychosis (FHR-P), 19 individuals at familial high risk for bipolar disorder (FHR-BD), and 19 Healthy Controls. Participants from familial high-risk groups were identified through patient records or outpatient settings at the Early Diagnosis and Intervention Department of Psychiatry at Dokuz Eylül University. All participants underwent MRI sessions using a 3 Tesla scanner. We conducted diffusion tensor imaging (DTI) analyses using FSL toolboxes. Voxel-wise statistical analysis was performed on Fractional Anisotropy (FA), Radial Diffusivity (RD) and Axial Diffusivity (AD) values using the Tract-Based Spatial Statistics (TBSS) toolbox. FA, RD and AD values were compared between healthy controls and familial high-risk groups separately. T-test comparisons were carried out using the randomise tool in FSL, with multiple comparison corrections performed using threshold-free cluster enhancement (TFCE). The statistical maps revealed significant tracts, identified by thresholding the p-value below 0.05.

Results: Investigating whole-brain Fractional Anisotropy (FA) and Radial Diffusivity (RD) comparisons revealed no significant clusters across all groups. Additionally, whole-brain Axial Diffusivity (AD) comparisons between the Familial High Risk for Psychosis (FHR-P) and Healthy Control (HC) groups did not show any significant clusters. However, in the comparison between Familial High Risk for Bipolar Disorder (FHR-BD) and HC groups, significant clusters were identified in the body of the corpus callosum. Further analysis, using the randomise tool with the superior longitudinal fasciculus as a mask, revealed that the FHR-P group exhibited significant clusters characterized by lower FA values and higher RD values compared to the HC group.

Discussion: Our investigation revealed notable distinctions in white matter microstructure among familial high-risk groups for bipolar disorder and psychosis. Notably, the familial high-risk for bipolar disorder (FHR-BD) group exhibited significantly higher Axial Diffusivity (AD) clusters in the body of the corpus callosum, potentially indicative of compensatory mechanisms. Conversely, whole brain analyses showed no significant clusters for Fractional Anisotropy (FA) and Radial Diffusivity (RD) values, suggesting that these measures, unlike in chronic patients, may not be as informative in the context of familial risk groups. Further analyses, particularly when employing a mask for the superior longitudinal fasciculus, revealed significant clusters. This outcome implies that the microstructural anomaly might be subtle, making it challenging to detect at the whole-brain level with stringent multiple comparison corrections, underscoring the importance of focused analyses on specific tracts.

T186. LONGITUDINAL CHANGES IN CORTICAL NETWORKS OF FIRST EPISODE SCHIZOPHRENIA PATIENTS

Peter Van Dyken^{*1}, Michael MacKinley², Ali Khan³, Lena Palaniyappan⁴

¹University of Western Ontario, ²London Health Sciences Centre, ³Robarts Research Institute, London, Ontario, ⁴Douglas Mental Health University Institute, Montreal, Quebec

Background: Patients with chronic schizophrenia have marked disruption of white matter connectivity as shown by diffusion MRI (Kelly et al., 2018). However, this disruption appears to be limited or absent in first episode psychosis (FEP) patients (Van Dyken, 2023, in review). Thus far, most studies of FEP have been cross-sectional or short-term follow-up on

treatment effects. This has precluded the disambiguation of two distinct issues that may explain the white matter disruption that characterized established illness: (1) a dynamic post-onset process of white matter-alterations in early phases of this illness vs. (2) a more severe extent of pre-onset white matter changes resulting in a chronic, intractable pattern of illness. Here, we investigate this issue in a longitudinal cohort of FEP patients and healthy controls to investigate the first possibility in this dichotomy: whether early phase of schizophrenia is characterised by ongoing changes in white matter diffusivity over time.

Methods: N=21 FEP patients and N=13 healthy controls (HCs) were recruited from an established cohort (TOPSY) in London, Ontario, Canada. Participants were scanned twice with follow-up 6-12 months after baseline. Baseline scans of patients were performed following initial diagnosis, before initiation of treatment. Data was acquired with 7T MRI using diffusion-weighted ($b=0,1000$; 64 directions; 2mm res) and T1-weighted (MP2RAGE; 0.75mm res) protocols. Diffusion data was preprocessed with and FSL pipeline (degibbs, susceptibility distortion correction with topup, motion and eddy current correction with eddy) and probabilistic tractography was performed with MRTrx using Constrained Spherical Deconvolution, the iFOD2 tracking algorithm, and Anatomically Constrained Tractography. Tract Based Spatial Statistics (TBSS) was used to measure voxel-wise decreases in fractional anisotropy (FA) and increases in mean, radial, and axial diffusivity (MD, RD, AD) between sessions. After defining structural connectivity matrices using the Brainnetome atlas, a graph theory-based clustering approach called the Network Based Statistic (NBS) was used to identify connections with significant increases in FA, and decreases MD, RD, and AD. For all analyses, data were fit to a mixed linear model, with subjects as a random effect and time by group as the fixed effect. Results were compared to a null distribution generated by 10,000 permutations.

Results: On average across the white matter, in FEP patients FA significantly declined between sessions ($z(73)$; $p = 0.017$), while MD ($z(73)$; $p \text{ LESS THAN } 0.01$) and RD ($z(73)$; $p \text{ LESS THAN } 0.001$) significantly increased. HCs had no change in these metrics, and the changes of MD ($z(73)$; $p \text{ LESS THAN } 0.01$) and RD ($z(73)$; $p \text{ LESS THAN } 0.05$) in FEP were significantly greater than that of HCs. Regionally, significantly lower FA and higher RD in the second scan was found in the left hemisphere in the genu of the corpus callosum and the centrum ovale. Connections with decreased FA and increased RD were found predominantly in the left hemisphere, particularly between the frontal, parietal, and temporal lobes. No regional or connectivity effects were seen in healthy controls, however, changes in FEP patients were not significantly different from changes in healthy controls.

Discussion: A change in diffusivity toward the patterns observed in chronic patients can be seen in FEP patients during the immediate aftermath of the first psychotic episode, however, it is unclear if this change is mediated by schizophrenia or an effect of physical, pharmacological, and social effects of a psychotic episode. Disruption localized in the left hemisphere may contribute to disruption of language networks.

T187. GLUCOSE-DOPAMINE INDEX: A PROMISING NEW METRIC FOR SCHIZOPHRENIA RESEARCH

Irena Dajic^{*1}, Ulrich Sauerzopf², Ana Weidenauer², Katharina Landesmann², Cornelia Diendorfer², Nicole Praschak-Rieder², Matthäus Willeit²

¹Medical University of Vienna, ²Department of Psychiatry and Psychotherapy, Medical University of Vienna

Background: Dysregulated dopamine signaling and altered energy homeostasis are well documented in schizophrenia (SCZ) and mounting evidence suggests that the two findings are closely connected. We have previously shown that blood glucose levels exhibit a positive association with specific binding of the selective D2/3 dopamine receptor agonist [11C]-(+)-PHNO in healthy volunteers (HV), and that this relationship is inversed in patients with SCZ (Sauerzopf et al. 2021). Here, we operationalize the glucose-dopamine relationship as a simple ratio of [11C]-(+)-PHNO binding to blood glucose (henceforth, GD index) and examine the utility of this new measure in capturing clinically relevant features of the disorder.

Methods: 27 HV (14m, 13f) and 15 patients with first-episode SCZ (10m, 5f) underwent baseline [11C]-(+)-PHNO PET scans as further described in Sauerzopf et al. (2021) and Weidenauer et al. (2020). Regional and voxelwise estimates of [11C]-(+)-PHNO specific binding (BPND) were derived using the simplified reference tissue model with cerebellar cortex serving as the reference region. The resulting BPND values were divided by blood glucose concentrations (mmol/L) measured prior to tracer injection using a hand-held device. Thus derived GD indices were compared between study groups using independent sample t-tests. Exploratory analyses examined the correlations between the indices and PANSS subscale scores, as well as individual PANSS items.

Results: GD indices were significantly lower in patients with SCZ as compared to HV in the caudate ($p=0.037$), putamen ($p=0.015$), and ventral striatum ($p=0.033$). Voxelwise analyses across basal ganglia structures provided concordant results in the form of large clusters extending bilaterally across the striatum (p LESS THAN 0.05, false discovery rate-corrected). Of the three compound symptom scores, only positive symptoms displayed associations with GD indices and these remained at trend-level (putamen: $r=-0.49$, $p=0.07$; globus pallidus: $r=-0.45$, $p=0.09$). However, we observed striking correlations of regional GD indices with several PANSS items, most notably blunted affect (ventral striatum: $r=0.84$, p LESS THAN 0.001) and somatic concern (hypothalamus and ventral striatum: $r=-0.68$, p LESS THAN 0.01).

Discussion: Regional GD indices proved apt in capturing group differences between patients with first-episode SCZ and HV as well as clinical correlations within the patient group that were not evident when baseline BPND values or glucose levels were evaluated separately (Weidenauer et al 2020). Based on these preliminary results, the GD index seems to be a promising metric for characterizing systemic disturbances in SCZ. Further studies are needed to corroborate and extend these findings.

Background: Cognitive deficits are a key aspect of schizophrenia, yet a broad spectrum of cognitive impairment is seen in the disorder, ranging from severe impairment to nearly normal functioning compared to healthy individuals. Research into brain structure integrity among cognitively differentiated subtypes of schizophrenia is growing, with the goal of pinpointing significant underlying factors for each distinct cognitive profile. This study focused on delineating the morphology of deep brain structures in a large multi-site sample of cognitive subtypes in schizophrenia through advanced brain mapping techniques. It was hypothesized that those with preserved cognitive abilities would show structural features akin to those of healthy subjects, contrasting with those in a more typically impaired subgroup.

Methods: Participant data was derived from the federated SchizConnect data sharing project. Schizophrenia participants were clustered into cognitive deficit (CD=99) and cognitively spared (CS=223) subgroups using a k-means algorithm; matched healthy comparison subjects were also included (CON=208). Neuropsychological functioning was assessed with a comprehensive battery, and MR scanning included T1-weighted images. Shape features of the caudate (CAUD), putamen (PU), globus pallidus (GP), nucleus accumbens (NA), thalamus (TH), hippocampus (HPC), and amygdala (AM) were derived using surface-based processing pipelines. Statistical analyses included vertex-wise contrast maps to test specific group differences in deep brain morphology corrected for multiple comparisons using random-field theory.

Results: Examination of vertex-wise contrast surface maps revealed significant abnormal shape in CS relative to CON in AM, HPC, TH, PUT, CAUD, and NA, with a prominent bilateral strip of inward deformation along dorsal aspects of the TH in CON-CS deformation maps. As for the CS-CD contrast, a significant outward deformation in the right amygdala was observed. Finally, examination of CON-CD contrasts revealed both significant inward and outward deformation in HPC, GP, and PUT.

Discussion: Findings generally, but not completely, endorse the concept of neurobiological diversity corresponding to the cognitive characteristics of empirically-defined schizophrenia subtypes. The cognitively spared subgroup exhibited atypical surface morphology across various brain structures relatively to CON, indicating a unique subcortical brain profile. The lack of notable abnormalities in the cognitively impaired subgroup points to different brain mechanisms influencing the clinical manifestation of the disorder. Distinct pathophysiological features might be active in each schizophrenia subgroup, suggesting either different variants of the disorder or the presence of biological protective elements that mitigate the severity of the condition.

T189. EXTRASTRIATAL DOPAMINE D2/3 RECEPTOR AVAILABILITY CONTRIBUTES TO CONDITIONED HALLUCINATIONS

Ulrich Sauerzopf^{*1}, Irena Dajic¹, Katharina Landesmann¹, Ana Weidenauer¹, Cornelia Diendorfer¹, Karsten Bamminger¹, Cécile Philippe¹, Lukas Nics¹, Nicole Praschak-Rieder¹, Matthäus Willeit¹

¹Medical University of Vienna

Background: Both, delusional perceptions as well as hallucinations can be conceptualized as faulty inference based on over-reliance on expectation in determining the presence or content of percepts. These psychopathological phenomena are commonly found in schizophrenia. The current dopamine hypothesis of schizophrenia comprises a role for both, striatal hyper-dopamergeria and cortical hypo-dopaminergia in the pathogenesis of schizophrenic psychosis. Previous studies have highlighted the role of enhanced striatal dopamine levels in mediating expectation-induced perceptual experiences in animals as well as human volunteers.

The aim of the present study was to ascertain whether extra-striatal dopamine D2/3 receptor availability, as measured by a highly sensitive and selective D2/3 receptor agonist radioligand [11C]-(+)-PHNO, could likewise be linked to susceptibility to auditory hallucinations induced by a cross-modal sensory conditioning task.

Methods: Ten healthy volunteers (2 male, 8 female), aged 19-28 (24±3), underwent a [11C]-(+)-PHNO positron emission tomography (PET) scan combined with an amphetamine challenge eliciting a hyper-dopaminergic state. The tracer was administered as a bolus followed by constant infusion (kbol=80). After tracer equilibrium was achieved, 0.3 mg/kg of d-amphetamine were administered i.v.. The conditioned hallucination (CH) task was performed after the PET scan was completed and within 111 ± 39 min of the amphetamine challenge. PET images were pre-processed in an in-house pipeline and regional time-activity curves were extracted using a detailed multimodal parcellation atlas. Pre- and post-amphetamine BPND values were calculated using the equilibrium approach, with the cerebellum as the reference region. The effects of post-amphetamine BPND values on CH frequency and associated confidence ratings were estimated using logistic and linear regression models, respectively. Logistic regression model fit was assessed using McFadden's pseudo R²; all p values were bonferroni corrected.

Results: CH frequency was associated with post-amphetamine [11C]-PHNO BPND values in a widely distributed set of cortical and subcortical regions. The strongest positive effects of BPND values on CH frequency were observed in the left parahippocampal gyrus, inferior frontal gyrus (BA47), inferior frontal sulcus, parts of the cingulate gyrus (BA 23 and BA 32) and the orbitofrontal gyrus (BA8) (pseudo R : 0.35-0.52, p-value LESS THAN 2.2e-16)). There was a negative association between mean confidence ratings and BPND in subsections of the superior frontal gyrus, posterior insula, and dorsal anterior cingulate cortex (adjusted R² GREATER THAN 0.85, p-value LESS THAN 0.05).

Discussion: Under hyper-dopaminergic conditions, the propensity to experience conditioned hallucinations was in general positively correlated with the [11C]-(+)-PHNO BPND indicating that these experiences were more likely if less dopamine was available in these brain areas. The confidence in these percepts was, though, negatively correlated with BPND. These findings are consistent with the hypothesis that dysregulations in prefrontal dopamine levels could be an important factor contributing to clinical hallucinations and the formation of delusions.

T190. DISSECTING NEUROANATOMICAL DISEASE TRAJECTORIES OF SCHIZOPHRENIA ACROSS THE LIFESPAN

Foivos Georgiadis^{*1}, Katerina Manoli², Stefan Kaiser³, Erich Seifritz¹, Sofie Valk², Paul Thompson⁴, Theo van Erp⁵, Jessica Turner⁶, Philipp Homan¹, Matthias Kirschner³

¹University Hospital of Psychiatry, University of Zurich, ²Max planck Institute for Human Cognitive and Brain Sciences, ³University Hospital of Psychiatry, University of Geneva, ⁴Imaging Genetics Center, University of Southern California, ⁵Psychiatry and Human Behavior School of Medicine, University of California Irvine, ⁶Department of Psychology, Georgia State University

Background: Schizophrenia is associated with widespread cortical abnormalities, with a demonstrated developmental onset. Aligning with a neurodevelopmental model, highest prevalence is between 18-25 years; however, later-onset (GREATER THAN =35) schizophrenia cases are well-documented, markedly, with differences in both symptomatology and outcomes. Studies comparing the neurobiological substrates of different age of onset remain hitherto scarce and limited by small sample sizes. Here, in the largest sample to date, we characterize and compare neuroanatomical patterns of typical (N=1035) and later-onset (N=214) schizophrenia patients and matched healthy controls (HC; N = 2867).

Methods: Using linear regression models, controlling for age and sex, and after adjusting for batch effects, we first compared cortical thickness of 68 regions between the entire HC cohort, vs. typical-onset schizophrenia and later-onset schizophrenia patients separately. In a next step, we directly compared the cortical thickness alterations of typical-onset compared to later-onset schizophrenia. To this end, we first regressed out age, age² and sex from subject-level cortical thickness data and compared the resulting residuals between typical-onset and later-onset schizophrenia individuals. Linear models with total cortical thickness and the similar covariates were used to confirm the convergent effect of the separate brain region models. To further examine cortical thickness as a singular phenotype, linear mixed models with brain region as a random effect in the case of the 68 brain regions, and laterality in the case of total cortical thickness models were implemented.

Results: Typical-onset schizophrenia patients showed widespread cortical thickness reductions compared to HC, with strongest effect sizes observed in occipital-parietal-temporal regions and the inferior frontal gyrus (t-values GREATER THAN 10; all pFDR LESS THAN .05), while only the bilateral pericalcarine cortex was not significantly different from HC. In later-onset schizophrenia, strongest cortical thickness reduction was observed in predominantly tempo-frontal regions (all t-values GREATER THAN 4; all all pFDR LESS THAN .05). In terms of topographical pattern, the cortical maps of typical-onset SCZ and later-onset SCZ show a high degree of topographical similarity (r=0.78, pspin LESS THAN .05). In a direct comparison later-onset SCZ patients show convergently lower effect sizes (Cohen's D) reductions in CT across all regions (MDCohen = 0.07 [0.05,0.09], pt-test LESS THAN .0001, V = 2199, pwilcoxon LESS THAN .0001). The lower region-specific disease-related reductions in later-onset patients is confirmed in a linear mixed model with brain region as a random effect ($\beta_{\text{stand}}=0.03$ [0.025,0.035], p LESS THAN 0.0001). Our total cortical thickness linear mixed model with laterality as a random effect further supports lower disease-related cortical thickness reductions in later- vs early onset schizophrenia patients ($\beta_{\text{stand}}=0.05$ [0.03,0.07], p = 0.0188). Very similar results are obtained when additionally controlling for total intracranial volume. Separate linear models for each region separately and for each side separately, in the case of total cortical thickness show convergent results with the linear mixed models.

Discussion: Altogether, our findings suggest high overall topographical similarity of cortical thickness reductions in typical-onset and later-onset schizophrenia and show in the largest sample size to date indications for stronger age-adjusted cortical thickness reduction in

typical-onset compared to later-onset schizophrenia patients. In addition, subtle variations of cortical alteration patterns were observed suggesting additional occipital, parietal, and temporal regions being affected in typical-onset schizophrenia, which are relatively spared in later-onset schizophrenia. These preliminary findings suggest shared neurobiological mechanisms underlying cortical thickness reduction in typical-onset and later-onset schizophrenia, and hint to a sparing effect of later schizophrenia onset on neuroimaging correlates of cortical thickness. These sparing effects appear to be more pronounced in occipital-parietal-temporal regions.

T191. VARIABILITY IN THE DEFAULT MODE NETWORK INCREASES FOLLOWING THE ONSET OF PSYCHOSIS

Background: The default mode network (DMN) is a set of brain regions active during rest and self-referential thought. DMN abnormalities have been consistently found in schizophrenia. Some recent studies suggest that evaluating connectivity within the DMN can help us find those individuals at a higher risk of developing psychosis. We were interested to see if connectivity within 24 nodes within the DMN can help us differentiate individuals at risk (CHR) from those with recent onset psychosis (ROP).

Methods: Resting-state fMRI data acquired as part of the EU-FP7-funded PRONIA study have been used in this study. Based on Schaefer's local-global parcellation of the human cortex, masks have been used to extract the time series from 24 nodes linked to the DMN. Connectivity between these nodes compared between ROP and CHR.

Results: Our results suggest that differences in the connectivity between several nodes within the DMN are significant in comparing CHR and ROP. Most of these nodes, such as the Middle temporal gyrus and Inferior frontal gyrus, have higher connectivity in ROP than

CHR. However, some nodes, such as the Middle temporal gyrus and PCC, have lower connectivity in ROP than CHR.

Discussion: Our findings suggest that the development of pathology in psychosis is associated with increased variability in the resting state connectivity within the DMN. The next step in our analysis will be to explore the correlations with inflammatory markers and investigate their impact on the DMNS's connectivity.

T192. NEURAL DYNAMICS OF SOCIAL PERCEPTION IN SCHIZOPHRENIA

Daniel Vieira¹, Jessica Lee¹, Nicolas Foley¹, Gaurav Patel^{*2}

¹*Columbia University/NYSPI*, ²*Columbia University*

Background: Declines in social cognition lead to much disability in schizophrenia. We previously reported on how these social cognition changes relate to connectivity and functioning during naturalistic stimulation of the temporoparietal junction/posterior superior temporal sulcus (TPJ-pSTS). Here we present how connectivity changes with the type of stimulus, how the temporal dynamics of the neural activity relate to the viewing of the naturalistic stimulus, and how both these connectivity changes and dynamics differ in schizophrenia.

Methods: Participants watched a 12-minute audio/visual movie clip (22 healthy controls (HC) and 24 schizophrenia participants (SzP)), a 15-minute visual-only movie clip (27 SzP and 21 HC), or listened to a 7.5-minute audio-only story (23 HC and 20 SzP) while BOLD-fMRI data was collected. We first used weighted shortest path length (wSPL) from each region of interest (ROI) to either right A1 or V1 to quantify the stimulation-induced changes in network connectivity from rest. We then clustered (k-means) the audio/visual and visual-only movie-evoked BOLD time-courses into co-activation pattern (CAP) states. We examined the association of the time-course of each of these CAP states with both movie visual features and saccades recorded during the movie-viewing.

Results: Superior temporal sulcus (STS) ROIs demonstrated the largest change from rest in wSPL to A1 or V1 in both groups, and wSPL between unimodal sensory areas shortened more in SzP versus HC from rest ($p < 0.05$). Then, for both the visual and audio/visual clips, we found CAP states that involved all the TPJ-pSTS areas. These CAP states were significantly associated with the movie's visual motion intensity, degree of social engagement among characters, each individual's saccadic frequencies, the expression of sarcasm (audio/visual clip only), and the number of faces in peripheral vision (all $pFDR < 0.005$). SzP CAP states frequently diverged from HC when HC were in the TPJ-pSTS CAP states during both clips. These moments were associated with higher visual motion velocities in the visual-only clip, with the expression of sarcasm in the audio/visual clip, and with social interactions in both clips ($pFDR < 0.05$).

Discussion: These experiments highlight the role of the TPJ and STS areas in dynamic changes associated with aspects of social cognition, and how the functioning of these areas may differ in SzP. With these dynamic measures we plan to extend precision imaging methods to capture dynamics that can then be used for both diagnostic and treatment purposes.

T193. UNVEILING THE IMPACT OF SINGLE AND MULTI-CLASS TREATMENT WITH ANTIPSYCHOTICS ON RSEEG FUNCTIONAL CONNECTIVITY AND

NETWORK TOPOLOGY: A CROSS-SECTIONAL STUDY IN HOSPITAL-ADMITTED PSYCHIATRIC PATIENTS

Melissa Zandstra^{*1}, Hannah Meijs², Metten Somers¹, Cornelis Stam³, Bieke de Wilde⁴, Jan van Hecke⁴, Peter Niemegeers⁴, Jurjen Luykx¹, Edwin van Dellen¹

¹UMC Utrecht, ²UMC Utrecht, Maastricht University, ³VUmc, Amsterdam, ⁴Ziekenhuis Netwerk Antwerpen

Background: In the pursuit of delineating biomarkers for schizophrenia spectrum disorders, resting-state EEG (rsEEG) functional connectivity and network topology have emerged as promising avenues. However, medication use such as antipsychotics poses a potential confounding factor in biomarker research. We explored the impact of both single and multi-class antipsychotic treatments on rsEEG characteristics in a psychiatric population.

Methods: RsEEG was analyzed in a real-world cross-sectional sample of 900 hospital-admitted psychiatric patients. Patients treated with antipsychotics (AP) were compared to unmedicated patients and patients treated with antidepressants (AD), benzodiazepines (BDZ), and multi-class combinations of these treatments. To assess the associations between antipsychotic treatments and macroscale rsEEG characteristics, we employed a general linear model with post-hoc tests. Additionally, Spearman's rank correlation analyses were performed to explore potential dosage effects.

Results: Compared to unmedicated patients, single-class use of AP was associated with lower functional connectivity in both the delta and alpha bands. We also found correlations between AP dosage and functional connectivity in these frequencies. Importantly, we found evidence for cumulative or interaction effects of different classes of psychotropics on rsEEG characteristics: multi-class medication use was associated with differences in functional connectivity and network topology measures compared to single-class medication use. These effects were most pronounced for concomitant use of all three classes of psychotropics.

Discussion: Our cross-sectional study suggests small but significant associations between single and multi-class use of antipsychotics and macroscale rsEEG functional connectivity and network characteristics. These findings highlight the importance of considering the effects of antipsychotics, as well as their interaction with other psychotropics, when investigating rsEEG biomarkers in patients on psychotropic medication.

T194. NEURAL CORRELATES OF ANTICIPATION, DECISION MAKING AND FEEDBACK PROCESSING IN THE BALLOON ANALOGUE RISK TASK IN SCHIZOPHRENIA

Daniela Mier^{*1}, Alexander Wolber¹, Sarah Stumpp¹, Leonie Lipinski¹, Natascha Büchele¹, Michael Odenwald¹, Brigitte Rockstroh¹, Stephanie N.L. Schmidt¹

¹University of Konstanz

Background: Patients with schizophrenia are known to present impaired reward anticipation and decision making. These impairments are accompanied by aberrant activation and connectivity of fronto-parietal and fronto-striatal networks. However, previous tasks on risky decision-making were not suitable to separate reward anticipation from decision-making. Our novel variant of the Balloon Analogue Risk Task (BART) allows differentiating between reward anticipation and decision-making, as well as feedback processing in the context of risky monetary decisions.

Methods: In our preregistered study (<https://osf.io/rza63/>), 28 patients with schizophrenia and 31 healthy controls matched by age, gender and education, completed the novel BART variant during functional magnetic resonance imaging. In the BART, participants can inflate virtual balloons with increasing monetary gain going along with increasing risk of balloon explosion and with this increasing risk of losing money. Participants are informed about the increasing risk. Data was acquired with a 3 T Siemens Skyra Scanner and analyzed with SPM 12.

Results: Data collection has only recently been finished and analyses are ongoing, but current preliminary analyses across participants show strong activation in nucleus accumbens, insula and dorsolateral prefrontal cortex for all three decision making processes. Comparing patients with controls, patients behaved less risky with a lower number of adjusted pumps, and reduced activation in nucleus accumbens during anticipation, but not during decision-making or feedback of a monetary gain.

Discussion: Our preliminary findings replicate previous studies with the BART by showing involvement of frontal regions, the insula and the nucleus accumbens. In addition, they replicate reduced nucleus accumbens activation during reward anticipation, and risk averse behavior in the BART in schizophrenia. Final activation analyses, and results from additional connectivity analyses and parametric modulation, incorporating the influence of the riskiness of decisions are in progress and will be presented at the conference. These analyses will contribute to a differentiated understanding of impaired decision-making in schizophrenia.

T195. INVESTIGATING PREDICTIVE LANGUAGE PROCESSING IN INDIVIDUALS WITH PSYCHOTIC-LIKE SYMPTOMS – A MULTIMETHOD APPROACH

Elisabeth Sterner^{*1}, Lucy J. MacGregor², Verena Demler³, Christoph Mathys⁴, Franziska Knolle³

¹Klinikum Rechts der Isar, Technical University of Munich, ²University of Cambridge, ³Technical University of Munich, ⁴Interacting Minds Centre, Aarhus University

Background: Impaired language processing is a core symptom of psychosis and is critically involved in shaping positive (e.g., auditory hallucinations) and negative symptoms (e.g., social withdrawal). Predictive Coding accounts of psychosis suggest an imbalance in the weighting of prior beliefs and incoming sensory information as the underlying mechanism to drive symptom development. Due to its predictive nature, language processing offers an efficient way to test the interplay of prior information and sensory likelihood. Thus, the goal of this study was (I) to investigate the use of semantic prior beliefs relative to sensory information during predictive language processing as a trait marker for psychotic-like symptoms, (II) to examine whether an overreliance induces task-based hallucinations, and (III) to explore the underlying neurophysiological signatures of potential alterations.

Methods: 55 participants assessed for psychotic-like symptoms completed a predictive language paradigm while their brain activity was recorded with EEG. In the task, participants listened to sentences of varying predictability (e.g., high predictability: “The small dog was chewing on his ... bone”; low predictability: “The old man is sorting the ... coins”). The sentence-final word of each sentence (e.g., “bone” or “coins”) was degraded in clarity to different degrees, ranging from fully unintelligible to fully intelligible. Participants were asked to report the word they perceived to assess task-based hallucinations. To estimate the relative strength of semantic prior beliefs over the sensory input, we fitted a linear Bayesian

regression model. Additionally, we investigated the neurophysiological underpinnings of predictive language processing using EEG.

Results: Computational modeling showed that prior semantic knowledge relative to sensory information was overweighted with increasing psychotic-like symptoms. Interestingly, the overweighting of semantic prior beliefs was generally associated with experiencing more conditioned hallucinations. The EEG analysis revealed that increasing psychotic-like symptoms were linked to more negative N400 amplitudes – an ERP component that indexes lexico-semantic processing and has been discussed as a neurophysiological signature of a prediction error within the Predictive Coding framework.

Discussion: Our findings show that healthy individuals with enhanced psychotic-like symptoms more strongly rely on prior contextual information during predictive language processing. On a neurophysiological level, this is reflected in changes in the N400 component, indicating altered prediction error processing. Taken together, our findings provide initial evidence of how suboptimal predictive language processing gives rise to misperceptions and how these processing alterations are reflected on a neurophysiological level.

T196. FUNCTIONAL CONNECTIVITY PATTERNS ASSOCIATED WITH IMMUNE PROFILES IN PSYCHOSIS: PRELIMINARY RESULTS FROM THE UK BIOBANK DATABASE

Edward Palmer*¹, Jack Rogers², John Williams¹, Rachel Upthegrove³

¹*University of Birmingham*, ²*Institute for Mental Health, University of Birmingham*, ³*Institute of Mental Health, University of Birmingham, United Kingdom*

Background: There is a growing body of evidence showing that inflammation or changes in the immune system play a key role in certain mental health disorders, including psychotic disorders. In psychosis, pro-inflammatory states have been observed prior to the onset of illness and have been linked to specific symptoms, specifically negative symptoms such as anhedonia. The aim of this research is to explore the underlying neurobiological mechanisms that could inform different inflammatory profiles and identify immune-active subgroups that could help inform detection and targeted intervention. Evidence exploring different immune-active subgroups and alterations in brain structure has revealed differences in grey matter volume in the Middle temporal gyrus and hippocampus. In those with psychosis generally, decreased activity in the default mode network and increased activity in the salience network has been observed. However, less is known about the functional connectivity differences associated with inflammation as measured using resting-state functional MRI and whether these are mediated by negative symptoms.

Methods: Using data from the UK Biobank (UKBB, project number 92051), an open-access resource providing detailed characterisation of over half a million people aged 40–69 years and providing data on demographics, health records, genomics, clinical blood biomarkers and neuroimaging. We identified all participants with a Psychotic ICD10 diagnosis (F2XX|F302|F312|F315|F323|F333) from hospital admissions and for whom structural and resting state functional neuroimaging data was available (N=93). We then identified a group of matched healthy controls (HCs) based on age, gender, ethnicity and fluid intelligence. The images were pre-processed using FMRIB Software Library (FSL), with independent component analysis (ICA) and dual regression conducted using MELODIC (Multivariate Exploratory Linear Decomposition into Independent Component Analysis). Group-wise comparisons explored differences in functional connectivity between participants with a

diagnosis and HC, with further dimensional analysis exploring associations with measures of inflammation, notably the peripheral measure of CRP and negative symptoms such as mood, motivation and various cognitive measures.

Results: Using exploratory tensor ICA, 30 components were extracted representing group-average networks of brain regions. Three ICs were identified as representing networks of interest: the default mode network (DMN); the Central executive network (CEN) ; the salience network. Group-level comparison revealed a significant difference between cases and controls in the DMN and the CEN with dual regression analysis of functional connectivity (FC) revealing that the HCs showed greater FC in bilateral dorsal lateral prefrontal cortex compared to participants with a psychotic disorder. Differences in FC were also observed for those with high- versus low-level inflammation, with HC's showing increased FC within the left DLPFC and lateral posterior parietal cortex within the CEN compared to cases with high-CRP levels.

Discussion: Differences in resting-state neural FC provides important insight into the underlying neurobiological mechanisms linked to psychotic disorders. This work provides novel insight into neural connectivity changes in a large UK population database linked to different clinical and inflammatory profiles. This work could help refine prediction models that help identify immune-active subgroups linked to targeted intervention approaches and longer-term clinical and functional outcomes.

T197. AMYGDALO-FRONTAL CONNECTIVITY DISRUPTION AND EMOTION DYSREGULATION IN SCHIZOPHRENIA

Delfina Lahitou Herlyn^{*1}, Maite Aramburu², Deborah Pou², Araceli Lagostena³, Augusto Defelippe³, Elsa Costanzo³, Gabriela De Pino⁴, Mirta Fabiana Villareal⁵, Mariana Nair Castro⁶

¹CONICET, ²University of Buenos Aires - FLENI, ³FLENI, ⁴University of Buenos Aires - UNSAM, ⁵Instituto de Neurociencias FLENI - CONICET, ⁶Instituto de Neurociencias FLENI - CONICET - University of Buenos Aires

Background: Emotional regulation (ER), understood as the ability to influence one's own and others' emotions, is crucial for social functioning. Schizophrenia (SZ) is a highly prevalent disease, characterized by significant impairment of social skills. On the other hand, childhood is a critical period of neurodevelopment, highly susceptible to environmental changes. Therefore, adverse experiences during childhood (ACEs) increase the risk of psychopathology in adulthood, possibly by impairing circuits involved in ER and top-down processing. However, the relationship between functional brain connectivity and emotional dysregulation, as well as the impact of ACEs on the brain function of ER, remains unclear. This study aims to investigate brain connectivity and its relationship with difficulties in ER and ACEs exposure in patients with SZ.

Methods: Thirty participants (15 SZ and 15 healthy controls –HC–), aged between 18 and 60, were recruited. They underwent clinical evaluation using the Structured Clinical Interview for DSM-5 (SCID) to confirm the diagnosis or the absence of pathology in each case. Resting-state fMRI data were acquired using a GE Discovery MR750 3.0 T scanner. In addition to the PANSS (Positive and Negative Symptoms Scale), and the DERS (Difficulties in Emotion Regulation Scale), participants were also assessed using the Childhood Trauma Questionnaire (CTQ) to evaluate the presence of adverse childhood experiences (ACEs), processing and analysis of functional brain connectivity (FC) were performed utilizing FSL (FMRIB

Software Library v6.0), and statistical analysis was conducted using the R program (R Studio).

Results: A deficit in FC was observed between the right amygdala (rAMY) and three cortical clusters—left cerebellar hemisphere (p-value: 5.96e-08), bilateral frontal pole (p-value: 0.0395), and bilateral pre- and post-central gyri along with the precuneus (p-value: 0.0487)—in patients with SZ compared to HC. Interestingly, amygdalo-frontal hypoconnectivity was associated with difficulties in ER in daily life in SZ (p-value: 0.017). This association was primarily driven by dimensions related to impaired impulse control, limited ability to implement emotion regulation strategies, and a lack of emotional clarity. This FC disruption was also directly associated with the presence and severity of ACEs, particularly in sexual abuse (p-value: 0.049).

Discussion: The findings suggest a potential link between a key clinical feature of SZ, emotional dysregulation, and a disruption in fronto-amygdala connectivity. This neural pathway, involved in top-down mechanisms of emotion control, could underlie this association. In addition, the presence of ACEs, particularly sexual abuse, may significantly contribute to this connectivity deficit.

T198. STRUCTURAL ANOMALIES WITHIN THE THALAMUS OF EARLY PSYCHOSIS PATIENTS AND THEIR RELATIONSHIPS WITH PERIPHERAL REDOX/INFLAMMATORY MARKERS

Daniella Dwir¹, Gauvain Cung¹, Yasser Alemán-Gómez², Meritxell Bach-Cuadra³, Raoul Jenni¹, Patric Hagmann², Luis Alameda⁴, Kim Q Do¹, Philippe Conus⁴, Paul Klauser¹, Pascal Steullet*⁵

¹*Center for Psychiatric Neurosciences; Lausanne University Hospital (CHUV), Switzerland,*

²*Service of Diagnostic and Interventional Radiology, Department of Medical Radiology, Lausanne University Hospital (CHUV), Switzerland,* ³*Medical Image Analysis Laboratory (MIAL), Centre d'Imagerie BioMédicale (CIBM), Switzerland,* ⁴*Service of General Psychiatry, Department of Psychiatry, Lausanne University Hospital (CHUV), Switzerland,* ⁵*Center for Psychiatric Neurosciences, Lausanne University Hospital*

Background: Thalamus-related anomalies are parts of the pathology associated with the emergence of psychosis. In a recent multimodal MRI study on early psychosis patients (Alemán-Gómez et al. Schizophr Bull. 2023;49:196-207), we found disparate alterations: widespread diffusion-related anomalies (i.e., increased intraneurite volume fraction, IntraVF) within the whole thalamus, but reduced gray matter concentration (GMc) only in medial and posterior thalamic subregions. The pathological mechanisms underlying such anomalies remain however unknown. In search for factors contributing to these anomalies, we have investigated the relationships with peripheral markers of redox regulation associated with the GSH system (GSH peroxidase, GPx; GSH reductase, Gred) and oxidative stress/inflammation (metalloproteinase-9, MMP9; soluble receptor for advanced glycation end products, sRAGE).

Methods: Participants were 97 early psychosis patients (EPP) from the Lausanne Psychosis Cohort and 97 age-, sex-matched healthy subjects for whom we had MRI data. MRI was performed on a 3-Tesla scanner with T1w and Diffusion Weighted Imaging (DWI) sequences. Local GMc was estimated from T1w images, and IntraVF was calculated from DWI images using the Spherical Mean Technique. Each thalamus was subdivided in 7 nuclei to compute the mean GMc and IntraVF inside those regions. Peripheral markers: GPx and

Gred activities were measured in blood cells, while sRAGE level and MMP9 activity were quantified in plasma.

Results: GPx activity was higher in women than in man irrespective of the group and was positively correlated with Gred, specially in women of both groups. sRAGE level was higher in EPP than in controls independently of the sex, but no group or sex differences were found for MMP9 activity. We observed no correlation between MMP9 activity and sRAGE level in any of the groups. Likewise, these two markers did not correlate with GPx and Gred activities in both controls and EPP. Linear models revealed sex-group interactions in the relationships between blood markers and structural thalamic parameters. GPX activity was negatively correlated with IntraVF in the whole thalamus and positively correlated with GMc in the whole thalamus in women controls, but not in EPP. The relationship between GPx and GMc was most prevalent in the pulvinar. By contrast, MMP9 activity showed positive relationships with GMc in posterior thalamic subregions (pulvinar and lateral posterior-ventral posterior group) in women EPP only.

Discussion: To summarize, we found a sex-specific regulation of the GPx/Gred system independently of the pathology, and higher sRAGE levels in EPP. Moreover, our results suggest that redox homeostasis and MMP9/RAGE-related pathways may impact or modulate the thalamus macrostructure organization in a complex manner that differs among sex and clinical groups. These data also suggest that the thalamic anomalies revealed by DWI (IntraVF) and T1wI (GMc) in EPP are affected by different pathological mechanisms.

T199. LOWER ARTERIOLAR CEREBRAL BLOOD VOLUME IN RECENT-ONSET SCHIZOPHRENIA COMPARED TO CONTROLS MEASURED BY INFLOW-BASED VASCULAR-SPACE-OCCUPANCY (IVASO) MRI

Andor Bodnár¹, Adrian Paez², Kia Ultz², Christopher Ross³, Jun Hua², Russell Margolis³

¹Johns Hopkins University School of Medicine, ²F. M. Kirby Center, Kennedy Krieger Institute, ³Department of Psychiatry, Johns Hopkins University School of Medicine

Background: Schizophrenia is a complex and heterogenous disease, prominently associated with metabolic and microvasculature abnormalities. Arterioles may be the most sensitive component of the microvasculature to metabolic disturbances. Based on our preliminary work and other findings, we hypothesize that arteriolar cerebral blood volume (CBVa) is diffusely decreased in schizophrenia, including in individuals with recent onset of schizophrenia.

Methods: To explore this hypothesis, differences in CbVa were examined by iVASO (noninvasive blood nulling approach) MRI, extended to 3D whole brain coverage at 7T, between recent onset schizophrenia patients (N = 16, duration of illness mean = 1.5 yrs, SD = 1.8 yrs) and healthy controls matched for age and sex (N = 12). CbVa was examined in 98 distinct brain regions. CbVa values of each voxel within each brain regions were average for each participant and then within each group.

Results: 16/24 subregions within the frontal lobes had significantly reduced CbVa in schizophrenia (ranging from 16.2-36.9% change; $\eta^2 = 0.15-0.39$). All 10 subregions of parietal lobes had significant decreases in CbVa in schizophrenia (21.1-31.8% change; $\eta^2 = 0.29-0.40$) along with 12/14 subregions of the temporal lobes (17.4-40.6% change; $\eta^2 = 0.17-0.29$). CbVa in the insular cortices, and cerebellum were also significantly reduced in schizophrenia (13.1-36.3% change; $\eta^2 = 0.15-0.26$) along with most occipital regions (6/10 regions; 18.3-24.2% change; $\eta^2 = 0.23-0.26$). Similarly, both anterior and posterior cingulate cortices had significantly reduced CbVa in schizophrenia (6/10 regions; 13.9-23.4% change;

$\eta^2 = 0.21-0.41$). The only cortical region with significant increased CBVa in schizophrenia was the left cuneus (13.4% change; $\eta^2 = 0.19$). CBVa was also reduced in subcortical regions, but reduction only reached significance in the thalamus, amygdala, and medulla oblongata likely due to a limited number of voxels.

Discussion: Taken together, these findings replicate and extend previous iVASO results in schizophrenia patients and establish that CBVa is diffusely decreased in almost all areas of the brain, even in patients with recent onset of diagnosable disease. These findings suggest that, rather than being localized to particular circuits, schizophrenia is a disease that affects the whole brain. The relationships between CBVa and longitudinal course of disease (including prodromal stages), treatment response, or treatment resistance, remains to be determined.

This work was funded by T32MH015330, R21MH107016, and ABCD Charitable Trust.

T200. ANALYSING RESTING-STATE FMRI CONNECTIVITY PATTERNS IN INDIVIDUALS AT CLINICAL HIGH-RISK FOR PSYCHOSIS: PRELIMINARY INSIGHTS

Background: Individuals with psychotic disorders, including those at clinical ‘high-risk’ for psychosis (CHR-P), exhibit wide-spread alterations in brain functional connectivity, which might contribute to the cognitive, emotional and perceptual symptoms associated with psychosis. Studies using resting-state functional magnetic resonance imaging (rs-fMRI) have revealed disruptions in functional connectivity patterns within and between neural networks in psychotic disorders. Specifically, aberrant connectivity patterns have been found in neural networks such as the default mode network (DMN), which is important for self-referential processing, the salience network (SN), which is involved in task-switching and prioritising relevant information and the frontoparietal network (FPN), important for cognitive and executive functioning. These disruptions may contribute to distorted perceptions, difficulties distinguishing relevant information and deficits in cognitive and emotional processing that are associated with psychosis. However, research into the different connectivity patterns observed in the CHR-P population is limited, with the underlying neurobiological mechanisms linked to CHR-P and transition to a psychotic disorder unclear.

Methods: Preliminary analysis has investigated rs-fMRI connectivity patterns in young people at CHR-P compared to matched healthy controls (HC). The MATLAB-based CONN toolbox (RRID:SCR_009550) was used for anatomical and functional imaging pre-processing, denoising and first- and second-level connectivity network analysis. Whole-brain resting-state functional connectivity networks were analysed for all participants, with region-of-interest (ROI)-to-ROI connectivity applied to explore whether network functional connectivity differed between CHR-P and HC.

Results: Findings are considered in relation to previous studies showing disrupted functional connectivity in CHR-P. Abnormal connectivity patterns are shown within various neural networks including the DMN, SN and FPN in CHR-P individuals compared to HC. Weaker

connectivity between brain regions within these networks, including the posterior cingulate cortex and frontolateral prefrontal regions, were found in CHR-P young people compared to HC.

Discussion: The identification of differences in resting-state neural functional connectivity provides important insight into the underlying neurobiological mechanisms that could inform prognosis and early detection of CHR-P individuals. Specifically, this work provides insight into neural connectivity changes that occur before the onset of positive and negative psychotic symptoms and helps address heterogeneity in CHR-P research. Additionally, research into functional connectivity is important for developing prediction models that could help facilitate understanding of the progression of psychotic disorders and decrease longer-term clinical and functional outcomes. Overall, this research contributes to growing research on neural correlates of CHR-P and further provides specific brain regions and networks for future research.

T201. SEXUAL DIMORPHIC INFLUENCES ON AGE OF ONSET AND DURATION OF ILLNESS ON PATTERNS OF CORTICAL THICKNESS IN INDIVIDUALS WITH SCHIZOPHRENIA

Rachael Slate*¹, Aaron Clouse¹, Jacob Holker¹, Kaitlyn Greer¹, Barrett Humble¹, Madeleine Reading¹, Jacob Jensen¹, Kennedy Madrid¹, Sierra Jarvis¹, Seth Garrison¹, Stefan Ehrlich², Derin Cobia¹

¹Brigham Young University, ²Carl Gustav Carus of the Technische Universität Dresden

Background: Since the manifestation of schizophrenia varies across sexes (i.e., more mood symptoms and better overall functioning for women), the interaction between the diagnosis and sex is hypothesized to have a significant impact on morphology—making it an important contributor to schizophrenia’s neurological effects. Previous literature has yet to utilize high-dimensional brain mapping to assess how the brain morphology of men and women with schizophrenia differs as it pertains to age of onset (AOO)/duration of illness (DOI). Neuroimaging studies can provide evidence that brings the field closer to understanding whether later diagnosis among women may be due to prominent neurobiological features, thus excluding more sociological-leaning explanations. The purpose of this study was to utilize a sex-wise approach to examining cortical thickness alterations in men and women with schizophrenia, relative to healthy groups, and how it changes as a function of both AOO and DOI.

Methods: Participant data was derived from the federated SchizConnect data sharing project and the Human Connectome Project for Early Psychosis. Total samples included male schizophrenia (SCZ-M=273), female schizophrenia (SCZ-F=93), male healthy comparison (CON-M=247) and female healthy comparison subjects (CON-F=143). Whole brain vertex-wise cortical thickness was estimated from structural T1-weighted images using the FreeSurfer toolkit and compared between groups using SCZ-M/CON-M, SCZ-F/CON-F, CON-M/F, and SCZ-M/F contrasts. The relationship between whole brain cortical thickness and AOO/DOI variables were examined both separately and combined (interaction effects) per SCZ-M/SCZ-F groups by constructing vertex-wise correlation coefficients; age was included as covariate where appropriate, and all models were corrected for multiple comparisons.

Results: In the cortical thickness contrast between SCZ-M/CON-M, SCZ demonstrated significant thinning in the left isthmus cingulate region. For SCZ-F/CON-F contrast, significant thinning was noted in the left rostral anterior cingulate region for SCZ. There were

no significant findings noted for the CON-M/F contrast. For SCZ-M/F, SCZ-M demonstrated significant thinning in the left isthmus cingulate region. There were no significant findings observed across the AOO analyses for both SCZ samples. For DOI analyses, in SCZ-F there was a significant negative correlation with cortical thickness and the left entorhinal and the right superior frontal regions. Bilaterally, SCZ-M globally had a significant negative correlation against DOI. The SCZ-M/F interaction between cortical thickness and DOI differed in the left isthmus cingulate (negative correlation for males).

Discussion: Main findings from this study reveal more cortical thinning in SCZ-M compared to SCZ-F, especially within the left cingulate region. Additionally, DOI had a negative correlation with cortical thickness across patients, with females exhibiting negative thickness-DOI relationships in left entorhinal and right superior frontal regions, and males with bilateral global negative relationships between cortical thickness and DOI. These findings suggest DOI may have a more significant neurobiological impact on male patients, especially within cingulate regions. This may explain better overall functioning in female patients—thus, potentially leading to later diagnoses often observed in women compared to men with schizophrenia.

T202. A RETROSPECTIVE [11C]-(+)-PHNO PET DATA ANALYSIS ON THE CORRELATIONS BETWEEN SUBCORTICAL DOPAMINE SIGNALLING AND PERIPHERAL LIPID PROFILE IN SCHIZOPHRENIA

Katharina Landesmann^{*1}, Ana Weidenauer¹, Ulrich Sauerzopf¹, Irena Dajic¹, Cornelia Diendorfer¹, Nicole Praschak-Rieder¹, Matthäus Willeit¹

¹*Medical University of Vienna*

Background: One of the main reasons for the higher mortality rate among patients with schizophrenia is the increased risk of hyperlipidemia and its associated cardiovascular effects. It has been suggested that this co-occurrence may be due to shared underlying causes. This study aims to investigate the connection between subcortical dopamine signaling and peripheral metabolic indicators in both patients with schizophrenia (SZ) and healthy volunteers (HV).

Methods: Positron emission tomography (PET) imaging using [11C]-(+)-PHNO, an agonist radiotracer for dopamine D2/3 receptors, was employed to compare the neurochemical effects of amphetamine (AMPH), a dopamine-releasing agent, in HV and SZ. Additionally, the study examined the correlations between peripheral metabolic markers (list) and [11C]-(+)-PHNO binding (BPND) as well as amph-induced dopamine release.

Results: Opposing correlations were seen between [11C]-(+)-PHNO binding potentials (BPND) and metabolic markers in HV and SZ. Among HV, there was a positive correlation between both baseline and post-AMPH BPND and levels of total cholesterol (e.g. baseline globus pallidus (GP): $r=0.44$, $p=0.058$, GP post-AMPH: $r=0.53$, $p=0.023$) and LDL cholesterol (e.g. baseline GP: $r=0.49$, $p=0.038$, GP post-AMPH: $r=0.57$, $p=0.016$). Among SZ, negative correlations between BPND values and levels of total cholesterol (e.g. putamen post-AMPH: $r=-0.65$, $p=0.009$) and LDL cholesterol (e.g. putamen post-AMPH: $r=-0.69$, $p=0.0045$) were detected. Furthermore, HV displayed a negative correlation between BPND values and levels of HDL cholesterol (e.g. caudate after AMPH: $r=-0.71$, $p=0.0071$) while SZ demonstrated a positive correlation between subcortical BPND and HDL cholesterol levels (e.g. baseline ventral striatum: $r=0.61$, $p=0.02$). Lastly, HV displayed a positive correlation between amphetamine-induced dopamine release and levels of HDL cholesterol (e.g. SNVTA: $r=0.7$, $p=0.0081$), whereas SCZ displayed a positive correlation between

amphetamine-induced dopamine release and levels of LDL (Vstr: $r=0.71$ $p=0.003$) and total cholesterol (Vstr: $r=0.8$, $p=0.00038$).

Discussion: These findings indicate a physiological connection of subcortical D2/3 receptor availability and amphetamine-induced dopamine release with peripheral lipid markers. Additionally, PHNO's sensitivity to extracellular dopamine concentrations allows the interpretation of the correlations seen between BPND and peripheral lipid markers as correlations between subcortical dopamine concentration and peripheral lipid markers in opposing directionality. The results suggest that this relationship is altered in schizophrenia, as there are correlations with the same metabolic markers in patients, but in the opposite direction. Overall, the study suggests interactions between peripheral lipid metabolism and brain dopamine signaling, as well as potential pathological changes in dopamine-lipid interactions in individuals with schizophrenia.

T203. ASSOCIATIONS BETWEEN CEREBELLUM SUBREGION VOLUMES AND SEVERE VIOLENCE IN PSYCHOSIS PATIENTS AND NON-PSYCHOTIC VIOLENT OFFENDERS

Institute of Clinical Medicine, University of Oslo, Oslo, Norway; Centre for Research and Education in Forensic Psychiatry, Oslo University Hospital, Oslo, Norway

Background: The cerebellum contains more than 50 % of the human brain's neurons and has shown to play an important role far beyond regulating motoric processes. Cerebellar grey matter volume decrease has consistently been reported in schizophrenia. Further, these volume differences in the cerebellum have been linked to rule-breaking behaviour. Particularly, damage to the cerebellar subregions vermis and posterior lobules was reported to contribute to blunting of affect, impulsiveness, and aggressive behaviour. Hence, the cerebellum may be a key node in the complex interplay of both structural and functional alterations in the processes leading to both schizophrenia and violent behaviour, with subregional differences in volumetric patterns that may guide the search for possible explaining mechanisms.

Methods: 3-T MRI scans were obtained from 107 non-violent patients with schizophrenia spectrum disorders (SSD-NV), 36 SSD patients with a history of severe violence (SSD-V), 20 non-psychotic violent offenders (NPV) who were sentenced to indeterminate detention, and 411 healthy controls (HC). All participants were males. Cerebellar subregion volumes were obtained with ACAPULCO, a cutting-edge cerebellum parcellation algorithm that relies on convolutional neural networks. Group differences in total and subregional volumes were analysed using MANCOVA and ANCOVAs, covarying for confounders and significance values adjusted using Bonferroni correction for multiple tests.

Results: Total cerebellar grey matter volume was significantly lower in both SSD-NV ($p < .001$, Cohen's $d = .49$) and SSD-V ($p = .014$, Cohen's $d = .64$) compared to HC. The cerebellar lobules in SSD-NV had lower volumes in left Crus I ($p = .010$, Cohen's $d = .32$), right Crus II ($p = .003$, Cohen's $d = .46$), Vermis VIII ($p = .028$, Cohen's $d = .40$), Vermis IX ($p = .003$, Cohen's $d = .42$), and Vermis X ($p = .010$, Cohen's $d = .39$) compared to HC. Furthermore, we found significant volume decrease in right Crus I ($p = .025$, Cohen's $d = .62$), and Vermis IX ($p < .001$, Cohen's $d = .81$) between SSD-V and HC.

There were neither significant differences between SSD-NV and SSD-V, nor between NPV and the other groups.

Discussion: We found decreased grey matter volumes in the posterior cerebellar hemispheres and the vermal regions in both schizophrenia groups independent of violence history, but with a different subregional pattern. Interestingly, lower volumes specifically in the vermal region IX and right Crus I have been reported in individuals with Autism spectrum diagnosis. Hence, our results may give support to hypotheses pointing at autistic features like impaired social processing and poor mentalizing as crucial factors for violence proneness in some individuals with schizophrenia spectrum disorders.

T204. SCHIZOPHRENIA-SPECTRUM PSYCHOPATHOLOGY AS COMPARED TO ALTERED MICROSTRUCTURE OF THE WHITE MATTER LANGUAGE CONNECTIVITY

Werner Surbeck¹, Noemi Dannecker¹, Anna Steiner¹, Robin Samuel², Allegra Gasser¹, Dominic Fabian¹, Niklaus Denier³, Tobias Bracht³, Peter Brugger¹, Philipp Homan¹

¹Psychiatric Hospital of the University of Zurich, ²University of Luxembourg, Esch-sur-Alzette, Luxembourg, ³Translational Research Center, University Hospital of Psychiatry and Psychotherapy, University of Bern

Background: Schizophrenia-spectrum psychopathology appears to exist as a continuum in the general population, ranging from subtle, sub-clinical schizophrenia-like phenomenology in healthy individuals to overt schizophrenia. Language processing anomalies, clinically identified within formal thought disorders, are a core feature of schizophrenia-spectrum phenomenology. Pronounced structural changes in perisylvian cortical language areas have previously been associated with this phenomenon. Corresponding substrates in relation to white matter connectivity of language are far less well-characterized so far. Since semantic processing anomalies are crucially involved in the characteristic language disturbance of schizophrenia-spectrum psychopathology, and the left ventral language stream is increasingly associated with semantic processing anomalies, we postulate a pronounced microstructural change in ventral language connectivity.

Methods: Here we used Diffusion Tensor Imaging and applied manual fiber tractography to carefully reconstruct white matter fibers from individual brain scans. We included 40 individuals with early psychosis, 40 healthy individuals with high schizotypy, and 40 healthy individuals with low schizotypy. Schizotypy was assessed with the Oxford-Liverpool Inventory of Feelings and Experiences. For the ventral language stream, we assessed the inferior fronto-occipital fasciculus (IFOF), while the arcuate fasciculus (AF) was used as representative of the dorsal language stream. Since the corticospinal tract is not associated to language, it was used as control tract.

Results: With regard to the IFOF, early psychosis patients had lower MD than controls ($-.563$ standard deviation, 95% CI $[-.990, -.137]$, $t = -2.622$, $p = .010$) and high schizotypy controls had higher MD than low schizotypy controls ($.665$ standard deviation, $[.202, 1.129]$, $t = 2.849$, $p = .005$), as calculated by regression models of the two diffusivity measures FA and MD adjusted for age. Furthermore, the difference between early psychosis and high schizotypy was significantly greater than between early psychosis and low schizotypy ($F = 8.117$, $p = .002$). Although no significant results were found in relation to the AF per se, there were no significant differences of the MD measures between the IFOF and the AF. No significant group differences were found with regard to the corticospinal tract.

Discussion: Although the alteration of white matter microstructure in the IFOF differed significantly between early psychosis patients and healthy controls, there is no clear correlation between the severity of SS psychopathology and the microstructural changes (from low schizotypy to high schizotypy to early psychosis). Furthermore, the difference in white matter microstructure of the left IFOF, as manifested in the differences in MD measures, does not differ significantly from those observed with the AF. These results indicate an alteration of the entire perisylvian white matter language connectivity in early psychosis without a preference for its ventral parts.

T205. MULTIMODAL IMAGING OF NEUROINFLAMMATION IN EARLY-PHASE SCHIZOPHRENIA SPECTRUM DISORDERS

Shiral Gangadin^{*1}, Rene Mandl², Lot de Witte³, Neeltje Van Haren⁴, Maya Schutte⁵, Marieke Begemann², Rene Kahn⁶, Iris Sommer⁷

¹UMCG, ²University Medical Center Groningen, ³Department of Psychiatry, Icahn School of Medicine, Mount Sinai, NY, USA; Department of Psychiatry, Brain Center Rudolf Magnus, University Medical Center Utrecht, Utrecht University, Utrecht, The Netherlands, ⁴Erasmus Medical Centre, Rotterdam, Netherlands, ⁵Department of Neuroscience, UMC Groningen, ⁶Icahn School of Medicine at Mount Sinai, ⁷Department of Biomedical Sciences of Cells and

Systems and Department of Psychiatry, University of Groningen, University Medical Center Groningen, Groningen, the Netherlands

Background: Various lines of research suggest immune dysregulation as a potential therapeutic target for negative and cognitive symptoms in schizophrenia spectrum disorders (SSD). Immune dysregulation would lead to higher extracellular free-water (EFW) in cerebral white matter (WM), which may partially underlie the frequently reported lower fractional anisotropy (FA) in SSD. We aim to investigate differences in EFW concentrations - a presumed proxy for neuro-inflammation - between early-phase SSD patients (n = 55) and healthy controls (HC; n = 37), and to explore immunological and cognitive correlates.

Methods: To increase specificity for EFW, we study several complementary magnetic resonance imaging contrasts that are sensitive to EFW. FA, mean diffusivity (MD), magnetization transfer ratio (MTR), myelin water fraction (MWF) and quantitative T1 and T2 were calculated from diffusion-weighted imaging (DWI), magnetization transfer imaging (MTI) and multicomponent driven equilibrium single-pulse observation of T1/T2 (mcDESPOT). For each measure, WM skeletons were constructed with tract-based spatial statistics. Multivariate SSD-HC comparisons with WM skeletons and their average values (i.e. global WM) were not statistically significant.

Results: In voxel-wise analyses, FA was significantly lower in SSD in the genu of the corpus callosum and in the left superior longitudinal fasciculus (p LESS THAN 0.04). Global WM measures did not correlate with immunological markers (i.e. IL1-RA, IL-6, IL-8, IL-10 and CRP) or cognition in HC and SSD after corrections for multiple comparisons.

Discussion: We confirmed lower FA in early-phase SSD patients. However, nonFA measures did not provide additional evidence for immune dysregulation or for higher EFW as the primary mechanism underlying the reported lower FA values in SSD.

T206. NEGATIVE SYMPTOMS AND RSFC: LEVERAGING EMA AND INDIVIDUAL-SPECIFIC TECHNIQUES

Nada Dalloul*¹, Erin Moran¹, Deanna Barch¹

¹*Washington University in St. Louis*

Background: Motivational deficits have been well established in schizophrenia and have been shown to cut across psychotic and mood disorders. These deficits have been robustly associated with disability and distress. However, they are resistant to current treatments due to unknown underlying mechanisms. There are some indications that these motivational deficits are related to differences in resting state functional connectivity (RSFC). However, the findings are mixed in the literature – many studies report null relationships. These divergent results might be partly due to the limitations of traditional methods. First, most studies use clinical measures assessed at one time point which are limited in their ability to capture daily fluctuations in motivation. Second, traditional methods of determining RSFC use group-averaged data, which mask important inter-individual differences in functional connectivity. In contrast, ecological momentary assessment and individual-specific (IS-RSFC) techniques can account for intra-individual variability. By leveraging these methods, this study aims to elucidate the transdiagnostic relationships between motivational deficits and functional connectivity.

Methods: 144 participants (29 Schizophrenia/Schizoaffective Disorder; 38 Bipolar Disorder, 37 Major Depressive Disorder, 40 Controls) completed an EMA questionnaire on motivation and pleasure (MAP) for current and anticipated behaviors four times a day for 14 days.

Participants also completed two six-minute resting-state BOLD scans. Network connectivity matrices based on group-averaged parcels were created using the Gordon network parcellation. Individual-specific network connectivity matrices were calculated using an empirically validated template-matching technique. Averaged Fisher z-transformed pair-wise correlations within each network and averaged participation coefficient for six networks were assessed (Default Mode (DMN), Cingulo-Opercular (CON), Dorsal Attention (DA), Ventral Attention (VA), Salience (SAL), and Fronto-Parietal (FPN)). Bayesian hierarchical regression models assessed relationships between current and anticipatory MAP scores and RSFC metrics. These models included age and sex as covariates, as well as diagnosis and interactions between diagnosis and RSFC metrics to assess transdiagnostic relationships. IS-RSFC models will include average motion and number/size of parcels as additional covariates.

Results: The tests of effect presence produced mixed results for all twelve models. The 95% credible intervals indicated that within-network correlations and participation coefficients from the group-average parcellations of the six networks were not significantly related to anticipatory or current MAP when accounting for diagnosis, age, and sex. However, the probability of direction and region of practical equivalence tests revealed notable trends: MAP was negatively related to the participation coefficients for DMN, SAL, CO, and DA, positively related to the within-network correlations for SAL, DA, and VA, and negatively related to the within-network correlations for FPN (PD GREATER THAN 75%; ROPE LESS THAN 10%).

Discussion: The analyses partially supported relationships between RSFC derived from group-averaged parcellations and anticipatory and current MAP. While the credible intervals suggest no relationship, other tests indicate several non-zero effects. These results suggest small to null relationships between RSFC and MAP. However, they are limited by the use of group-averaged data, which might mask important inter-individual variability in functional connectivity. The planned analyses will address this by assessing the relationships of MAP with IS-RSFC.

T207. DISRUPTED NEURAL PROCESSING OF DYNAMIC NATURALISTIC STIMULI IN SCHIZOPHRENIA

Eric Reavis^{*1}, Yixuan Lisa Shen², Yasmeen Campos¹, Melodie Yen¹, Lourdes Concepción Esparza², Carolyn Parkinson²

¹*Semel Institute for Neuroscience and Human Behavior at UCLA*, ²*UCLA Department of Psychology*

Background: Schizophrenia (SZ) is associated with perceptual and cognitive impairments that are linked to poor functional outcomes. Extensive research has characterized such deficits using highly controlled laboratory tasks and neuroimaging. Yet, there have been few attempts to study stimulus processing in SZ under more dynamic and naturalistic conditions, leaving the field with little information about how perception and cognition might operate differently in SZ than in healthy samples under real-world conditions. The present study aims to bridge this knowledge-gap by using dynamic audiovisual stimuli and functional magnetic resonance imaging (fMRI) to investigate potentially aberrant naturalistic stimulus processing in SZ. In the current analyses, we focused on neural activity in regions of interest (ROIs) from the default-mode network (DMN). Specifically, we compared inter-subject correlation (ISC) measures of fMRI activity in SZ and healthy control (HC) participants for the medial

prefrontal cortex (MPFC), middle temporal gyrus (MTG), temporo-parietal junction (TPJ), and posterior cingulate cortex (PCC). These ROIs were selected a priori due to their importance in processing of naturalistic audiovisual stimuli in healthy samples.

Methods: An interim sample of 38 SZ and 38 HC participants completed a high-resolution T1 anatomical scan and fMRI as part of an ongoing study. Across three fMRI runs totaling about 40 minutes, participants viewed a set of naturalistic audiovisual clips in the same order. They were instructed to freely watch the videos as if they were watching television at home. MRI data were preprocessed and quality issues (e.g., excessive motion) were identified using a standardized pipeline (fMRIPrep). We used the Schaefer parcellation scheme, which divides the cortex into 200 regions based on neuroanatomical features of the T1, to define the DMN ROIs for each participant. We computed mean within-group ISCs for each participant in each ROI, quantifying the degree of similarity between the average activity in each region for each individual relative to all other members of the group. We then compared mean ISCs between the SZ and HC groups for each ROI using independent-samples t-tests.

Results: Seven SZ participants were excluded for excessive motion, leaving a usable sample of 31 SZ and 38 HCs. In each DMN ROI except MPFC, we found bilateral ISC reductions in SZ relative to HCs: right MTG [$t(67) = -3.38$, $p = 0.001$], left MTG [$t(67) = -3.45$, $p = 0.001$], right TPJ [$t(67) = -2.78$, $p = 0.007$], left TPJ [$t(67) = -3.02$, $p = 0.003$], right PCC [$t(67) = -3.03$, $p = 0.004$], and left PCC [$t(67) = -2.00$, $p = 0.0049$]. In MPFC, there was a significant group difference on the right [$t(67) = -2.82$, $p = 0.006$], but not the left [$t(67) = -1.85$, $p = 0.07$].

Discussion: The present results show that neural activity in DMN regions is aberrant in SZ while viewing naturalistic stimuli designed to approximate real-world perceptual experience. In particular, the results imply that stimulus processing in SZ tends to be more idiosyncratic than in HCs. This is consistent with prior research, which suggests that responses to perceptual stimuli tend to be more varied in SZ. However, the current results extend prior findings in a distinctly new direction, showing an effect under more naturalistic conditions, and providing a quantitative index of the degree to which individuals' perceptual experiences differ from an expected pattern. In future analyses with larger samples, we plan to investigate whether such indices relate to sociobehavioral functioning in SZ and determine whether they provide a basis for a novel biomarker of functioning in the disorder.

T208. DETERMINANTS OF CLOZAPINE AND NORCLOZAPINE PLASMA LEVELS IN A CHILEAN SAMPLE: NEW INSIGHTS FROM A MULTIVARIATE ANALYSIS

Maria De Los Angeles Herrera¹, Camila Diaz², Cristián Mena^{*3}, Alfonso Gonzalez-Valderrama⁴, Gabriela Barría-Santibañez⁵, Leticia Luna⁶

¹*Instituto Psiquiátrico Dr. José Horwitz, Santiago, Chile and School of Chemistry and Pharmacy, Faculty of Pharmacy, Universidad de Valparaíso, Chile.*, ²*Clozapine Pharmacovigilance Program, Instituto Psiquiátrico Dr. J. Horwitz Barak. Santiago, Chile.*,

³*Early Intervention in Psychosis Program at J. Horwitz Psychiatric Institute, Santiago; Finis Terrae University,* ⁴*Early Intervention in Psychosis Program at J. Horwitz Psychiatric Institute, Santiago, Chile and Finis Terrae University,* ⁵*Instituto Psiquiátrico Dr. José Horwitz, Santiago, Chile,* ⁶*School of Chemistry and Pharmacy, Faculty of Pharmacy, Universidad de Valparaíso, Chile.*

Background: Clozapine is the first-line antipsychotic drug for the management of treatment-resistant schizophrenia (TRS). It has a metabolism influenced by age, sex, smoking habit, and drug interaction with other medications. Variability in metabolism could be evidenced by clozapine and norclozapine plasma levels. Few studies in Latin American population have raised information regarding this therapeutic blood monitoring. Chile is the only country in South America with reported monitoring serum clozapine levels in tertiary attention centers. Considering this, we evaluate a sample treated at the largest Chilean clozapine clinic of the main national psychiatric hospital analyzing the plasma levels of clozapine/norclozapine in relation to the prescribed dose and other known factors that influence pharmacokinetics.

Methods: A retrospective observational study was carried out with information of clozapine users, over 15 years of age, who were treated at the Instituto Psiquiátrico Dr. José Horwitz (Santiago, Chile) between April 2022 and March 2023. Study variables included were gender, age at the sample moment, clozapine daily dose, weight (kg), height (m), body surface(m²), smoking status, other medications administrated (including daily doses) and plasma concentrations of clozapine (ng/ml) and norclozapine (ng/ml). Data analysis included a multivariate linear regression to evaluate together the linear relationship between plasma concentrations of clozapine and norclozapine with different variables of interest. Statistical significance was considered with a two-tailed p-value less than 0.05.

Results: We included 566 clozapine/norclozapine plasma levels from 333 clozapine users. Median age of patients was 40.9 years (IQR 29 – 53.3). Most samples were obtained from male patients (356 samples, 62.9%). 262 (46.7%) of samples were obtained in smoker patients. Daily doses of clozapine range from 75 to 800 mg/day (median 400 mg/day). Plasma concentrations of clozapine varied between 20.8 and 3461.4 ng/mL (median 278 ng/mL) and of norclozapine between 22.9 and 1287, 4 ng/mL (median 176.3 ng/mL). Smokers had concentrations 35% lower than non-smokers. In the multivariate analysis related to clozapine plasma levels we found a significative association with daily number of cigarettes (β -coefficient -0,152, t -3,703, p LESS THAN 0,001), gender (β -coefficient 0,154, t 3,655, p LESS THAN 0,001), age (β -coefficient 0,113, t 2,706, p LESS THAN 0,007) and fluoxetine dose (β -coefficient 0,116, t 2,905, p LESS THAN 0,001). We obtained a β -coefficient of 0,296 (t 7,209, p LESS THAN 0,001) for the overall correlation of clozapine plasma levels and clozapine dose adjusted for body surface, gender, age and fluoxetine dose. For norclozapine plasma levels we found significative association with daily number of cigarettes (β -coefficient -0,182, t -4,664, p LESS THAN 0,001), gender (β -coefficient 0,198, t 4,926, p LESS THAN 0,001), age (β -coefficient 0,115, t 2,887, p LESS THAN 0,004) and valproic acid dose (β -coefficient -0,116, t -4,291, p LESS THAN 0,001). The correlation β -coefficient was 0,393 (t 10,025, p LESS THAN 0,001) for the overall correlation of norclozapine plasma levels and clozapine dose adjusted for body surface, gender, age, and valproic acid dose.

Discussion: The present results provide valuable information to apply in the clinical context in order to optimize treatment and improve therapeutic goals for Latin American populations. More studies are necessary to improve clinical recommendations of the use clozapine/norclozapine plasma levels.

T209. CLOZAPINE AS A THERAPEUTIC CHOICE: LONGITUDINAL ANALYSIS OF POSITIVE AND NEGATIVE SYMPTOM SCALE SCORES IN A NATURALISTIC SETTING

Rachel Scheinberg¹, Zhirui Fu¹, Laura Scott¹, Arlene Cuerdo¹, Lilian Zhong¹, Chloe Bethany¹, Malaka Harper¹, Leslie Nucifora¹, Allison Brant¹, Russ Margolis¹, Gayane Yenokyan¹, Frederick Nucifora*¹

¹*Johns Hopkins School of Medicine*

Background: Treatment resistant schizophrenia (TRS) occurs in up to 35% of patients and leads to a substantial burden on patients, families and society. The only medication approved by the FDA for TRS is clozapine. Unfortunately, clozapine is dramatically underutilized due to rare but potentially severe side effects, and FDA REMS requirements that result in the need for regular blood draws and enrollment of patients, prescribers, and pharmacies in an associated registry. Increasing clozapine use could decrease symptoms and improve the quality of life for patients with TRS. However, while the value of clozapine for TRS has been well-established, the pattern of improvement on clozapine is less-well established, particularly in naturalistic clinical settings. Establishing this pattern could strengthen the case for clozapine utilization and provide practical guidance for prescribers. The objective of the current study is therefore to assess the symptom trajectories on clozapine using longitudinal data from a clinical setting with the goal of determining the time to improvement, the duration of improvement, the extent of improvement, and the particular symptom domains that improve.

Methods: The study population consisted of patients treated with clozapine at a specialty clozapine clinic of the Johns Hopkins Bayview Community Psychiatry Program. Each patient is assigned to a psychiatrist and a therapist, one therapist oversees clozapine REMS issues, and site nurses provide some assistance with managing side effects. Approximately 100 patients are treated in the clinic at any one point in time. This preliminary study focused on 28 patients started on clozapine after enrolling in the clinic. These patients had been designated treatment resistant based on standard criteria, and were at least moderately ill as defined by Positive and Negative Symptoms Scale (PANSS) scores of GREATER THAN 58 or by overall clinical presentation. PANSS symptoms were assessed approximately every 6 months while patients were enrolled in the clinic and taking clozapine, including prior to the onset of clozapine treatment. Patients were considered clozapine-responders if PANSS score declined to less than 58 or improved by 20%.

Results: PANSS scores of patients started on clozapine significantly improved during the first year of treatment. The improvement was generally sustained during subsequent treatment. All subdomains of the PANSS significantly improved during the course of the first year of treatment. Mean improvement for the PANSS total score within the first year was 13.9 [95%CI: -22.2, -5.6], and 3.6 [95%CI: -6.2, -1.0], 3.1 [95%CI: -6.4, 0.3] and 7.3 [95%CI: -11.6, -2.9] respectively for the positive, negative and general subdomains. 25% of patients who did not respond at 6 months responded at 12 months, and an additional 17% who had not responded at 12 months improved by their last PANSS assessment with the average duration of 6.64 years.

Discussion: These results suggest that treatment with clozapine is associated with improvement of symptoms across positive, negative and general domains of the PANSS in a naturalistic setting. Notably, in some individuals, improvement may take a year or more, justifying prolonged treatment with clozapine, particularly in the absence of established alternatives. The results further support the use of clozapine for patients with TRS.

T210. OPEN BOARD

T211. EFFECT OF ACUTE OLANZAPINE TREATMENT ON TRANSCRIPTOMICS IN THE HYPOTHALAMUS

Sandra Pereira*¹, Laura Castellani¹, Chantel Kowalchuk¹, Khaled Alganem², Xiaolu Zhang², William Ryan², Raghunath Singh¹, Sally Wu¹, Emily Au¹, Roshanak Asgariroozbehani¹, Sri Mahavir Agarwal¹, Adria Giacca³, Robert McCullumsmith², Margaret Hahn¹

¹*Centre for Addiction and Mental Health*, ²*University of Toledo*, ³*University of Toronto, Physiology*

Background: Antipsychotics dysregulate glucose metabolism and increase the risk of type 2 diabetes mellitus. We have reported that the antipsychotic olanzapine acutely impairs the ability of insulin or glucose administered into the brain (3rd ventricle) to maintain glucose homeostasis in rats. The hypothalamus, which is adjacent to the 3rd ventricle, plays a key role in the regulation of glucose metabolism throughout the body. In the current study, we assessed how acute administration of a clinically relevant dose of olanzapine per se affects transcription in the hypothalamus of rats. The objective of this study is to further understand the central pathways altered by olanzapine and to identify interventions to minimize its metabolic side effects.

Methods: Male Sprague Dawley rats underwent surgery to implant an intracerebroventricular (i.c.v., 3rd ventricle) cannula. Following recovery, catheters were inserted into the jugular vein and carotid artery for infusion and blood sampling, respectively. After 4-5 days, rats underwent a 2-hour pancreatic euglycemic clamp, which maintains basal (fasting) circulating concentrations of insulin and glucose. A single subcutaneous injection of olanzapine was administered immediately before the start of the clamp and therefore, the effects of olanzapine were investigated under controlled levels of insulin and glucose. The dose of olanzapine (3mg per kg of body weight) corresponds to clinically relevant occupancy of dopamine D2 receptors. Throughout the clamp protocol, i.c.v. saline was infused at the same rate as i.c.v. glucose, as per our previous publication on the effects of olanzapine on glucose sensing by the brain. At the end of the clamp, hypothalamus samples were collected, stored, and subsequently analyzed using RNA sequencing (RNA-seq). The effect of olanzapine on hypothalamic gene expression was assessed by comparing two groups: one that received olanzapine vs. another that received the vehicle for olanzapine. Both groups received i.c.v. saline. Full transcriptome pathway analysis was performed using fgsea R package. To identify compounds (perturbagens) that have the opposite (discordant) effects on gene expression compared to olanzapine, integrative LINCS was used.

Results: Olanzapine upregulates pathways associated with inflammation in the hypothalamus. In contrast, it downregulates hypothalamic pathways involved in protein folding. The latter is linked to endoplasmic reticulum (ER) stress, which occurs when there is a build-up of unfolded or misfolded proteins in tissues. Olanzapine also blocks the pathways of G protein-coupled receptors. Leading edge gene analysis identified genes driving these changes, for example the upregulation of inflammatory cytokines such as Tnf, Il1b, and Il6. Perturbagen analysis identified compounds that block inflammation and ER stress, such as radicicol, as agents that have the opposite effect compared to olanzapine on hypothalamic gene expression.

Discussion: Using RNA-seq, which is an unbiased approach, we found that olanzapine acutely stimulates inflammation and ER stress in the hypothalamus. In the literature, inflammation and ER stress are linked and both impair glucose homeostasis. Future studies should assess if anti-inflammatory agents or chemical chaperones, which reduce ER stress, can restore the ability of central insulin and nutrients to control glucose metabolism in the

presence of olanzapine. Since these compounds are used clinically for other disorders, the translational potential of such interventions in the context of olanzapine treatment is substantial.

T212. MUSCARINIC RECEPTOR AGONISTS AND POSITIVE ALLOSTERIC MODULATORS IN ANIMAL MODELS OF SCHIZOPHRENIA: A SYSTEMATIC REVIEW AND META-ANALYSIS

Nobuyuki Nomura*¹, Spyridon Sifakis², Malcolm R. MacLeod³, Johannes Schneider-Thoma², Irene Bighelli², Alexandra Bannach-Brown⁴, Sameer Jauhar⁵, Sridhar Natesan⁵, Anthony C. Vernon⁵, Sabine M. Höller⁶, Andrea de Bartolomeis⁷, Georgia Salanti⁸, Stefan Leucht²

¹*Section Evidence-Based Medicine, Technical University of Munich*, ²*Department of Psychiatry and Psychotherapy, Section Evidence-Based Medicine, Technical University of Munich, Munich, Germany*, ³*The University of Edinburgh, Edinburgh, Scotland, UK*, ⁴*Berlin Institute of Health at Charité Universitätsmedizin Berlin, CAMARADES, Berlin, Germany*, ⁵*Institute of Psychiatry, Psychology and Neuroscience, Kings College London, London, UK*, ⁶*Helmholtz Zentrum München Neuherberg, Germany*, ⁷*University of Naples, Naples, Italy*, ⁸*University of Bern, Bern, Switzerland*

Background: The current antipsychotics, all acting through dopamine D2 receptor occupancy, demonstrate efficacy in improving symptoms in acute schizophrenia and preventing relapses. However, they are associated with burdensome side effects and non-response rates of approximately 30%. Therefore, there is pressing need for non-dopaminergic antipsychotics. Recent findings from three phase III randomized controlled trials indicate that xanomeline (an M1/M4-preferring muscarinic receptor agonist) is efficacious in improving symptoms in acute schizophrenia. Additionally, numerous muscarinic medications with different mechanisms of action (e.g., emraclidine, an M4 positive allosteric modulator) are undergoing clinical or preclinical development. Given the urgency for novel antipsychotics and the promising findings for muscarinic receptor agonists, this study aims to conduct a systematic review and meta-analysis of muscarinic agonists in animal models of schizophrenia.

Methods: We employ a comprehensive search strategy, covering numerous databases including PubMed, MEDLINE, Web of Science, and preprint servers, to identify published and unpublished studies on muscarinic agonists in animal models of schizophrenia. Studies describing primary experiments using various methods for inducing psychosis-like behaviors in animals, including stimulant or NMDA antagonist-induced models of schizophrenia, were eligible for inclusion in the review. Two independent reviewers screen the records found in the search, extract data, and evaluate the risk of bias using the SYRCLE tool. Our primary outcomes are behavioral assays with predictive validity to identify antipsychotic effects in animal models of schizophrenia, i.e., locomotor hyperactivity and prepulse inhibition (PPI) impairment. Other behavioral outcomes are also analyzed as secondary outcomes. Data are aimed to be synthesized using multilevel multivariable meta-regression models with robust variance estimation. The confidence in the evidence is evaluated using the GRADE approach.

Results: The systematic review is ongoing, and we present our preliminary data at the conference.

Discussion: We expect that this review builds a body of evidence on the effects of muscarinic agonists in animal models of psychosis-like paradigm, which aims to provide

insights into the search for innovative molecular targets and the development of novel antipsychotics.

T213. CLOZAPINE AND LONG-TERM MORTALITY RISK IN PATIENTS WITH SCHIZOPHRENIA IN HONG KONG: EVIDENCE FROM THE CLINICAL DATA ANALYSIS AND REPORTING SYSTEM

Huiquan ZHOU^{*1}, Hao Luo¹, Jennifer Tang², Sherry Kit Wa Chan¹

¹*The University of Hong Kong*, ²*The Chinese University of Hong Kong*

Background: Schizophrenia patients experience a significantly elevated mortality risk, primarily attributed to suicide-related deaths. The impact of long-term clozapine use on mortality risk remains uncertain, as this medication has been associated with both increased infectious and cardiovascular mortality risks, as well as potential protective effects against suicidal behavior. Furthermore, it is hypothesized that continuous and discontinuous users of clozapine may exhibit distinct mortality risks. Hence, this study aims to comprehensively investigate the association between clozapine use and both all-cause mortality and suicide mortality risks in individuals diagnosed with schizophrenia.

Methods: Individuals with a schizophrenia diagnosis (ICD-9-CM 295) between January 1993 and March 2021 were retrieved from the Hong Kong Clinical Data Analysis and Reporting System (CDARS). The case group consisted of schizophrenia patients who initiated clozapine treatment between 2003 and 2012, with the index date set as the date of clozapine initiation. Controls were matched using propensity score matching in a 1:2 ratio, considering demographic factors and physical and psychiatric comorbidities, and were individuals who had never received clozapine during the follow-up period. Continuous clozapine users were differentiated from discontinuous users by two metrics: (1) having received a clozapine prescription within the last year, and (2) having been prescribed clozapine for more than 90% of the total follow-up duration. We applied accelerated failure time (AFT) models to estimate hazard ratios (HR) for all-cause mortality and suicide death comparing both discontinuous and continuous clozapine users to non-clozapine users. Any covariates with standardized mean difference (SMD) GREATER THAN 0.05 were adjusted for in the survival models.

Results: A total of 3,152 individuals using clozapine were identified, with 1,132 classified as discontinuous users and 2,020 as continuous users. Propensity score matching successfully matched 6,304 controls. Among the matched groups, imbalanced covariates included age (SMD: 0.29), schizophrenia duration (SMD: 0.21), and count of previous antipsychotics (SMD: 1.40). Using adjusted accelerated failure time models that controlled for the imbalanced covariates and accounted for Bonferroni Correction, the findings revealed that both continuous (HR: 0.38, 97.5% confidence interval [CI]: 0.23–0.62) and discontinuous (0.53; 0.31–0.90) clozapine users exhibited a lower risk of suicide mortality when compared to non-clozapine users. No significant associations were found between clozapine use and all-cause mortality risk.

Discussion: The findings of this study suggest that both continuous and discontinuous use of clozapine, compared to non-clozapine use, is associated with a lower risk of suicide mortality among individuals with schizophrenia. This indicates a potential protective effect of clozapine, especially continuous use in reducing the risk of suicide-related deaths in this population. However, it is essential to note that no significant association was also found between clozapine use and all-cause mortality. This highlights a potential trade-off between the benefits and risks of clozapine treatment. Healthcare providers should carefully consider

the patient's risk profile and weigh the potential benefits against other risks when making treatment decisions.

T214. COMPARATIVE EFFECTIVENESS OF ANTIPSYCHOTICS FOR RELAPSE PREVENTION AMONG 131,476 REAL-WORLD PATIENTS WITH A SCHIZOPHRENIA-SPECTRUM DISORDER

Aleksi Hamina*¹, Heidi Taipale², Johannes Lieslehto³, Markku Lähteenvuo⁴, Antti Tanskanen⁵, Ellenor Mittendorfer-Rutz⁶, Jari Tiihonen⁷

¹Niuvanniemi Hospital, ²Niuvanniemi Hospital, University of Eastern Finland, ³Niuvanniemi Hospital, Kuopio, Finland, ⁴University of Eastern Finland, Niuvanniemi Hospital, Kuopio, Finland, ⁵Karolinska Institutet, ⁶Department of Clinical Neuroscience, Karolinska Institutet, Stockholm, Sweden, ⁷Niuvanniemi Hospital, University of Eastern Finland; Karolinska Institutet

Background: We aimed to compare the real-world effectiveness of antipsychotics, including recently marketed drugs, in relapse prevention among persons with schizophrenia-spectrum disorder.

Methods: Utilizing nationwide data, we identified all persons between the ages of 16-65 diagnosed with schizophrenia-spectrum disorder (ICD-10 F20-F29) from the registers of inpatient and specialized outpatient care, sickness absence and disability pension in Sweden (N=131,476). An incident cohort with first-episode psychosis was also identified (N=39,355). Twenty most common antipsychotic monotherapies were identified, and the risk of relapse, defined as hospitalization due to psychosis, was investigated in within-individual design to minimize selection bias, by adjusting for the temporal order of treatments, time since cohort entry and concomitant drugs. The follow-up covered the years 2006-2021.

Results: Mean age of the study cohort was 45.7 (SD 16.2) years and 53.3% were men. During the follow-up (max 15 years, mean 10.4, SD 5.7), 48.5% (N=63730) experienced relapse at least once. All specific antipsychotics were associated with decreased relapse risk compared with non-use of antipsychotics. Paliperidone 3-month long-acting injectable (LAI) (HR 0.39, 95%CI 0.30-0.51), olanzapine LAI (0.44, 0.40-0.48), aripiprazole LAI (0.46, 0.42-0.51) and clozapine (0.50, 0.48-0.52) ranked best in relapse prevention, followed by other LAIs including paliperidone 1-month LAI (0.54, 0.51-0.58). Quetiapine was associated with the highest risk of relapse. Of newer antipsychotics, cariprazine showed rather similar results as other non-clozapine second-generation orals, however, confidence intervals were wide. Antipsychotics showing significantly lower aHRs among incident cases compared to prevalent cases included olanzapine LAI, clozapine, oral paliperidone and oral aripiprazole.

Discussion: Antipsychotics, especially long-acting injectables, are effective in preventing relapses in real-world circumstances among persons with schizophrenia-spectrum disorders.

T215. UNDERSTANDING PATIENT, CAREGIVER, AND PRESCRIBER PREFERENCES FOR AN ANTIPSYCHOTIC REGIMEN ADMINISTERED ONCE EVERY 2 MONTHS FOR SCHIZOPHRENIA: A QUALITATIVE SINGLE-PERSON INTERVIEW STUDY CONDUCTED IN EUROPE AND THE USA

Stephanie Loomer¹, MURAT YILDIRIM*², Jessica Madera-McDonough³, Arun Micheelsen², Kristine Harrsen², Bolu Oladini³, Clodagh Beckham⁴, Soma Nag³, Dawn Bates¹, Xavier Guillaume¹, Pedro Such²

¹Oracle Life Sciences, ²H. Lundbeck A/S, ³Otsuka Pharmaceutical Development and Commercialization, Inc., ⁴Otsuka Pharmaceutical Europe Ltd.

Background: Schizophrenia is a chronic condition that requires consistent pharmacological treatment to maintain symptom control. Long-acting injectable (LAI) formulations of antipsychotics are associated with improved adherence compared with daily oral treatment. When selecting a treatment, prescribers should consider the preferences of patients and caregivers to ensure that treatment goals are met.

Methods: This ongoing, qualitative study will explore patient, caregiver, and prescriber preferences for LAI dosing frequency, and factors influencing preferences for an LAI administered once every 2 months for the treatment of schizophrenia. The study is being conducted in France, Germany, Italy, Spain, and the USA, and is recruiting adults aged GREATER THAN =18 years diagnosed with schizophrenia, caregivers, and prescribers. Data are being collected via web-assisted telephone in-depth interviews using a semi-structured discussion guide to harmonise conversation flow across stakeholder groups and countries. Thematic analysis of the data is being undertaken. The target sample size is 20 patients, 10 caregivers, and 10 prescribers, with data collection ongoing.

Results: Preliminary findings from interviews with 9 patients, 7 caregivers, and 10 prescribers are reported here. While patients and caregivers have mixed feelings on once-monthly LAIs, most mentioned treatment effectiveness as a benefit and value less-frequent administration and fewer medications to manage symptoms. Patients consider that an ideal treatment would offer flexibility of administration, while caregivers prioritise fewer/no adverse events (AEs). Factors influencing prescriber selection of an LAI are a history of low adherence, patient characteristics and preferences, caregiver involvement, and symptom severity. Some prescribers feel that LAIs may lessen “control” for patients (loss of autonomy) and clinicians (inability to change dose or address AEs).

Patients and caregivers have generally favourable views on an LAI with a 2-month dosing interval, as this would translate to less time spent attending appointments and on associated travel. Words like “freedom” and “serenity” were used to describe feelings on an LAI with a 2-month dosing interval, along with noting that it would mean less responsibility and being able to go on holiday. Some patients feel that less burden on their caregiver is most influential when considering a switch to an LAI administered once every 2 months. The primary concern of patients and caregivers is the medication wearing off before the next injection and the potential for more AEs. Remembering when they are due for an injection is seen as a challenge by some; others note they may forget the appointment.

Prescribers feel that fewer consultations with an LAI administered once every 2 months may benefit doctors and patients, and that patients may feel well for a longer period of time with a gradual-release medication. Perceived disadvantages include a potential need for supplemental oral antipsychotics; a concern with all LAIs, regardless of dosing interval, is an inability to alter dosing. Prescribers would be open to recommending an LAI with a 2-month dosing interval for patients stable on oral medication and desiring decreased dosing frequency.

Discussion: There may be acceptance for an LAI administered once every 2 months to treat schizophrenia, due to greater freedom and less burden. Critical factors for uptake are treatment effectiveness and duration of efficacy.

T216. FACILITATING ANTIPSYCHOTIC DRUG CHOICE WITH THE "SHARED DECISION MAKING ASSISTANT" APP

Stefan Leucht^{*1}, Natalie Peter², Spyridon Sifakis³, Katharina Müller⁴, Alessandro Rodolico¹, Peter Brieger⁴, Alkomiet Hasan⁵, Wolfgang Strube⁵, Ingrid Bauer⁵, Johannes Hamann⁶

¹*Technical University of Munich*, ²*Department of Psychiatry and Psychotherapy, Klinikum rechts der Isar, School of Medicine and Health, Technical University of Munich*, ³*Department of Psychiatry and Psychotherapy, Klinikum rechts der Isar, School of Medicine and Health, Technische Universität München*, ⁴*kbo IsarAmper Klinikum München*, ⁵*Department of Psychiatry, Psychotherapy and Psychosomatics, University of Augsburg*, ⁶*Klinikum Mainkofen*

Background: According to current estimates, it takes an average of 17 years for a scientific innovation to be put into practice. There are many reasons for this. On the one hand, it is certainly the case that clinicians do not have the time to read scientific journals. According to already outdated estimates, a general practitioner would have to read 19 articles every day, 365 days a year, to cover the articles relevant to him. Even if clinicians read that many articles, the scientific jargon and technical terms would make it difficult for them to understand them. Guidelines are a way of summarizing the evidence in a selected and condensed way. However, in situations such as antipsychotics for schizophrenia treatment, for example, there are so many drugs, with varying efficacy but above all so many different side effects, that guidelines can only present very rough selection criteria.

Methods: In this situation, digital applications in the form of visualisations or APPs for computers, tablets and smartphones are the solution of choice. With the Shared Decision Making Assistant, we have developed such a visualisation in which the efficacy and six different side effects are presented graphically based on the results of a current network meta-analysis. With one click, the antipsychotics can be sorted according to effectiveness or a specific side effect. Medications that are out of the question can be clicked away. One can also view the effectiveness and various side effects side by side. The app/visualisation is supported by the presentation of essential information about the individual antipsychotics "in a nutshell". It enables doctors to access information quickly and involve patients in the form of shared decision-making.

Results: The usefulness of the app has been tested in a randomized controlled trial which is currently analysed. We will present the results and briefly demonstrate the functions of the app/visualisation. It is freely available also here <https://ebmapp.org/de/tools/sdma-app>).

Discussion: Digital solutions are an important way to go to reduce the evidence-practice gap. Work is needed to better understand how results are best displayed, what is the most important for clinicians and patients, and in which circumstances such visualisations are most useful.

T217. DRUG ADHERENCE AND ATTITUDE TOWARDS MEDICATION DURING TREATMENT WITH LONG-ACTING INJECTABLE ANTIPSYCHOTICS VS. ORAL ANTIPSYCHOTICS: AN EXPLORATORY STUDY

Sofia Francesca Aprile¹, Pierfelice Cutrufelli^{*1}, Alessandro Rodolico¹, Ludovico Mineo¹, Antonino Petralia¹, Maria Salvina Signorelli¹, Filippo Caraci¹

Background: Inadequate adherence to pharmacological regimens in psychiatric treatment is linked to numerous adverse consequences, such as an increased risk of disease relapse, frequent hospital admissions, impaired daily functioning, overall decline in quality of life, and increased resistance to medications. While Long-Acting Injectable (LAI) antipsychotics are recognized for their efficacy in enhancing adherence, their connection with patients' overall attitudes toward antipsychotic drugs remains less explored. This study aimed to investigate the differences in adherence levels and therapeutic attitudes between patients administered LAI antipsychotics and those administered oral antipsychotic medications.

Methods: A cross-sectional study was conducted on patients receiving antipsychotic treatment. The study included 18 patients taking LAI antipsychotics and 20 taking oral antipsychotics. Compliance and therapy perception were assessed using the Drug Attitude Inventory (DAI-30) and adherence using the Brief Adherence Rating Scale (BARS), supplemented by monitoring delays or absences in LAI treatment; absences were noted when patients missed their treatment window; delays were recorded when administration exceeded the scheduled day but occurred within the adequate timeframe. Welch's t-test was used for statistical analysis to identify significant differences between groups in scales, subscale and individual items.

Results: Statistically significant differences were observed in both adherence and attitude. The LAI group showed significantly higher ($p < .001$) adherence rates (mean=97%, SD=0.04) than the oral group (mean=79%, SD=0.16). Conversely, the oral group scored significantly higher ($p = 0.009$) on the DAI-30 (mean = 19.8, SD = 6.01) than the LAI group (mean = 9, SD = 14.8). Additionally, the LAI group exhibited significantly lower scores on both DAI-30 subscales (subjective response to antipsychotics and attitude towards therapy) and on item 27 ($p < .001$), related to perceived control.

Discussion: The findings from this study highlight the significant differences in adherence and attitudes toward therapy between patients on LAI antipsychotics and those on oral antipsychotics. Notably, the higher adherence rate in the LAI group confirmed the effectiveness of LAI formulations in ensuring consistent medication intake. Conversely, the higher DAI-30 scores in the oral antipsychotic group suggest a more positive attitude toward therapy. Further research is needed to clarify this aspect and understand the causal relationship: whether it is the use of LAI antipsychotics that leads to a different attitude towards therapy or whether the preference for LAI over oral antipsychotics is influenced by a pre-existing variation in attitude, determining the directionality of the relationship between LAI use and patient attitudes towards their treatment. The lower scores on item 27 of the DAI-30 within the LAI group, reflecting a perceived lack of control, underscore the importance of this factor in future investigations, reinforcing the notion that perceived control could be a critical element in understanding patient attitudes towards LAI antipsychotics.

T218. SENSORY PROCESSING DEFICITS OF MK-801 RESPONDS TO RISPERIDONE ACROSS ASSR-EEG, PPI AND 5-CSRTT

Ashley Bernardo^{*1}, John Huxter², Lukasz Dlugosz¹, Cam MacMillan¹, Lauren Giggins², Guy Higgins¹

¹Transpharmation Ltd Canada, ²Transpharmation Ltd. UK

Background: A common characteristic of untreated symptoms in Schizophrenia (SZ) is difficulty processing sensory information. Auditory Steady State Response (ASSR) is an

electroencephalography (EEG) based response reflecting ones ability to integrate auditory sensory information by cortical networks. Pre-Pulse Inhibition (PPI) similarly considers cortical processing efficiency by using auditory sensory information and the resulting reflex motor output. 5-Choice Serial Reaction Time Task (5-CSRTT) uses sensory stimuli to elicit a learned response and specifically considers processing related to attention and impulse control. The NMDA antagonist MK-801, modulates the rats response and performance across all assays (ASSR, PPI and 5-CSRTT). Atypical antipsychotics such as risperidone aim to overcome processing impairments by primarily targeting the serotonin (5-HT) system.

Methods: Sprague Dawley rats were used in all studies. ASSR: N=7 (crossover design), PPI: N=12 (parallel design), 5-CSRTT: N=32 (crossover design). In these assays, the dose response of MK-801 (0.01-0.3 mg/kg) was established followed by reversal effects of either risperidone. ASSR: Animals were implanted to DSI telemetry devices and presented with click-train stimuli. PPI: Startle response was quantified as %PPI following trial types including, startle pulse alone, startle pulse plus pre-pulse, pre-pulse alone. 5-CSRTT: Animals were trained to perform a nose poke into an illuminated aperture to receive a food reward. During testing, a 5s intertrial interval was used over 100 trials.

Results: ASSR: In a dose response manner, MK-801 reduced ASSR, significantly enhanced 50-100 Hz high-gamma power and suppressed frequencies below 30Hz. Risperidone was able to partially reverse the MK-801 ASSR deficit (p LESS THAN 0.001) and reversed the increased high-gamma dose dependently (p LESS THAN 0.001). PPI: MK-801 reduced % PPI in a dose dependent manner (p LESS THAN 0.001). 5-CSRTT: MK-801 increased premature (p LESS THAN 0.001) and perseverative responding (p LESS THAN 0.001) relating to increased impulsivity and compulsivity respectively. Risperidone reversed premature responses (p LESS THAN 0.001) and perseverative responding (p LESS THAN 0.001).

Discussion: The sensitivity of different sensory processing assays varies such that ASSR-EEG and 5-CSRTT are highly sensitive and require low doses of MK-801 to produce a change in response and behavioral. PPI however requires higher doses of MK-801 to elicit a change in behavioral output. In conclusion, MK-801 impairs processing of environmental stimuli across multiple assays including ASSR-EEG, PPI and 5-CSRTT. Risperidone improves some aspects of sensory processing across ASSR-EEG, PPI, and 5-CSRTT.

T219. HYPERCLOZAPINEMIA: CLINICAL IMPLICATIONS AND THE RISK OF MISINTERPRETING PSYCHOTIC SYMPTOMS

Sharon Taub¹, Noa Menkes-Caspi², Shiri Kamhi-Nesher¹, Amir Krivoy*²

¹Geha Mental Health Center, ²Geha Mental Health Center, Petach Tikva

Background: The consensus regarding the therapeutic threshold for clozapine blood level is between 350-600 µg/L and blood levels above 1000 µg/L are associated with an increased risk of developing CNS- related side effects. Hyperclozapinemia refers to elevated blood levels of clozapine, which may result from factors like drug interactions, metabolic changes, or overdose. Elevated clozapine levels can potentially lead to various symptoms ranging from mild anticholinergic effects to various psychopathological manifestations, altered consciousness states, and serious complications such as myocarditis, respiratory depression, and seizures. However, it is often the case that high clozapine levels may appear as psychotic exacerbation, which in turn may lead to a wrong clinical decision to increase dose, rather than decrease, thus resulting in full intoxication.

Methods: We examined the clinical presentation and management of four cases of misdiagnosed clozapine intoxication. Clozapine serum level test has been available in Israel since 2017. We were able to link clinical data from hospitals and community from the database of Clalit Health Services (CHS) the largest health maintenance organization in Israel (N=4.8 million members, 53% of Israel's population). We extracted all cases with serum clozapine levels from 2017 to 2023 and focused on individuals with levels of 1000 ng/ml or higher (hyperclozapinemia). We further explored factors that might be associated with hyperclozapinemia such as dosing, blood laboratory and concomitant medications. Finally, we assessed the clinical management following the detection of hyperclozapinemia with regard to dose adjustments, consecutive serum level measurement, and utilization of medical services.

Results: Among the four clinical cases of clozapine intoxication, two were associated with concomitant fluvoxamine treatment, one with concomitant cytotoxic chemotherapy and one had a seizure that was misdiagnosed as idiopathic epilepsy and due to what was misdiagnosed as psychotic exacerbation resulted in clozapine dose gradually increased. Maximum clozapine blood levels of the cases ranged between 2000-3621 ng/ml. management eventually was based on detecting hyperclozapinemia, reducing clozapine dose, adjusting by further blood tests, and stopping fluvoxamine.

Between the years 2017-2023, 1362 patients had been tested for clozapine serum level, among the CHS members. This is a rate of 24.8% (out of 5524 patients purchasing clozapine during this period). Of them 200 (14.6%) had a maximal clozapine level of 1000-1500 ng/ml (42.5% women, mean age 42.4 ± 14 years) and 94 (6.9%) had a maximal level of 1500 ng/ml and above (52.1% women, mean age 44.3 ± 13.2 years), of them 58 (61.7%) were detected on their first test. Two people had levels above 3000, maximum level was 3621. Compared with lower levels, hyperclozapinemia (level above 1000 ng/ml) was associated with higher mean dose (450.8 mg/d 415 mg/d for level of GREATER THAN 1500 and 1000-1500, respectively), being women, lower smoking rate, and older age. There were significant associations between higher clozapine levels and lower red cell indices (hemoglobin, hematocrit and RBC count), decreased eosinophils count, and an increase in neutrophil count. Extreme hyperclozapinemia was associated with a higher proportion of concomitant use of fluvoxamine (12 out of 94, 12.8%, compared to 0.9%-3% in the other groups, $p < 0.0001$). There was no association between hyperclozapinemia and other blood tests (lipids, chemistry, liver functions tests, CRP, prolactin, CPK, HbA1c) as well as diagnoses of diabetes mellitus, ischemic heart disease, epilepsy, EEG testing, using concomitant valproic acid or death rate. In most cases, following maximal clozapine level above 1000 ng/ml, there was dose reduction (by a mean of -15 mg/d) and retesting clozapine blood level (in 90% of cases), however, this still resulted in mean high levels (1332 ng/ml and 954 ng/ml for above 1500 and 1000-1500 groups, respectively). There was no difference in rates of general hospital admissions, however higher rates of emergency department referrals (17% and 13% for above 1500 and 1000-1500 groups, respectively) between groups of clozapine levels.

Discussion: Hyperclozapinemia (levels of 1000-1500 ng/ml) and extreme hyperclozapinemia (GREATER THAN 1500 ng/ml) are not usually associated with a specific clinical syndrome (even not with a higher rate of seizures), and can easily be mistaken for psychotic exacerbation, potentially leading to dangerous dosage increases. However, clozapine intoxication is a severe clinical situation with potential fatal consequences. A heightened suspicion for intoxication is crucial when there is concomitant fluvoxamine treatment or a drop in red blood cell indices and eosinophils in combination with neutrophilia. Management typically involves discontinuation or dose reduction of clozapine based on the severity of

symptoms, and retesting clozapine level to confirm therapeutic level. Monitor vital signs closely. For severe intoxication, admission to an intensive care unit may be necessary.

T220. EFFECT OF GLUTAMATE MODULATOR JNJ-46356479 AND CLOZAPINE ON GLUTAMATE AND GABA BRAIN-LEVELS IN A POSTNATAL KETAMINE MOUSE MODEL OF SCHIZOPHRENIA

Albert Martínez-Pinteño^{*1}, Natalia Rodríguez², David Olivares Berjaga², Santiago Madero³, Llucia Prohens², Constanza Morén⁴, Alex Gonzalez-Segura¹, Irene Martínez-Serrano⁵, Sergi Mas⁶, Eduard Parellada⁷, Patricia Gassó⁸

¹University of Barcelona, ²Department of Basic Clinical Practice, University of Barcelona, ³Department of Psychiatry, Hospital Clinic, Neuroscience Institute, Barcelona, Spain, ⁴Hospital Clinic of Barcelona - IDIBAPS-CIBERER, ⁵University of Barcelona, Hospital Clinic, ⁶Department of Basic Clinical Practice, University of Barcelona, IDIBAPS, CIBERSAM, Spain., ⁷Barcelona Clinic Schizophrenia Unit (BCSU). Neurosciences Institute. Hospital Clinic of Barcelona. University of Barcelona. CIBERSAM, IDIBAPS. Barcelona, Spain, ⁸University of Barcelona-IDIBAPS-CIBERSAM

Background: Alterations in glutamatergic neurotransmission have been postulated to be a key pathophysiologic mechanism of schizophrenia (SZ) [1]. Given the lack of efficacy of antipsychotics in treating negative and cognitive symptoms, glutamate (GLU) inhibitors could represent a promising pharmacological strategy to ameliorate these symptoms. Positive allosteric modulators (PAM) of the mGlu receptor 2, such as JNJ-46356479 (JNJ), inhibit the presynaptic release of GLU. We have previously reported that JNJ treatment during a critical period of neurodevelopment mitigates neuropathological impairments in a postnatal ketamine (KET) mouse model [2]. Dealing with GLU storm during the early stages of SZ may be particularly effective in preventing the onset of the disease or slowing its progression and the clinical deterioration of patients.

Aim: To evaluate the efficacy of an early JNJ treatment in reversing neuropathological deficits induced in a postnatal KET mouse model of schizophrenia. We investigated the immunofluorescence-based quantification of vesicles labeled with GLU transporter (VGLUT) and GABA transporter (GAD65/67) as markers of glutamatergic and GABAergic neurotransmission, respectively.

Methods: A total of 36 C57BL/6J pups were exposed to KET (30mg/kg) on postnatal days (PND) 7, 9, and 11 to disrupt NMDAR function. Subsequently, mice were treated daily with subcutaneous injections with 10mg/kg of JNJ-46356479 (JNJ) or clozapine (CLZ), as a clinical antipsychotic of reference, during the adolescent period (PND 35-60). On PND 120, mice were perfused with phosphate buffer saline 1X followed by 4% paraformaldehyde. Coronal sections of the prefrontal cortex (PFC) and hippocampus (HPC) were prepared for immunofluorescent double labeling with antibodies for Vglut1 and GAD65-67. Confocal images were automatically analyzed using ImageJ software to quantify the number of GLU and GABA vesicles.

Results: Due to sex differences in immunofluorescence-based quantification of GLU and GABA vesicular transporters, we conducted a multivariate analysis of variance. The analysis revealed significant differences in the number of GLU vesicles among the HPC subregions across treatment groups (CA1 (F (11,30) = 5,39, p LESS THAN 0.001), CA2 (F (11,30) = 2,23, p = 0.049 and CA3 (F (11,30) = 5,39, p LESS THAN 0.001)). Post-hoc test indicated a

significant increase in the number of GLU vesicles between the KET group and vehicle (VEH) group, particularly in the CA3 region ($p = 0.012$). Although the difference between the groups in GLU levels in CA1 did not reach statistical significance ($p = 0.056$), a notable trend was observed. The administration of JNJ treatment in the KET mice model significantly reduced the levels of GLU in both CA1 and CA3 regions ($p = 0.004$ and $p = 0.001$, respectively), whereas no effect was observed with CLZ treatment. While we observed differences in GABA levels in the CA3 region, these differences did not reach statistical significance according to the post-hoc test. No significant differences were found in GLU and GABA vesicular levels in the dentate gyrus and PFC regions.

Discussion: These findings indicate the effectiveness of JNJ treatment in attenuating GLU dysregulation in both CA1 and CA3, suggesting its potential as a therapeutic approach for mitigating GLU-related pathology in SZ. Comparatively, JNJ appears to exert a more pronounced effect than clozapine.

T221. PREVENTION, DETECTION, AND MANAGEMENT OF CLOZAPINE-INDUCED MYOCARDITIS

Mishal Qubad*¹, Gabriele Dupont², Martina Hahn², Simon S Martin³, Valentina Puntmann⁴, Eike Nagel⁴, Andreas Reif², Robert A Bittner²

¹Goethe University Frankfurt, University Hospital, ²Goethe University Frankfurt, University Hospital, Department of Psychiatry, Psychosomatic Medicine and Psychotherapy, Germany,

³Goethe University Frankfurt, University Hospital, Department of Radiology, Germany,

⁴Goethe University Frankfurt, University Hospital, Department of Cardiology, Institute for Experimental and Translational Cardiovascular Imaging, Germany

Background: Approximately one-third of patients diagnosed with schizophrenia develop treatment resistance (treatment-resistant schizophrenia, TRS). Currently, clozapine remains the most effective and only approved drug for TRS. Clozapine-induced myocarditis (CIM) ranks among the most important side-effects necessitating immediate clozapine termination. This often results in its permanent discontinuation. Overall, the scarcity of sufficient alternative treatment approaches warrants concerted efforts to minimize permanent discontinuation.

Methods: In this narrative review, we provide a critical literature review of relevant aspects of CIM including pathophysiology, risk factors, prevention, timely detection, and management strategies as well as post-CIM re-challenge approaches. We based our research on a MEDLINE and Google Scholar search for all publications addressing CIM and post-CIM re-challenges. We included both relevant clinical studies as well as meta-analyses and reviews. We selected all articles that were published until November 2023. We searched for articles addressing the following MeSH terms: treatment-resistant schizophrenia, schizoaffective disorder [AND] treatment resistance, bipolar disorder [AND] treatment resistance, clozapine [AND] xx, with xx reflecting the topic we aimed to focus at, at that time point (e.g., myocarditis, re-challenge [AND] myocarditis, pharmacokinetics).

Results: Slowing clozapine titration rates and early routine use of therapeutic drug monitoring (TDM) can reduce the risk of dangerously fast increases in plasma clozapine levels which constitutes an established risk factor for CIM. Prescribers should also consider the pharmacokinetic effects of concomitant medication including valproate, olanzapine, and altered clozapine metabolism related to changes in CYP1A2 enzyme activity due to inflammation. Additionally, stringent CIM screening and management ensure timely

detection of CIM thus increasing patient safety and the chance for a restitutio ad integrum. In this context, a central issue arises from the widely different clinical practices regarding clozapine use in different psychiatric healthcare systems. Such differences comprise diverging titration rates and monitoring regimes respectively. These issues are illustrated with a special focus on the relevance of C-reactive protein, troponin, N-terminal-pro-hormone-and-brain-natriuretic-peptide, TDM, and cardiac magnetic resonance imaging. Moreover, recent findings indicate that the efficacy of clozapine re-initiation is superior compared to alternative approaches including treatment with olanzapine, long-acting injectable antipsychotics, and electroconvulsive therapy. Therefore, post-CIM clozapine re-challenges gain increasing attention. Success rates have been estimated at 60 %. Such a re-challenge requires considerable slow titration regimes and intensified monitoring.

Discussion: Permanent clozapine discontinuation can be associated with a detrimental course of illness. In this narrative review, we illustrate systematic CIM prevention strategies considering CIM pathophysiology and established risk factors. We highlight how the use of stringent screening methods allowing a timely CIM detection can facilitate a successful clozapine re-challenge. Moreover, while we focus on schizophrenia, we also discuss the relevance of CIM for treatment resistance in related disorders such as schizoaffective and bipolar disorder. Notably, these strategies should also reduce clozapine underutilization.

T222. METABOTROPIC GLUTAMATE RECEPTORS IMMUNODENSITIES IN SCHIZOPHRENIA SUBJECTS BRAIN AND IN A TWO-HIT MOUSE MODEL OF SCHIZOPHRENIA

Jon Ander Santos^{*1}, Oihane Martínez-Peula², Jon DelaCuesta-Barrutia², Amaia M Erdozain³, Benito Morentin⁴, Javier González-Maeso⁵, Luis Felipe Callado⁶, J Javier Meana⁶, Alfredo Ramos-Miguel⁶, Guadalupe Rivero⁶

¹University of the Basque Country (UPV/EHU), ²Department of Pharmacology, University of the Basque Country (UPV/EHU), Spain, ³Department of Pharmacology, University of the Basque Country (UPV/EHU) and Centro de Investigación Biomédica en Red de Salud Mental (CIBERSAM), Spain, ⁴Basque Institute of Legal Medicine and Biobizkaia Health Research Institute, Spain, ⁵Department of Physiology and Biophysics, Virginia Commonwealth University School of Medicine, United States, ⁶Department of Pharmacology, University of the Basque Country (UPV/EHU), Centro de Investigación Biomédica en Red de Salud Mental (CIBERSAM) and Biobizkaia Health Research Institute, Spain

Background: Postmortem brain studies showed reduced densities of class II metabotropic glutamate receptors (mGluR2/3) in the dorsolateral prefrontal cortex (DLPFC) of schizophrenia (SZ) subjects. These alterations were exacerbated (mGluR2) or reversed (mGluR3) by antipsychotic (AP) medication. mGluRs have been tested as targets for novel AP drugs, and some mGluR polymorphisms have been associated with genetic susceptibility to SZ. Thus, this work aimed to study the regulation of class I mGluR1 and 5 and class III mGluR4 and 7 in postmortem DLPFC of subjects with SZ, and class I, II and III mGluRs in a two-hit mouse model of SZ combining poly(I:C)-induced maternal immune activation (MIA) and Grm2 genetic deficiency.

Methods: Human cohort was comprised of 21 pairs of SZ and control subjects, matched by age, sex and postmortem delay. DLPFC specimens were obtained at autopsies in the Basque Institute of Legal Medicine. Standard plasma toxicological assays were used to separate SZ cases who were (AP-positive; n=10) or were not (AP-free; n=11) taking APs by the time of

death. The two-hit murine model was generated by administration of poly(I:C) (5 mg/kg, i.p.) or saline to pregnant dams at gestational day 9.5. The offspring (n=48) were divided in 12 groups according to sex, MIA exposure and Grm2 genotype, and were sacrificed at postnatal day 84. Western blot (WB) analysis with selective antibodies evaluated the cortical expression of mGluR1, 4, 5 and 7 in human samples, and mGluR1, 3, 4, 5 and 7 in samples of mouse origin. Data were analyzed by paired t-test (human study) and or three-way ANOVA (mouse study).

Results: WB experiments in human and murine brain extractions detected specific monomeric immunoreactive bands for mGluR1 (~150 kDa), mGluR3 (~100 kDa), mGluR4 (~100 kDa), mGluR5 (~150 kDa) and mGluR7 (~90 and ~100 kDa). mGluR4 ~100 kDa expression was significantly lower in SZ subjects (-27.8%, p LESS THAN 0.05), but this effect could not be specifically attributed to AP-free or AP-positive SZ subjects. mGluR7 ~90 kDa expression was significantly lower in total SZ (-63.9%, p LESS THAN 0.001) and AP-positive subjects (-70.5%, p LESS THAN 0.001), compared to control subjects. Similar downregulation was observed for mGluR7 ~100 kDa immunodensity in SZ samples (-31.3%, p LESS THAN 0.05), which could also be attributed to AP-positive cases (-43.3%, p LESS THAN 0.05). No alteration in mGluR1 or 5 ~150 kDa expression was found in SZ subjects compared to controls. Mice study showed that Grm2 deficiency was not associated with compensatory effects on other mGluRs. Indeed, mice that were partially and totally deficient in Grm2 displayed lower cortical amounts of mGluR7 ~90 kDa (-18%, p LESS THAN 0.05). MIA exposure had a sex-dependent effect on ~150 kDa mGluR5 expression (p LESS THAN 0.05), so that its brain immunodensities increased in females, while decreased in males.

Discussion: Similar to class II (mGluR2 and 3), class III (mGluR4 and 7) but not class I (mGluR1 and 5) mGluRs were reduced in cortical samples from subjects with SZ. The two-hit model did not completely reproduce the alterations in class II and III mGluR densities observed in DLPFC samples of SZ subjects, but altered mGluR5 sex-dependently. In addition, lower cortical levels of mGluR2 were associated with mGluR7 downregulation in both humans and mice. The present results suggest that SZ-associated cortical downregulation of class II and III mGluR densities may be specific to human pathology or AP treatment.

This work was supported by grants PID2022-137848OB-I00 (MCIU/AEI/FEDER) and IT1512/22 (Basque Government). Santas, J.A. is a recipient of a predoctoral fellowship from the Basque Government.

T223. ARGENTINE CONSENSUS-STATEMENT ON MANAGEMENT TREATMENT-RESISTANT SCHIZOPHRENIA: UP-TO-DATE

Background: Approximately 30 % of people with schizophrenia fail to respond to antipsychotic treatment which impacts the burden of the disease. Treatment-Resistant Schizophrenia (TRS) denotes patients with failure to respond to at least two adequate trials of different antipsychotics. Clozapine is a unique drug approved for treating treatment schizophrenia resistant, however 1/3 of patients fail to respond to clozapine. Even though different strategies have been proposed for treating clozapine-resistant treatment, the evidence is very limited, unclear, and of poor quality. The expert consensus statement in diagnostic and treatment of TRS is the result of experts from the main national scientific societies under the organization of the Argentine Association of Biological Psychiatry.

Methods: A formal literature search was conducted and then, panel members were asked to complete 35 questions addressing different aspects of TRS. The modified Delphi method was used to unify expert opinions and obtain a consensus [4]. The panel achieved consensus statements after two rounds of discussion. The scope of the consensus statement included: definition, diagnosis, pseudo-resistance, comorbidities, risk factors., neurobiology aspects, measurement instrument, cognitive function, psychosocial intervention and management of TRS.

Results: Ten statements on TRS reach a consensus, that focused on the following high-yield. TRS was defined as, no response to at least two antipsychotics, one of second-generation antipsychotics (SGA), either at doses equivalent to 600 mg chlorpromazine or full doses of second-generation antipsychotics, for at least six weeks each. SGA with a long-acting formulation must be considered when nonadherence occurs. Pseudo-resistance, comorbidities such as substance abuse, and no-adherence to pharmacological treatment should be assessed before considering TRS. Measurement instruments (e.g. PANNS, CGI-S) should be used for monitoring the treatment response, symptoms severity, and illness progress. Psychosocial intervention, psychoeducational and CBT augmentation approaches are recommended. Although distinctive underlying neurobiological mechanisms of TRS have been proposed, more studies are needed to address this issue. Male gender and the early onset are most prominent risk factor in TRS. TRS patients show greater cognitive impairments compared to no treatment-resistant schizophrenia patients and this may be associated with poor outcomes. Clozapine is primely recommended for treatments TRS. The evidence for augmentation strategies is limited. Despite the reported benefits being modest, some augmentation strategies have been mentioned in this paper for clozapine-resistant schizophrenia. Further augmentation strategies studies are needed to improve treatments and outcomes for those patients. Electroconvulsive therapy may be a possible treatment as an augmentation strategy for patients with clozapine-resistant schizophrenia.

Discussion: This is the first TRS consensus in Argentina. In this consensus report, we provide a comprehensive literature review as well as a lengthy debate on TRS. As a result of this work, we developed recommendations. The recommendations are based on evidence and expertise and, are aligned with international consensus. This report will be of interest to anyone involved in the management of patients with TRS.

T224. SYNDROME METABOLIC INDUCED BY ANTIPSYCHOTICS AND HEMATOLOGICAL ABNORMALITIES

Alejo Corrales*¹, Pedro Damian Gargoloff², Tomas Maresca³, Federico Rebok⁴

¹Argentine National University UNT, ²Hospital "Dr. Alejandro Korn", Servicio de Subagudos Hombres., La Plata, Argentina, ³Institute of Biological Psychiatric. IPBI, Pharmacology, Buenos Aires, Argentina., ⁴Hospital "Dr. Braulio A. Moyano", Servicio de Emergencia, Buenos Aires, Argentina.

Background: increased in cardiovascular diseases risk. The component of the syndrome include, hypertension, central obesity, dyslipidemias (high triglycerides and low high density lipoprotein cholesterol HDLc) and impaired glucose tolerance. MS is well known to be highly prevalent among individuals affected by psychosis. Part of this increased risk is attributable to the use of antipsychotic medications, especially second-generation antipsychotics. Independent studies suggest that about 50% of patients treated with APs develop metabolic complications. Metabolic Syndrome is also well recognized as being associated with an increased cardiovascular risk resulting mortality. The link between antipsychotics and venous thromboembolisms is known. It is estimated that the risk of venous thromboembolism is twice that of the general population. Atypical antipsychotics have different effects than typical antipsychotic. But the biological mechanism are still unknown. To date there are few evidence of hematological changes (platelets and cross fibrin mesh) in metabolic syndrome caused by psychotropic agents.

Objective: To determinate whether metabolic syndrome caused by antipsychotic drugs produce changes in hematological system (in particular platelets and cross fibrin mesh) and increase risk of thromboembolism and explore at the relationship between hematological changes and cardiometabolic side effect.

Methods: We elaborate a Rabbit model of syndrome metabolic induced by antipsychotics. We feed a rabbits with normal diet and rabbits with high fat diet (cholesterol 1%) plus olanzapine 0,25 mg/kg/day during 5 week. Blood samples were collected from the two rabbits groups. The blood was centrifugate for 20 minutes then platelet rich plasma (PRP) was collected. We compare the ultrastructure of rabbits platelet (morphology) and cross-linking fibrin mesh, by scanning electron microscopy (SEM), between two groups. Haemostatic profile (activated partial thromboplastin time, Thrombin Time, platelets count) was analyzed as well.

Results: We found morphologic differences between two groups. The platelets of rabbits with metabolic syndrome show many pseudopods (that means platelets activations) We found disorganized and less strained cross-linking fibrin mesh among rabbits with cardio metabolic syndrome (CMS). The fibrin fiber diameter was increased in MCH compared to controls CD (P LESS THAN 0.05). Haemostatic profile differences between the two groups were not observed (P GREATER THAN 0.05)

Discussion: Ours findings demonstrated premature platelet activation (as a result of the chronic inflammation) and this trigger morphological alteration of cross-linking fibrin mesh. This condition would predispose to protrombotic state. The future investigation must put particularly focus on 1- the association between metabolic syndrome induce by antipsychotics and protrombotic state 2- whether this condition could, in part, mediate cognitive deficit in schizophrenia. Even though more studies are needed to validate this

finding, psychiatrists should be aware of the potentials platelets activations and morphological alteration of cross-linking fibrin mesh caused by of antipsychotics.

T225. CBD ALTERS SENSITIVITY TO THC IN PEOPLE WITH PSYCHOSIS AND COMORBID CANNABIS USE DISORDER

Edward Chesney^{*1}, Dominic Oliver², Ananya Sarma¹, Doga Lamper¹, Ikram Slimani¹, Millie Lloyd¹, Irma Gasparini-Andre¹, Michael Welds³, Natavan Babayeva³, Will Lawn¹, Matilda Kråkström⁴, Alex Dickens⁴, Matej Orešič⁴, Tom P Freeman⁵, Amir Englund¹, John Strang¹, Philip McGuire²

¹*Institute of Psychiatry, Psychology and Neuroscience, King's College London*, ²*University of Oxford*, ³*South London and Maudsley NHS Foundation Trust*, ⁴*University of Turku*, ⁵*University of Bath*

Background: Cannabidiol (CBD) is a candidate novel treatment for both psychotic disorders and cannabis use disorder. Experimental studies in healthy volunteers suggest that pre-treatment with CBD can reduce the acute adverse effects of delta-9-tetrahydrocannabinol (THC). We investigated whether oral CBD can reduce the effects THC in people with psychosis and a comorbid cannabis use disorder.

Methods: We recruited people with schizophrenia or schizoaffective disorder (mean age 40 years) who also had a cannabis use disorder (n=30). All participants were regular and heavy cannabis users (mean use = 5 days/week; 1.1 g/day). Participants were studied on two occasions, in a double-blind, randomised, placebo-controlled, within-subjects crossover trial. In one session, participants received cannabidiol (1000 mg, oral) 3 hours before administration of 20 mg THC via a vaporiser. In the other session, pre-treatment was with a placebo. Primary outcomes were change in Positive and Negative Syndrome Scale-Positive subscale (PANSS-P), and delayed verbal recall on the Hopkins Verbal Learning Task-Revised. Blood samples were collected for measurement of plasma THC, CBD and their metabolites at six timepoints. The statistical analysis plan was pre-registered. Linear mixed models were used to assess the effect of CBD on continuous outcomes, including arm and visit order as fixed effects and participant as a random effect. McNemar's test was used to compare categorical outcomes.

Results: Following pre-treatment with CBD, the mean change in PANSS-P after administration of THC was +5.0, compared to +2.9 following placebo (mean difference [MD] = 2.1 [95% CI: 0.60 to 3.7]; p = 0.011). A PANSS-P increase of ≥ 9 was evident in seven experiments following CBD, but not in any following placebo (p = 0.0000045). PANSS scores on conceptual disorganisation (MD = 0.65 [95% CI: 0.17 to 1.1]; p = 0.012) and suspiciousness/persecution (MD = 0.55 [95% CI: 0.15 to 0.95]; p = 0.012) were higher following CBD than after placebo. Delayed verbal recall following CBD pre-treatment was 3.5 words, compared to 4.8 words following placebo (MD = -1.3 [95% CI: 0.61 to 2.0]; p = 0.0011). Pharmacokinetic analyses indicated that CBD pre-treatment had no effect on plasma THC levels (Cmax: +6.6 ng/ml; p=0.43; AUC0-90 = +481 ng*min/ml, p=0.22).

Discussion: In people with psychosis and a cannabis use disorder, pre-treatment with CBD increased sensitivity to the effects of THC on psychotic symptoms and cognition. This effect was not attributable to a pharmacokinetic interaction between CBD and THC. Cannabis use disorder is associated with alterations in brain CB1 receptor density, which might account for

the results. Further studies are needed to clarify whether this effect of CBD is evident in people with psychosis that are occasional cannabis users.

T226. BEHAVIORAL EFFECTS OF SUB-CHRONIC KETAMINE ADMINISTRATION IN ADULT ZEBRAFISH

Matheus Gallas Lopes*¹, Daniela V. Müller¹, Thailana Stahlhofer-Buss¹, Leonardo M. Bastos¹, Sofia Z. Becker¹, Samara M. Bruck¹, Angelo Piato¹, Ana P. Herrmann¹

¹*Universidade Federal do Rio Grande do Sul*

Background: Ketamine (KET), a glutamatergic NMDA-receptor antagonist, is used to recapitulate schizophrenia-related behavioral phenotypes in model animals. Despite the focus on the use of rodents in this field, the zebrafish (*Danio rerio*) is a model organism that, given its potential to mitigate species-specific biases arising from employing specific strains or species, is on the rise in the neurosciences, showing a highly conserved genetic and physiological background when compared to humans. However, behavioral assays relevant to the neurobiology and the symptoms of schizophrenia are not well-established and validated in this species. The aim of this study was to evaluate the effects of sub-chronic exposure to KET on the behavior of adult zebrafish in the Social Preference Test (SPT) and the Open Tank Test (OTT).

Methods: We used 128 4-month-old wild-type zebrafish, with an equal distribution of males and females (ethics committee 35525/2019). Following block randomization procedures, animals were allocated to one of four experimental groups: control, KET 10 mg/L, KET 20 mg/L, or KET 40 mg/L (n = 32). Zebrafish were exposed to water or KET for 20 min in groups of 4 for 5 consecutive days; after a washout period on day 6, animals were re-exposed on day 7 to the same treatment. Behavioral tests were performed on experimental days 1, 5, and 7 immediately after the treatments. Animals were sequentially subjected to the SPT and OTT individually. Social preference (as measured by the time spent near a stimulus shoal) and locomotor parameters were automatically scored using ANY-Maze software. Experiments were run in two batches and the pooled data were analyzed by two-way ANOVA with the experimental group and the experimental day as factors. This project was preregistered in the Open Science Framework (<https://osf.io/r7xdy>).

Results: In the SPT, subchronic exposure to KET reduced the time fish spent in the interaction zone ($F(3,362) = 54.94$, p LESS THAN 0.0001) and increased the total distance traveled ($F(3,362) = 97.54$, p LESS THAN 0.0001), maximum speed ($F(3,362) = 30.55$, p LESS THAN 0.0001), and line crossings ($F(3,362) = 123.0$, p LESS THAN 0.0001). Total distance traveled by animals decreased over the experimental days in the SPT ($F(2,362) = 3.36$, $p=0.0357$). In the OTT, KET treatment also increased the total distance traveled ($F(3,362) = 50.14$, p LESS THAN 0.0001), maximum speed ($F(3,362) = 15.48$, p LESS THAN 0.0001), and rotations ($F(3,362) = 11.40$, p LESS THAN 0.0001). A significant effect of the experimental day was observed for the distance traveled ($F(2,362) = 19.24$, p LESS THAN 0.0001), maximum speed ($F(2,362) = 7.90$, $p=0.0004$), and rotations ($F(2,362) = 9.85$, p LESS THAN 0.0001) in the OTT, indicating a reduction of these behaviors over time. No interactions between group and experimental day were observed.

Discussion: In general, KET treatment induced behavioral alterations that recapitulate schizophrenia-related phenotypes in every experimental day. Our findings also show a higher effect size and reproducibility of KET in recapitulating such phenotypes in zebrafish when compared to our own experience with MK-801. Unlike experiments conducted with rodents, there was no sensitization or tolerance in the response to KET exposure throughout the days.

Our data also corroborate previous observations of context-dependency regarding the hyperlocomotor effects of NMDA antagonists, as the presence of a social stimulus led to hyperlocomotion in all KET concentrations in the SPT, while only the highest KET concentration induced hyperlocomotion in the OTT. Further studies are still needed to assess the long-lasting effects of KET treatment in zebrafish.

T227. SWITCHING PATIENTS WITH SCHIZOPHRENIA TO TV-46000, A LONG-ACTING SUBCUTANEOUS ANTIPSYCHOTIC (LASCA), FROM RISPERIDONE MICROSPHERES (R064766): AN EXPLORATION OF POPULATION PHARMACOKINETIC (POPPK)–BASED STRATEGIES

Itay Perlstein¹, Jonathan Meyer², Ziqi Yue³, Joel Owen³, Vijay Ivaturi³, Kelli R. Franzenburg⁴, Mark Suett⁵, Rolf Hansen⁶, Avia Merenlender Wagner⁷, Rajendra Singh⁸, Rolf Hansen III^{*9}

¹*Magic Wand Research LLC, Philadelphia, PA United States*, ²*Department of Psychiatry, University of California, San Diego, CA, United States*, ³*Pumas-AI Inc., Annapolis, MD, United States*, ⁴*Teva Branded Pharmaceutical Products R and D, Inc., West Chester, PA, United States*, ⁵*Teva UK Limited, Harlow, United Kingdom*, ⁶*Teva Branded Pharmaceutical Products R and D, Inc., Parsippany, NJ, United States*, ⁷*Teva Pharmaceutical Industries Ltd., Netanya, Israel*, ⁸*Teva Branded Pharmaceutical Products R and D, Inc., West Chester, PA, United States*, ⁹*Teva Pharmaceutical Industries, Ltd.*

Background: Differences in pharmacologic properties between various long-acting injectable antipsychotics (LAIs), combined with a lack of clinical studies on switching between them, represents a large data gap in psychiatry. Data on such switches are necessary to help inform clinicians who transition patients between LAI products. The objective of this analysis was to use PopPK modeling to characterize dosing conversions and switching strategies from R064766 (an intramuscular [im] LAI formulation of risperidone microspheres administered once every 2 weeks [q2w]; Risperdal Consta®) to TV-46000 (a LASCA formulation of risperidone administered once monthly [q1m] or once every 2 months [q2m]).

Methods: Total active moiety (TAM; risperidone + 9-OH risperidone) concentration-time profiles were simulated based on published PopPK models for R064766 (Gefvert O, et al. *Int J Neuropsychopharmacol.* 2005; 8:27–36) and TV-46000 (Perlstein I, et al. *Schizophrenia International Research Society*; May 11–15, 2023; Toronto, Ontario) with virtual populations of 5000 patients. Simulations were performed to predict PK exposures for TAM when switching to TV-46000 q1m and q2m 2–6 weeks after the last injection of R064766 at steady state.

Results: R064766 displayed a delayed-release profile that started around 3 weeks post injection, hence the need for 21 days of oral supplementation during initiation. TAM concentrations were then maintained at therapeutic levels for 4–6 weeks, after which (at week 7) they began to diminish. TV-46000 has a rapid initial release that results in therapeutic plasma levels within 6–24 hours of the first injection and eliminates the need for loading dose(s) and/or oral supplementation during initiation. This is followed by a slower secondary release that results in maximal plasma concentration (C_{max}) at 8–14 days, and then maintains therapeutic concentrations over 1–2 months, depending on dosing. Based on comparisons between a variety of simulated PK exposures, TV-46000 50 mg q1m/100 mg q2m (2 mg/day [d] oral risperidone equivalent), 75 mg q1m/150 mg q2m (3 mg/d oral risperidone equivalent), and 100 mg q1m/200 mg q2m (4 mg/d oral risperidone equivalent) correspond

most closely with R064766 25 mg, 37.5 mg, and 50 mg q2w, respectively. Once comparable doses were identified, suitable washout durations, defined by similar TAM plasma exposures during and after the switch, were determined. Initiating TV-46000 4–6 weeks after the last dose of R064766 resulted in similar trends for C_{max} and C_{min} ratios for all TV-46000 doses, durations (q1m, q2m), and sites of administration (abdomen, upper arm), compared with R064766 at steady state (albeit at different magnitudes depending on dose and washout duration). A 4-week gap resulted in a higher C_{max}, but a similar C_{min}, for TV-46000 versus R064766 at steady state. A 6-week gap provided a C_{max} that was similar to R064766 at steady state, but a lower C_{min}. A 5-week gap provided the most comparable C_{max} and C_{min} values overall. For all washout durations, C_{max} and C_{min} ratios began to approach 1.0 with subsequent injections.

Discussion: These PopPK simulations revealed switching to TV-46000 at 4–6 weeks after the last dose of R064766 provided generally comparable PK exposures by the second dose of TV-46000. Among the simulated scenarios, initiating TV-46000 at 5 weeks after the last dose of R064766 provided PK exposures that were closest to that achieved with R064766 at steady state. Clinician discretion will determine which switching strategy is best in context based on a variety of factors such as patient preference, scheduling convenience, and concerns about tolerability or symptom breakthrough.

T228. VISUAL PERCEPTUAL DISTURBANCES IN PSYCHOSIS IN REAL, AUGMENTED, AND VIRTUAL ENVIRONMENTS: A SYSTEMATIC REVIEW AND EXPERIMENTAL DATA

Léon Franzen^{*1}, Chaya Chromik¹, Fabian Müller², Marco Heide¹, Will Palmer³, Kristina Hedelt¹, Frederike Schröpfer¹, Sofia Eickhoff¹, Ben Alderson-Day⁴, Malte Wöstmann⁵, Stefan Borgwardt¹

¹University Hospital Schleswig-Holstein/University of Lübeck, ²University of Basel, ³Yale University, ⁴Durham University, ⁵University of Lübeck

Background: While much is known about the frequency and phenomenology of auditory hallucinations in psychotic disorders, distortions and hallucinations in the visual modality remain elusive. Investigation of these perceptual disturbances bears much potential for early detection and individualized interventions since 60% of people on the psychosis spectrum experience visual distortions. These are associated with conversion to full-blown psychosis. This substantial proportion demonstrates that visual disturbances occur frequently, but their role has been underestimated. Further, tracking visual perception in psychosis is important as free-viewing eye-tracking studies demonstrate limited visual exploration, scaling with risk and clinical status. These studies build the basis for tracking gaze behavior in virtual and augmented reality (VR and AR). We tap into these technologies' unique potential to present controlled, immersive, and ecologically valid simulations of visual disturbances. Combining both lines of research will allow insights into the nature of visual disturbances and open avenues for potential individualized interventions.

Methods: First, we conducted a systematic review on evidence for use cases of immersive technologies in the early detection and intervention of psychosis, with a specific focus on visual disturbances. This review screened 1130 studies and paves the way for the following empirical investigations. Second, we are empirically studying the relation between visual disturbances and psychosis using visual search and perceptual decision-making paradigms in real-world and VR environments. We will collect behavioral, eye-tracking, and cognitive data on altered perceptual processing that can originate from changes in perceptual sensitivity or

decision bias. Our approach gains strength by testing the same participants from across the psychosis continuum (i.e., general population, patients at risk, and with manifested psychosis) within each environment. We aim to collect data from 50 participants. We will use machine learning to identify patterns in these multimodal data and attempt to stratify participants accordingly – with results being compared to official clinical information.

Results: The systematic review identified 20 relevant studies across immersive technologies. Synthesis shows that these technologies offer significant advantages for understanding, assessing, and treating psychotic disorders, including VR simulations of psychotic perceptual experiences. VR is safe and well-tolerated by patients with psychosis. However, only few studies have used immersive technology to screen for visual disturbances. This may be partly explained by patients' difficulty with describing those experiences. More challenges include patients' worse spatial recognition performance in VR and accurately simulating visual disturbances that mirror psychotic experiences. Data collection is on-going. Our hypotheses include increasingly restricted free-viewing eye movement patterns with increasing schizotypy and clinical severity, consistent across real-world and VR environments.

Discussion: Paradigms screening for visual disturbances in truly immersive environments are in their infancy and interventions remain scarce. Our new, well-controlled VR environments, also allow for acquiring rich information on attention and cognition from eye movements within the same group of patients, which has rarely been considered together thus far. This approach could uncover mechanistic links associated with individual phenomenology and may lay the foundation for developing individualized interventions of positive visual symptoms of psychosis.

T229. INVESTIGATING THE EFFECTS OF ADJUNCTIVE TRANSCRANIAL DIRECT CURRENT STIMULATION ON TREATMENT ADHERENCE IN SCHIZOPHRENIA: STUDY PROGRESS

Jianmeng Song^{*1}, Julia Kim¹, Yasaman Kambari¹, Aron Amaev¹, Edgardo Torres Carmona², Ali Abdolizadeh³, Teruki Koizumi¹, Vincenzo De Luca¹, Daniel Blumberger¹, Gary Remington¹, Bruce Pollock¹, Ariel Graff-Guerrero¹, Philip Gerretsen¹

¹*Centre for Addiction and Mental Health, University of Toronto*, ²*Centre for Addiction and Mental Health and University of Toronto*, ³*Centre for Addiction and Mental Health (CAMH), Toronto, Ontario; Institute of Medical Science, University of Toronto, Toronto, Ontario*

Background: Medication adherence is critically important to the treatment of schizophrenia. Nonadherence occurs in up to 60% of patients with schizophrenia with more than 80% of nonadherent patients discontinuing their medication by 6 months. Nonadherence is not only associated with worse symptom severity, but also increased rates of relapse and hospitalization. Impaired insight into psychosis is one of the principal drivers of antipsychotic drug nonadherence. This study seeks to explore for the first time the effects transcranial direct current stimulation (tDCS) as an adjunctive treatment to improve antipsychotic medication adherence in patients with schizophrenia. The intervention will target brain regions implicated in insight into psychosis.

Methods: Participants with schizophrenia with stable medication treatment were randomized to receive either bilateral PPA active or sham 2mA tDCS for 20 sessions. Antipsychotic medication adherence will be assessed post-tDCS as follows: (1) pill count by pharmacy weekly; (2) plasma concentrations every 4 weeks; and (3) the clinician rated measure of adherence every 4 weeks during the 12-week follow-up period.

Results: 17 participants (9 active and 8 sham, 9 (53%) treated with clozapine) have completed the study intervention, with 1 dropped out during follow-up. The mean age is 43.5 (SD = 14.6). The male to female ratio is 15:2. The baseline mean illness severity PANSS score is 64.6 (SD = 13.7).

Discussion: The study is actively recruiting. Positive results will demonstrate that adjunctive tDCS has the potential to alter patients' attitudes toward their illness and treatment, in turn, improving antipsychotic medication adherence and clinical outcomes.

T230. BASELINE FUNCTIONAL CONNECTIVITY PREDICTS THE IMPACTS OF YOGA AND AEROBIC EXERCISE ON MEMORY AND ATTENTION IN EARLY PSYCHOSIS

Peilun Song¹, Xiujuan Geng², Sherry KW Chan³, Wing Chung Chang³, Edwin HM Lee³, Eric YH Chen⁴, Yaping Wang¹, Jessie JX LIN*⁴

¹Zhengzhou University, ²Chinese University of Hong Kong, ³The University of Hong Kong,

⁴The Hong Kong Polytechnic University

Background: Impairments of attention and memory are evident in early psychosis, and are associated with functional disability. Exercise intervention including yoga and aerobic exercise have been shown to improve cognitive functioning in psychosis. Yet, the underlying neural basis related to the impacts of these exercise interventions, particularly whether the functional connectivity at baseline predicts the cognitive outcomes after exercise interventions remains unknown.

Methods: A total of 140 female patients with early psychosis were recruited and 124 received the allocated intervention in a randomized controlled study of 12 weeks of yoga or aerobic exercise compared with a waitlist group. The primary outcomes were cognitive functions including memory and attention. Secondary outcome measures were the severity of psychotic and depressive symptoms, and structural and functional magnetic resonance imaging (MRI). This is a secondary analysis of the resting-state functional connectivity in 71 patients with completed MRI scans (27 in yoga, 24 in aerobic exercise, and 20 in the waitlist group). After the preprocessing, the Power-264 atlas was used to obtain mean time courses of 264 regions of interest (ROIs). The ROI-wise functional connectivity was obtained by computing the Pearson correlation coefficients between each pair of time courses of the ROIs. Thus, the functional connectivity within and between neural networks was measured to investigate the correlations between the network metrics at baseline and the pre-post changes of memory and attention in three groups. Age, duration of illness, and medication dosage were controlled as covariates.

Results: The correlation between one-versus-all-others functional connectivity of the Ventral Attention Network (VAN) at baseline and the changes of short-term memory, and the correlation between one-versus-all-others functional connectivity of the Memory Retrieval Network (MRN) at baseline and the changes of verbal memory were significantly different among the three groups.

Further post-hoc analyses showed that in yoga group, one-versus-all-others functional connectivity of MRN at baseline was negatively associated with the changes of verbal memory, within-network connectivity of the Fronto-Parietal Network (FPN) and pairwise network connectivity between the Default Mode Network (DMN) and the Dorsal Attention Network (DAN) were positively associated with the changes of psychomotor coordination and attention, respectively. In aerobic exercise group, only one-versus-all-others functional

connectivity of VAN at baseline was found to be negatively associated with the changes of short-term memory.

Discussion: Our findings suggested that VAN and MRN were significantly related to the effectiveness of exercise intervention on memory. Compared with aerobic exercise, yoga had impacts on more brain networks including FRN, DMN and DAN, which were significantly associated with psychomotor coordination and attention. Functional connectivity within and between these brain networks at baseline may predict different cognitive outcomes after different exercise interventions.

T231. REMOTE CARE IN A TIME OF CRISIS: REACT-NORV - A VIDEO-BASED FAMILY INTERVENTION FOR CAREGIVERS TO PEOPLE EXPERIENCING PSYCHOSIS

Erlend Mork*¹, Kristin Hatløy², Marit Holter³, Inger Stølan Hymer⁴, Kristine Kling⁵, Fiona Lobban⁶, Ingrid Melle⁷, Jenny Pedersen⁸, Hilde Kristin Aam Szabo⁸, Kristin Lie Romm⁹

¹*Oslo University Hospital, Division of Mental Health and Addiction, Early Intervention in Psychosis Advisory Unit for South East Norway*, ²*Stavanger University Hospital, TIPS - Centre for Clinical Research in Psychosis, Stavanger, Norway*, ³*Division of Mental Health and Addiction, Vestfold Hospital Trust, Toensberg, Norway*, ⁴*Early Intervention in Psychosis Advisory Unit for South East Norway*, ⁵*Early Intervention in Psychosis Advisory Unit for South East Norway, Clinic of Mental Health and Addiction, Oslo University Hospital, Oslo, Norway*, ⁶*Lancaster University*, ⁷*Institute for Clinical Medicine, University of Oslo, Oslo, Norway*, ⁸*Sanderud Hospital, Psychiatric Health Services Division, Innlandet Hospital Trust, Norway*, ⁹*Oslo University Hospital, Division of Mental Health and Addiction, Norway*

Background: Psycho-educative family interventions have been shown to reduce caregiver burden and improve health outcomes in carers of family members with psychoses. However, during the COVID-19 pandemic, such interventions was difficult to access. The Relatives Education and Coping Toolkit (REACT) consists of a toolkit for caregivers, offering psychoeducation and tasks to enable the user to identify and work on solutions. The program has been tested in a small Norwegian pilot study previously, with phone support. During the pandemic, video support became possible. Due to a hasty need for new solutions during the pandemic, we were able to test the implementation of this program in a realistic clinical setting in combination with remotely delivered video-consultations. The aim was to investigate the feasibility of REACT-NORV delivered during, and in the aftermath of the Covid-19 pandemic and to explore potential characteristics that might influence the benefit of the intervention.

Methods: Carers of people with psychosis (n=62) were asked to participate when offered access to REACT-NORV within mental health in Norway during the Covid-19 pandemic. Consecutively recruited carers received up to weekly support for 16 weeks from trained family therapists. The main form of support was through video consultation, but the supporters could be flexible if needed. Data was collected at baseline and at 6 months and included questions regarding the influence of the pandemic on the family, user friendliness of the intervention (System usability scale), level of distress (Relatives stress Scale) and expressed emotions (the Family Questionnaire).

Results: Fifty nine percent of carers had 8 or more consultations (range 1-16). The majority (60%) reported received most of the support during video sessions. However, a substantial minority received mixed support, and reported to receive most of the support by phone (32%)

or face to face (8%). Having the first consultation face to face was important to many carers, but carers who received support primarily by video were less inclined to deem this. Caregivers experienced a significant reduction in distress and in expressed emotions post-intervention. Change in distress and expressed emotions were primarily observed among mothers/female carers, and not fathers/male carers. A majority of both male (60%) and female (51%) carers reported that the burden on their own health was reduced after the REACT-NORV intervention. Carers rated the intervention as user friendly (System usability scale mean score 82), but emphasized the importance of the human support by the family therapists. Changes attributed to the Covid-19 pandemic at baseline, such as worsening of symptoms or reduced access to treatment/services for the sick family members, did not seem to influence the benefit for the carers. The main barriers to attend to the program were challenges related to the situation in the household and lack of time.

Discussion: The intervention proved feasible to deliver in standard clinical care with support from trained family therapists. REACT-NORV was well received by the participating carers, but the observed gender differences should be further explored. REACT-NORV may contribute to increased access to support for carers of people with psychosis when options for delivering face to face interventions are limited. There is a need to explore further, who will benefit from guided online programs directed towards families, and who will need more extensive single and multiple family work to be able to reach a broader group with appropriate help.

T232. SHIFTING PERSPECTIVES: SUBSTANCE USE DISORDER'S ROLE IN PHYSICAL ACTIVITY AMONG INDIVIDUALS WITH SCHIZOPHRENIA AND PSYCHOSIS DISORDER

Florence Piché¹, Lucie Venet-Kelma¹, Chantal Plourde², Ahmed Jérôme Romain³

¹University of Montreal, ²Université du Québec à Trois-Rivières, ³University of Montreal Hospital Research Centre

Background: People with psychotic disorder, such as schizophrenia, tend to have a low physical activity level and a more sedentary lifestyle. This can be attributed to various obstacles such as side effects of antipsychotic medication, comorbidities, low mood, and lack of social support. While substance use disorder (SUD) is commonly viewed as a detrimental aspect of individuals with mental disorder, recent research challenges this notion. In our recent study, higher levels of physical activity were observed in people with SUD compared to other mental disorders (such as bipolar disorder, major depression, etc.) Our study aims to verify whether, when compared to a population with psychotic disorders and schizophrenia, this remains true. Objective: (1) Compare the level of physical activity between people with psychotic disorder as well as SUD with people with psychotic disorder only. (2) Compare the level of physical activity between people with schizophrenia with SUD with people with schizophrenia only.

Methods: Cross-sectional study using the database SIMPAQ (23 countries) including 1013 participants all evaluated by a psychiatrist. Mental disorder included schizophrenia spectrum disorders, bipolar disorder, depressive disorders, anxiety disorders, obsessive-compulsive disorders, substance-related and addictive disorders, neurocognitive disorders, and other disorders. We form groups using the severity of symptom for SUD and psychotic disorder. Individuals must reach the threshold (slight or greater) in the questionnaire DSM-5 self-rated level 1 cross-cutting symptoms measure to be considered in the SUD group or in the psychotic disorder group. For the schizophrenia group, we use the diagnosis made by the

psychiatrist. We formed four groups, G1: people with the psychotic disorder and SUD, G2: people with only psychotic disorder, G3: people with schizophrenia and SUD, G4: people with only schizophrenia. To evaluate physical activity, we used the simple physical activity questionnaire and to compare physical activity levels, we used a one-way ANOVA.

Results: Characteristic for groups 1 and 2 were similar for age (G1: 37.7 ± 12.1 years; vs. G2: 38.4 ± 13.6 years), but different for the proportion of women (G1: N = 44, 35.2% vs. G2: N = 72, 51.1%). Characteristic for groups 3 and 4 groups were also similar for age (G3: 36.1 ± 12.3 years vs. G4: 36.2 ± 12.4 years) and different for the proportion of women (G3: N = 28, 21.1% vs. G4: N = 67, 40.6%). For the objective 1, we found a significant difference in physical activity levels between people with SUD and psychotic disorder (2.44 ± 1.91 h of physical activity/week) compared with people with only psychotic disorder (1.97 ± 1.63 h of physical activity/week; $p=0.04$). For objective 2, we found that among people with schizophrenia, no difference was found regarding physical activity levels (G3: 2.15 ± 1.73 ; vs. G4: 1.80 ± 1.54 h of physical activity/week; $p=0.08$).

Discussion: People with SUD seem to have different lifestyles compared with people with psychotic disorder that in people with schizophrenia in terms of level of physical activity. This study has the potential to help reshape our perception of SUD beyond its negative connotation. The observation that individuals dealing with both psychotic disorder and substance use issues appear to be more physically active suggests an opportunity to create pathways for guiding them toward healthier lifestyle habits. Naturally, further research is essential to comprehensively understand the interplay between physical activity, SUD, and psychotic disorder, as well as to identify the most effective approaches for treating and using physical activity in this population.

T233. EVENT - A CLUSTER-RANDOMIZED CLINICAL TRIAL ON THE USE OF THE DECISION SUPPORT APP SDM-ASSISTANT TO SELECT THE MOST APPROPRIATE ANTIPSYCHOTIC IN HOSPITALIZED PATIENTS WITH SCHIZOPHRENIA

Natalie L. Peter^{*1}, Spyridon Sifas², Katharina Müller³, Ivana Ivandic², Keelin Hyde², Natascha Wilde², Sophie Peter², Alessandro Rodolico², Alkomiet Hasan⁴, Peter Brieger³, Stephan Heres⁵, Johannes Hamann⁶, Stefan Leucht²

¹*Sektion Evidenzbasierte Medizin in der Psychiatrie und Psychotherapie, Klinik für Psychiatrie und Psychotherapie, Klinikum rechts der Isar, School of Medicine and Health, Technische Universität München,* ²*Sektion Evidenzbasierte Medizin in der Psychiatrie und Psychotherapie, Klinik für Psychiatrie und Psychotherapie, Klinikum rechts der Isar, School of Medicine and Health, Technische Universität München, Deutschland,* ³*kbo Isar Amper Klinikum München,* ⁴*Department of Psychiatry, Psychotherapy and Psychosomatics, University of Augsburg,* ⁵*kbo-Klinik für Psychiatrie und Psychotherapie Nord. Koelner Platz 1, Haus 7 80804 Muenchen, Germany,* ⁶*Klinikum Mainkofen*

Background: Selecting the most suitable antipsychotic based on the latest scientific evidence repeatedly presents doctors and patients with major challenges. By introducing our digital decision aid SDMA, we aim to provide the latest meta-analytic data in an easily accessible way and thus promote evidence-based shared decision-making.

Methods: A total of 18 wards at 4 centres in the cities of Munich and Augsburg were randomly assigned to either the control or intervention setting using a matched-pair design. Included patients (schizophrenia spectrum disorder, acutely ill, 18-65 years) were interviewed

at two time points during their inpatient stay and 3 months after discharge. At the same time, the treating physicians assessed the severity of illness, level of functioning and patient involvement in treatment decisions. After the first appointment (baseline), the patients and doctors in the intervention group were given access to the app, in which the patients were able to indicate treatment goals, previous experience and preferences with certain medications. Then, the doctors could indicate any previous illnesses or special patient characteristics. In the end, the app presented more detailed information on the antipsychotics in question, as well as a graphical overview of the effectiveness and the frequency of various side effects in comparison with other drugs. Our primary outcome was the patient version of the SDM-Q-9 (per protocol), which measures the perceived degree of involvement in treatment decisions. Secondary outcomes included patients' attitude towards treatment and medication, preferred extent of shared decision-making, and side effects of medication. Qualitative surveys accompanied the quantitative assessments.

Results: (at the time of submission still preliminary): Of the n=153 included patients, n=74 were recruited from intervention wards, and n=79 were recruited from control wards. The drop-out rate in the intervention and control group was 0.46 and 0.39, respectively. The difference between intervention and control was small and considered clinically insignificant (intervention mean (SD): 25.90 pts. (8.02); control 26.23 pts. (9.01); difference (linear mixed-effects model): -0.57 pts. (95%-CI -7.46 to 4.00)). The other outcomes are currently analysed.

Discussion: We successfully implemented the use of a shared decision-making app in an acute inpatient setting. The acuteness and extremely high workload of clinicians posed several challenges to the strict implementation of our protocol. While our primary outcome failed to exhibit considerable differences between intervention and control, the application was well received by both patients and providers, and facilitated discussions on the topics of treatment choice and side effects. We think the application could be of even more use in outpatient settings later in the course of treatment, when a certain stabilization has been reached and emerging or persisting side effects begin to play a bigger role for treatment choice and adherence. As a next step, we will make our decision-making aid SDMA available in other languages and extend it to different medication groups.

T234. LOST CONNECTIONS: NEGATIVE SOCIAL EXPERIENCES HEIGHTEN PSYCHOTIC SYMPTOMS IN A COMMUNITY SAMPLE

Elyssa Barrick¹, Grant Nelson¹, Sarah Hope Lincoln¹

¹Case Western Reserve University

Background: Several current theories suggest that social disconnection may underlie psychotic symptoms. The social defeat hypothesis (Selten et al., 2013) links exclusion from a majority group to increased risk of psychotic disorders, and the social deafferentation hypothesis (Hoffman, 2007) proposes that social withdrawal and isolation result in neural changes associated with psychotic symptoms. However, much of the supporting evidence for these hypotheses is correlational. Experimental validation of such hypotheses often entails assessing changes in outcome variables based on a predictor, a common approach in affective research using mood-induction paradigms. The field of psychosis research encounters unique challenges in this area due to the absence of established psychosis-induction paradigms for neurotypical individuals. Despite these challenges, this concept is not beyond the realm of feasibility. Even among individuals with psychotic disorders, there are observable daily and momentary fluctuations in symptoms. While psychotic symptoms are often measured in the

laboratory as traits, their real-world manifestation tends to be more transient in nature. This study aimed to 1) explore whether psychotic-like experiences (PLEs) could be temporarily induced in a non-psychiatric community sample, and 2) test whether simulating socially excluding experiences increased momentary PLEs.

Methods: Online participants (N = 862) recruited via Prolific completed the study using Qualtrics. Inclusion criteria included: US residency, no reported neurodiversity or ongoing/history of mental illness, and English as a primary language. We created the Momentary Assessment of Psychotic-like Experiences (MAPE), a 20-item measure, to assess in-the-moment positive and negative dimensions of PLEs. Higher MAPE scores indicate increased endorsement of PLEs. Following randomization into one of four conditions (inclusion, exclusion, sadness, neutral), participants completed the MAPE (pre score), engaged in a 5-minute writing session where they recounted an experience consistent with their condition, followed again by the MAPE (post score).

Results: Our main analysis tested the impact of writing conditions on PLEs. First, change scores (post-MAPE minus pre-MAPE) were computed within participants. Next, a Kruskal-Wallis test was conducted to examine group differences in change scores. Results revealed a statistically significant group difference $\chi^2(3) = 234.35$, $p < .001$, $\epsilon^2 = 0.26$. Pairwise comparisons using Dunn's test and Bonferroni showed significant increases in PLEs for exclusion (M = 2.71) compared to inclusion (M = -2.88) and neutral conditions (M = -1.71; all p s $< .001$). Additionally, there were significant increases for the sadness condition (M = 6.02) compared to inclusion, neutral and exclusion conditions (p s $< .001$). We then compared changes in specific symptoms between exclusion and sadness conditions. Using t-tests with Bonferroni corrections, we found that negative affect increased more following sadness (M = 3.84) than exclusion (M = 2.19), $t(407.27) = -4.57$, $p < .001$. Similarly, negative symptoms increased more for sadness (M = 1.70) than exclusion (M = 0.80), $t(420.32) = -3.14$, $p = .01$. However, paranoia increased more for exclusion (M = 0.97) than sadness (M = 0.25), $t(435.64) = 4.45$, $p < .001$.

Discussion: To our knowledge, this is the first study to provide evidence that PLEs can be temporarily induced in neurotypical individuals through a behavioral paradigm, a phenomenon induced by recalling socially negative and isolating events. Interestingly, the results show a unique dissociation: recalling sad experiences heightens affective and negative symptoms, whereas recalling exclusionary events increases paranoia.

T235. SOCIAL STIGMA AND PSYCHOSIS: EXAMINING HALLUCINATION VALENCE, DIAGNOSTIC CONTEXT, AND EXPOSURE TO INDIVIDUALS WITH MENTAL ILLNESS

Alicia Villanueva van den Hurk^{*1}, Julie Walsh-Messinger²

¹University of Detroit Mercy, ²University of Dayton

Background: Individuals with psychosis face profound social stigma, contributing to the perception that they are uniquely dangerous and aggressive. Previous research has shown that hallucination valence (positive vs negative) affects stigma, but neutrally valenced hallucinations have not been studied. Additionally, individuals with schizophrenia and other serious mental illness experience greater stigmatization than those diagnosed with other psychiatric disorders, but this stigmatization has not been compared to psychosis in the context of a non-psychiatric disorder. The present study examined the effects of clinical

diagnosis and auditory hallucination valence on stigmatization of fictional patients with psychosis. Additionally, because social contact is an effective strategy against all stigmas, the effect of exposure to individuals with mental illness (EMI) and its interaction with the aforementioned variables was also explored.

Methods: Undergraduate students (N=120) completed the Level of Contact Report online to measure EMI. The following week participants were presented with six fictional patient descriptions, three diagnosed with bipolar I disorder and three with a brain tumor. After each description five audio recordings were presented as examples of that patient's auditory hallucinations, which were pleasant, unpleasant, or neutral in valence based on ratings provided in a previous study. Participants then completed the Bogardus Social Distance Scale to assess the extent to which they would be willing to accept a social relationship with each of the fictional patients.

Results: There were no differences in stigmatization of bipolar I patients compared to those with a brain tumor, but there was a main effect for valence ($F=41.33$, $p < .001$, partial $\eta^2 = .259$). Stigmatization was higher for patients with negatively valenced auditory hallucinations compared to neutral ($p < .001$) and positive ($p < .001$). Similarly, participants were less accepting of a social relationship with patients experiencing neutral hallucinations than they were of patients with positive hallucinations ($p < .001$). Regarding EMI, participants with low exposure reported greater stigmatization compared to participants with high EMI ($F=5.05$, $p=.026$, partial $\eta^2 = .021$) and there was a significant interaction between hallucination valence and EMI ($F=5.04$, $p=.007$, partial $\eta^2 = .041$). Participants with high EMI reported greater stigmatization of patients with negatively valenced hallucinations compared to those with neutral ($p < .001$) and positive ($p < .001$); stigmatization for neutral hallucinations was higher compared to those with positive ($p < .001$). In the low EMI group, stigmatization was only higher for patients with negative hallucinations compared to positive ($p=.03$).

Discussion: These results suggest that hallucination valence has greater impact on psychosis stigmatization than diagnostic context, and that exposure to individuals with mental illness may reduce this stigmatization. These findings propose potential mechanisms that may underlie the stigmatization of psychosis, which can potentially inform future interventions aimed at reducing social stigma towards psychosis. This can be particularly beneficial given the negative effects of stigma on psychosis prognosis. Future studies should examine cross-cultural effects and explore whether diagnostic context only affects certain types of stigmatizations (i.e., physical proximity, friendship, romantic relationship).

T236. COMPARATIVE EFFICACY OF ORAL VS. LAI FORMULATIONS OF EIGHT SECOND-GENERATION ANTIPSYCHOTICS IN ACUTE SCHIZOPHRENIA TREATMENT: A NETWORK META-ANALYSIS AND SYSTEMATIC REVIEW

Dongfang Wang^{*1}, Johannes Schneider-Thoma², Spyridon Sifakis³, Yikang Zhu⁴, John M Davis⁵, Josef Priller⁶, Stefan Leucht⁷

¹Section Evidence Based Medicine in Psychiatry and Psychotherapy; Klinikum Rechts der Isar, Technical University of Munich, ²Department of Psychiatry and Psychotherapy, School of Medicine, Technical University of Munich, ³Department of Psychiatry and Psychotherapy, Klinikum rechts der Isar, School of Medicine, Technische Universität München, ⁴Klinikum Rechts der Isar, Technical University of Munich; Shanghai Mental Health Center, Shanghai Jiao Tong University School of Medicine, ⁵University of Illinois, ⁶Technical University of

Munich, School of Medicine, ⁷Department of Psychiatry and Psychotherapy, Klinikum rechts der Isar, Technische Universität München

Background: There is a long-standing debate about whether long-acting injectable antipsychotics (LAIs) are better than oral formulations. Therefore, this study aimed to compare second-generation LAIs with their oral formulations for the acute treatment of schizophrenia by network meta-analysis (NMA).

Methods: We conducted a systematic review and network meta-analysis of randomized controlled trials (RCTs). We focused on adult patients in the acute phase of schizophrenia. Interventions and control groups considered were risperidone, paliperidone, aripiprazole, olanzapine, and placebo, administered either orally or via injection. We synthesized data on overall symptoms, complemented by 17 other efficacy and tolerability outcomes. The synthesis was achieved through a frequency-based NMA. Confidence in the evidence was assessed using CINeMA (Confidence in Network Meta-Analysis).

Results: We analyzed 115 eligible RCTs, encompassing 25,550 participants. All drugs were significantly more efficacious than placebo with the sequence olanzapine LAI -0.66 [-1.00; -0.33], risperidone LAI -0.59[-0.73;-0.46], olanzapine oral -0.55[-0.62;-0.48], aripiprazole LAI -0.54[-0.71; -0.37], risperidone oral -0.48[-0.55;-0.41], paliperidone oral -0.47[-0.58;-0.37], paliperidone LAI -0.45[-0.57;-0.33], aripiprazole oral -0.40[-0.50; -0.31]. Further sensitivity analysis concerning overall symptoms yielded consistent findings. Confidence in the evidence was generally moderate to low according to our evaluation with CINeMA.

Discussion: In conclusion, during the acute treatment phase, the efficacy of LAIs does not surpass that of orals, while LAIs present some advantages over oral formulations in the realm of side effects. These findings equip clinicians with insights to weigh the risks and benefits between oral and injectable agents when managing patients in the acute phase.

T237. ENHANCING SCHIZOPHRENIA CLASSIFICATION THROUGH QUANTILE-BASED POLYGENIC RISK SCORE ANALYSIS

Gianluca Christos Kikidis^{*1}, Leonardo Sportelli², Alessandro Bertolino¹, Daniel Weinberger², Giulio Pergola²

¹University of Bari Aldo Moro, ²Lieber Institute for Brain Development

Background: In the latest Genome-Wide Association Study (GWAS) on schizophrenia (SCZ), common variants surviving correction for multiple comparisons were identified at 287 distinct genomic loci. Polygenic risk score (PRS) analysis explained a median variance of 0.073 in liability, specifically focusing on Single Nucleotide Polymorphisms (SNPs) with GWAS p-values below .05. It is commonly preferred to select the PRS containing variants with p LESS THAN .05 for best trade-off between number of variants included and proportion of liability explained. Notably, the rank of an individual within a group can change remarkably based on the classifier used, e.g., different PRSs computed at variable thresholds of SNP inclusions. We hypothesize that, given the inherent uncertainty in the multitude of classifiers, a centrality measure of an individual's position in a cohort may yield superior classification performance compared to the current optimal classifier, i.e., the standard PRS. Our proposed approach involves calculating the mean and standard deviation from all risk percentiles within each individual to capture the risk distribution and predict case/control status more accurately.

Methods: Our study involved 1686 genotypes of Caucasian adults (45% female) from the University of Bari (UNIBA) cohort, comprising 1098 neurotypical controls (NC) and 588

patients with SCZ, as well as 1280 postmortem genotypes of Caucasian adults (40.2% female) from the NIH SIB Study cohort, including 648 NC and 632 SCZ patients. Additionally, genotypes from the Psychiatric Genomics Consortium wave 2 sites, totaling 36,000 individuals with SCZ and over 113,000 NC in 39 sites, were included. After quality controls, we calculated the PRS based on the latest GWAS SCZ variants. Risk percentiles were then calculated for each commonly used p-value threshold. We introduced a novel approach, quantile-based Polygenic Risk Score (qPRS), utilizing the mean and standard deviation from all risk percentiles within each individual to determine the quantile risk of an individual. We predicted case/control status using a generalized linear regression model, comparing the classic PRS approach with our qPRS. Sensibility/sensitivity analyses were performed with the area under the receiving operating curve of different scores on diagnosis. Finally, we conducted a meta-analysis with a paired t-test between each different PGC site.

Results: Our findings revealed a superior performance of the qPRS compared to the standard PRS. In UNIBA, Nagelkerke's pseudo-R² for qPRS was 0.20, surpassing the classic PRS with a pseudo-R² of 0.15. Similarly, in the NIH SIB Study cohort, the qPRS demonstrated higher Nagelkerke's pseudo-R² (0.23) compared to the PRS (0.16). Moreover, enhanced accuracy and precision in classifying case/control status were observed with the qPRS (AUC 78% vs 75% with PRS). Meta-analysis across all PGC2 sites indicated that the qPRS explained an average of 22% of variance (95% CI [0.19, 0.25]), outperforming the classic PRS (17%, CI [0.15, 0.20]). Our approach consistently outperformed the classic approach in terms of variance explained across PGC sites ($t(38) = 8.37$, $p = 1.72 \times 10^{-10}$).

Discussion: Our analyses suggest that genetic classifiers without genome-wide significant SNPs contribute to SCZ heritability. The consideration of the entire PRS distribution, potentially representing diverse genetic pathways, enables a more accurate classification of patients and controls. Additionally, this method employs a population-based approach, using risk percentiles within a population, thus potentially increasing its potential applicability to diverse datasets.

T238. FEASIBILITY AND EFFECTIVENESS OF DIGITAL HEALTH INTERVENTIONS IN PEOPLE WITH SCHIZOPHRENIA: A SYSTEMATIC REVIEW AND META-ANALYSIS

Urska Arnautovska¹, Kathryn Vitangcol², Mike Trott², Alyssa Milton³, Ellie Brown⁴, Namal Balasooriya⁵, Joseph Firth⁶, Dan Siskind⁷, Dan Siskind^{*8}

¹Faculty of Medicine, The University of Queensland, ²The University of Queensland, ³University of Sydney, ⁴University of Melbourne, ⁵Centre for Health Service Research, The University of Queensland, ⁶University of Manchester, ⁷School of Medicine, The University of Queensland, Brisbane, MIRT, Woolloongabba Community Health Centre, Addiction and Mental Health Services and MIRT, ⁸Metro South Addiction and Mental Health Service

Background: People living with schizophrenia are at increased risk of chronic diseases and can experience persisting psychosis symptoms which significantly impair their quality of life. The advancement in digital technology such as smartphones has the potential to improve health outcomes and social functioning in this at-risk group. This systematic review aimed to examine the effect of digital health interventions delivered among people with schizophrenia on a range of health-related outcomes, including psychosis symptoms, cognition, depression, medication adherence, self-management, and functioning.

Methods: A search of PubMed, CINAHL, EMBASE, Scopus and Cochrane databases was conducted to identify randomised controlled trials that reported outcomes of interventions delivered via a website, mobile phone, or other devices in people with schizophrenia (or related psychotic disorders). All potential studies were screened for eligibility by two reviewers.

Results: Our search produced 47,364 from which 35 eligible articles were identified. Primary and secondary outcomes of each study were grouped into psychosis symptoms (total, positive, and negative); quality of life; global functioning; social functioning; global cognition; medication adherence; and depression. The interventions examined in these trials were found to be feasible, with low recruitment but high retention rates. The effects of interventions on outcomes were variable (Hedge's g range -0.06-1.25) and showed potential for improving psychosis symptoms, depression, and cognition.

Discussion: This systematic review provides strong evidence on the feasibility of digital health interventions for people living with schizophrenia and supports the potential for clinical effectiveness of such treatment designs in improving mental health in this population.

T239. CAN RECOVERY-ORIENTED REHABILITATION LANGUAGE IN CLINICAL DOCUMENTATION ENHANCE RECOVERY-ORIENTED PRACTICE?

Veronica De Monte¹, Angus Veitch², Frances Dark¹, Carla Meurk³, Marianne Wyder¹, Maddison Wheeler¹, Kylie Carney¹, Stephen Parker³, Steve Kisely³, Dan Siskind^{*1}

¹*Metro South Addiction and Mental Health Service*, ²*Independent Researcher*, ³*University of Queensland Faculty of Medicine*

Background: In alignment with recovery-oriented practice principles, this study introduces a novel method for assessing the presence of recovery-oriented rehabilitation language in clinical documentation. It also evaluates the impact of a training intervention aimed at improving the use of such language within a community-based rehabilitation team.

Methods: Eleven case managers underwent training that provided instruction in recovery-oriented rehabilitation principles. The effectiveness of this training was quantified using automated textual analysis of clinical documentation, which utilised a specialised dictionary comprising rehabilitation-consistent, person-centred, and pejorative terms. This analysis was conducted on the KNIME platform. Pre-training and post-training documents, 50 and 77 respectively, were compared using inferential statistics to identify changes in language frequency.

Results: Post-intervention analysis revealed a significant increase, from 37% to 48%, in the average percentage of sentences containing recovery-oriented rehabilitation terms, marking a 28% relative rise ($P < 0.001$). Despite this improvement, there was no notable change in the use of person-centred or pejorative terms, which could be attributed to the already high baseline use of person-centred language (22%) and the minimal use of pejorative language (2.3%).

Discussion: The findings demonstrate that the computer-assisted text analysis method can successfully detect enhancements in the use of recovery-oriented rehabilitation language following brief training interventions. The study suggests that such training can influence the language of clinical documentation and that automated text-analysis offers a promising technique for rapidly assessing language use within mental health services.

T240. INFLAMMATORY AND COGNITIVE EFFECTS OF COVID-19 INFECTION IN SCHIZOPHRENIA

Stephanie Kulaga^{*1}, Matthew Glassman², Shawna Dougherty³, Sathyaikumar Korrapati³, Mallory Shriver⁴, Kristen Marx⁴, Fang Liu⁵, Sharon August⁵, Deanna L. Kelly⁶

¹MPRC, University of Maryland SOM, ²Maryland Psychiatric Research Center, University of Maryland School of Medicine, ³Maryland Psychiatric Research Center, ⁴University of Maryland, ⁵University of Maryland Baltimore, Maryland Psychiatric Center, ⁶University of Maryland Baltimore, Maryland Psychiatric Research Center

Background: The role of viral infections in the pathophysiology of schizophrenia-related disorders (SRD) has been well-characterized and appears to be primarily mediated through inflammatory effects. Individuals with SRD have been shown to have both elevated serum viral antibody titers and increased pro-inflammatory cytokine levels. Several such cytokines are involved in activation of the kynurenine pathway (KP), which breaks down tryptophan (TRP) and may be disturbed in SRD. Kynurenic acid (KYNA), a breakdown product of the KP, is thought to contribute to cognitive impairments observed in SRD. Coronaviruses have been shown to have increased antibody titers in individuals with SRD and it has been postulated that the COVID-19 pandemic could lead to increased SRD diagnoses in the future. COVID-19 has been associated with neuropsychiatric presentations, including psychosis, and notable cognitive effects sometimes following even mild to moderate infection. COVID-19 has also been associated with increases in pro-inflammatory cytokines and KP metabolites, both of which have been linked to both acute infection severity and long-COVID symptoms. Individuals with SRD have had higher morbidity and mortality from COVID-19 than other populations, which may be related in part to baseline immune disturbances. Literature on COVID-19 infection in those with SRD is limited and largely focused on severe infection requiring hospitalization. Little is currently known about the effects of mild to moderate COVID-19 infection on immune parameters, cognition and other clinical parameters in people with SRD.

Methods: We aimed to recruit 40 individuals with SRD diagnoses, half with history of COVID-19 infection 1 month to 1 year prior and half without. No participants were hospitalized for COVID-19. All participants completed a MATRICS cognitive testing battery, psychiatric symptom questionnaires, and a blood draw at a one-time study visit. Serum was analyzed for kynurenine, KYNA, TRP, inflammatory markers and SARS-CoV-2 anti-nucleocapsid and anti-spike antibodies. Complete blood counts (CBC), metabolic panels (CMP) and vital signs were also measured.

Results: 23 participants (57.5%) had a history of COVID-19 infection and 17 did not (42.5%). There were no significant differences between groups in kynurenine, KYNA, TRP, CBC, CMP, positive or negative psychotic symptom scores, overall MATRICS scores or cognitive subdomain scores. The COVID-19 group had significantly higher mean IL-8 than the non-infected group (14.48 vs 7.73, $p=0.01$), as well as higher IL-6 (8.75 vs 3.81, $p=0.069$) and TNF-alpha (24.97 vs 8.83, $p=0.057$), though these did not reach significance. Participants with history of COVID-19 infection reported a mean of 11.4 (SD=13.9) long-COVID symptoms. We will also report on the relationships of antibody levels, cytokines, and KP metabolites to cognitive and psychiatric outcomes, as well as to long-COVID symptoms.

Discussion: In our population of participants with SRD, those with a history COVID-19 infection had higher levels of several inflammatory cytokines. Most existing literature on COVID-19 in individuals with SRD focuses on those hospitalized with severe infection. To our knowledge, this is the first evidence that mild to moderate COVID-19 infection leads to

lasting inflammatory changes in individuals with SRD. Further analyses will examine the relationship of these inflammatory markers to outcome variables.

T241. PHYSICAL HEALTH AND TRANSITION TO PSYCHOSIS IN PEOPLE AT CLINICAL HIGH RISK

Andrea De Micheli^{*1}, Umberto Provenzano², Kamil Krakowski², Dominic Oliver³, Stefano Damiani⁴, Natascia Brondino⁵, Philip McGuire⁶, Paolo Fusar-Poli⁷

¹*Early Psychosis: Interventions and Clinical-Detection (EPIC) Lab, Institute of Psychiatry, Psychology and Neuroscience, King's College London,* ²*Department of Brain and Behavioural Sciences, University of Pavia,* ³*Early Psychosis: Interventions and Clinical Detection (EPIC) lab, Department of Psychosis Studies, Institute of Psychiatry, Psychology and Neuroscience, King's College London,* ⁴*University of Pavia, Department of Brain And Behavioral Sciences,* ⁵*Department of Brain and Behavioural Sciences, University of Pavia,* ⁶*Department of Psychiatry, University of Oxford,* ⁷*Early Psychosis: Interventions and Clinical-detection (EPIC) lab, Department of Psychosis Studies, Institute of Psychiatry, Psychology and Neuroscience, King's College London, OASIS Service, South London and Maudsley NHS Foundation Trust, Department of Brain and Behavioral Sciences, University of Pavia, National Institute for Health Research, Biomedical Research Centre for Mental Health, South London and Maudsley NHS Foundation Trust,*

Background: The clinical high risk for psychosis (CHR-P) construct represents an opportunity for prevention and early intervention in young adults, but the relationship between their psychosis risk and physical health is still unclear.

Methods: We conducted a RECORD-compliant clinical register-based cohort study, selecting the long-term cumulative risk of developing a persistent psychotic disorder as the primary outcome. We investigated associations between primary outcome and physical health data with Electronic Health Records at the South London and Maudsley (SLaM) NHS Trust, UK (January 2013–October 2020). We performed survival analyses, using Kaplan-Meier curves, long-rank tests, and Cox proportional hazard models.

Results: The database included 137 CHR-P subjects, 21 CHR-P developed psychosis during follow-up and the cumulative incidence of psychosis risk was 4.9% at 1 year and 56.3% at 7 years. Using log-rank tests, psychosis risk might change between different levels of nicotine and alcohol dependence. Kaplan-Meier curve indicates that non-hazardous drinkers may have a lower psychosis risk than non-drinkers. In the Cox proportional hazard model, nicotine dependence presented a hazard ratio of 1.34 (95%CI. 1.1 – 1.64) (p-value 0.01), indicating a 34% increase of psychosis risk for every additional point on the Fagerström Test for Nicotine Dependence (FTND).

Discussion: Our findings confirmed that a comprehensive assessment of tobacco and alcohol intake, diet, and physical activity in CHR-P subjects is key to understanding how physical health contributes to psychosis risk.

T242. MUVA PHYSICAL ACTIVITY INTERVENTION IMPROVES SOCIAL FUNCTIONING IN PEOPLE WITH A SEVERE MENTAL ILLNESS: A PRAGMATIC STEPPED WEDGE CLUSTER RANDOMIZED TRIAL

Lisanne Koomen*¹, Ilona van de Meent¹, Jeroen Deenik², Edwin van Dellen¹, Hugo Schnack³, Henri van Werkhoven¹, Wilma Swildens⁴, Prof. dr. Berno van Meijel⁵, Wouter Staal⁶, Frederike Jorg⁷, Floor Scheepers⁸, Wiepke Cahn¹

¹UMC Utrecht, ²GGz Centraal, Amersfoort, ³University Medical Center Utrecht, ⁴Altrecht Institute for Mental Health Care, ⁵Department of Psychiatry, Amsterdam UMC, ⁶Karakter, ⁷University of Groningen, ⁸Department of Psychiatry, University Medical Center Utrecht, Utrecht

Background: Severe mental illness (SMI), including psychosis, places a substantial burden on individuals, resulting in persistent symptoms, reduced social functioning, and compromised physical health. While physical activity (PA) interventions show promise in enhancing both mental and physical well-being, individuals with SMI encounter significant obstacles in engaging in PA. This study aimed to assess the impact of the Muva physical activity intervention on social functioning and secondary outcomes.

Methods: Employing a pragmatic stepped-wedge cluster randomized trial design, we evaluated Muva, which focused on addressing barriers to PA for individuals with SMI by actively involving mental health workers. Muva incorporates a serious game, provides additional lifestyle education, and optimizes medication regimens through medication reviews. The control group received standard care. We conducted mixed-effects linear regressions to measure changes in the primary outcome, social functioning, and secondary outcomes including quality of life, psychiatric symptoms, PA levels, BMI, waist circumference, and blood pressure.

Results: We enrolled 84 patients in three intervention clusters and 38 patients in the control cluster. In comparison to the control group, patients receiving Muva demonstrated clinically significant improvements in social functioning, in interpersonal communication (B=9.07, CI=4.05-14.09) and independence competence (B=5.03, CI=2.49-7.56).

Discussion: The Muva physical activity intervention improved social functioning among individuals with SMI. However, strategies for overcoming implementation barriers are essential to ensure better integration into everyday clinical practice.

We received funding from the Dutch Heart Association [2019T101] for the conduct of the study.

T243. LONG-TERM IMPACT OF ANTIPSYCHOTIC TREATMENT ON RENAL FUNCTION IN INDIVIDUALS WITH A FIRST EPISODE OF PSYCHOSIS: A 3-YEARS PROSPECTIVE STUDY

Claudia Ovejas Catalán¹, Paloma Fuentes Pérez¹, Carmen Flor Gómez¹, Javier Sastre Yáñez¹, Jorge Romay González¹, Rocio Perez-Iglesias¹, Maria Juncal Ruiz¹, Paula Suarez-Pinilla¹, Benedicto Crespo Facorro², Javier Vázquez-Bourgon*³

¹University Hospital Marques de Valdecilla -IDIVAL; University of Cantabria, ²Hospital Universitario Virgen del Rocío. CIBERSAM. Universidad de Sevilla, IBiS, Sevilla, ³University Hospital Marques de Valdecilla -IDIVAL; University of Cantabria; CIBERSAM

Background: Patients with schizophrenia display a wide variety of medical conditions. Chronic kidney diseases are highly prevalent in schizophrenia increasing its morbidity and early mortality. These kidney alterations may be present even from early stages of the psychosis, thus we recently reported that drug-naïve patients suffering a first episode of psychosis presented a poorer renal function when compared with a control group (García-

Rizo et al. 2022). Besides, it has been proposed a nephrotoxic effect of antipsychotic treatments. Our aim is to compare the long-term (3 years) progression of the glomerular filter rate between a cohort of individuals with a first episode of psychosis and a control group. We hypothesize that baseline differences in renal function between patients with psychosis and controls will increase throughout follow-up, possibly due to a nephrotoxic effect of antipsychotics.

Methods: The study was part of a larger prospective longitudinal study on first episode non-affective psychosis, the PAFIP program, in the Marqués de Valdecilla University Hospital (Santander, Spain). 440 drug-naïve first episode psychosis (FEP) patients and 81 controls were evaluated for renal function according to its glomerular filter rate (GFR). Confounders such as age, sex, body mass index, blood pressure and tobacco use were also considered. Estimated Glomerular Filter Rate (eGFR) was calculated with the CKD-EPI Creatinine Equation (version 2009) (Levey et al., 2009) as follows: $eGFR_{cr} = 141 \times \min(Scr/\kappa, 1)^\alpha \times \max(Scr/\kappa, 1)^{-1.209} \times 0.993^{Age} \times 1.018$ [if female]. Where: Scr = standardized serum creatinine in mg/dL; $\kappa = 0.7$ (females) or 0.9 (males); $\alpha = -0.329$ (female) or -0.411 (male); $\min(Scr/\kappa, 1)$ is the minimum of Scr/ κ or 1.0; $\max(Scr/\kappa, 1)$ is the maximum of Scr/ κ or 1.0; Age (years).

Analyses of covariance (ANCOVA) were performed to compare means between groups discarding the possible confounding effect of basal eGFR. In the model, change in glomerular filter rate overtime was included as the dependent variable, while age, sex, BMI, basal eGFR and tobacco use were included as co-variables. The Statistical Package for Social Science (SPSS) version 23.0 (IBM Corp., Armonk, NY, USA) was used for statistical analyses. All statistical tests were two-tailed, and significance was determined at the 0.05 level.

Results: A significant reduction in GFR was found between FEP and healthy controls both at baseline (97.4 vs 108.4 ml/min/1.73 m², p LESS THAN 0.001) Indeed, when categorized the GFR following usual cut-points references (LESS THAN 90, and ≥ 90 ml/min/1.73 m²) significant differences were also displayed, with significantly more psychosis patients among the poorer kidney function group (LESS THAN 90 ml/min/1.73 m²) at baseline (39.1% vs 9.9%, p LESS THAN 0.001) and at 3-years follow-up (28.6% vs 2.5%, p LESS THAN 0.001). ANCOVA analysis covarying for potential confounders (i.e.: age, sex, BMI, tobacco use, and basal GFR) showed a significant differences between psychosis and control groups in GFR change; although both groups increased their GFR overtime, the increase was significantly smaller among psychosis patients (estimated marginal means: 2.7 vs 6.4 ml/min/1.73 m², $p=0.021$). ANCOVA analyses comparing the effect of 6 different antipsychotic treatments (i.e. aripiprazole, risperidone, olanzapine, quetiapine, ziprasidone, and haloperidol) on GFR change over the 3-years follow-up showed significant differences between groups (p LESS THAN 0.001). Interestingly, those patients initially treated with olanzapine and haloperidol showed a reduction in mean GFR (-6.7 and -8.8 ml/min/1.73 m², respectively) while the other antipsychotics showed increments in mean GFR. Olanzapine and haloperidol showed significantly smaller changes in GFR than the rest of antipsychotic treatments. These results were also observed following a per protocol approach.

Discussion: Our results showed that the reduced renal function observed at early staged of psychosis is maintained at long-term. However, unexpectedly we did not observe a worsen in GFR overtime in the psychosis group. Interestingly, specific antipsychotic treatments (olanzapine and haloperidol) appeared to have a deleterious effect on GFR. These findings suggest some vulnerability associated with the diagnosis which might produce a greater

impact on kidney function depending on the type of antipsychotic to which the patient is exposed.

T244. PATIENT CHARACTERISTICS AND CARDIOVASCULAR HEALTH BEHAVIORS FOR COMMUNITY-DWELLING ADULTS WITH SCHIZOPHRENIA IN KOREA

Seon-Young Hwang¹, Yu-Mi Song², Pil-Hwa Heo³, Sra Kim¹, Katherine Cahir*⁴, Heeyoung Lee⁴

¹Hanyang University, ²Hanmaeum Independent Living House, ³Seongbuk Community Health Center, ⁴University of Pittsburgh School of Nursing

Background: Cardiovascular disease (CVD) is a leading cause of death and is prevalent among individuals with severe mental illness (SMI), such as schizophrenia. The incidence of metabolic syndrome, a cluster of CVD risk factors, is found to be two to three times higher in individuals with SMI compared to the general population, partly due to unhealthy lifestyle behaviors. Notably, the death rates of people with SMI aged 50–75 have a nearly two-fold increased risk of CVD. Given the significant health disparities and elevated CVD risk among people with SMI, the purpose of this study is to compare patient characteristics and cardiovascular health behaviors by age group (i.e., those under the age of 50 and those aged 50 or older) living in the community to inform the development of interventions tailored to the unique needs of individuals with schizophrenia.

Methods: A cross-sectional observational design was employed, and participants were recruited from 13 mental health service centers in Korea. Inclusion criteria comprised individuals: a) diagnosed with schizophrenia/schizoaffective disorder based on DSM-5 criteria; b) aged 30 years and older, capable of communication, and willing to participate; c) who signed the consent form; and d) for those residing in group homes, they had to have lived there for more than three months. Excluded from the study were individuals with cognitive decline, communication difficulties, or intellectual disabilities. Data were collected with a survey for demographic and clinical information and standardized instruments, including dietary habit attitude, the International Physical Activity Questionnaire (IPAQ), and cardiovascular health behaviors. Descriptive statistics, t-test, and one-way ANOVA were employed.

Results: A total of 237 participants completed the surveys. Of these, 133 (56.1%) were aged under 50, while 104 (43.9%) were aged 50 or older. There were 67 (50.4%) males and 66 (49.6%) females under the age of 50. In the 50 or older age group, there were 41 males (39.4%) and 63 (60.6%) females. One hundred sixteen participants lived in group homes. Both groups exhibited similar behavioral patterns of smoking, alcohol drinking, snack intake, and physical activity (ps GREATER THAN .05). Of those under age 50, 33% reported having medical conditions such as hypertension, diabetes, dyslipidemia, or angina, while 45.2% of those aged 50 or older had medical conditions (ps GREATER THAN .05). Participants aged 50 or older were taking medications for their medical conditions, while 27.8% of participants under 50 were taking medications for their medical conditions (p=.02). Among participants aged 50 or older, their engagement in cardiovascular health behaviors and dietary habits attitude were significantly higher compared to those under 50 (ps LESS THAN .05).

Discussion: More attention is warranted for individuals under the age of 50 with schizophrenia, as they do not engage in health-promoting behaviors. These findings highlight

the importance of implementing education and early behavioral interventions to promote a healthy lifestyle and encourage regular follow-ups with health care providers to effectively manage cardiovascular risks among people with schizophrenia.

T245. LONG TERM EVALUATION ABOUT THE MAINTAIN OF HIGH INTENSITY INTERVAL TRAINING EFFECTS ON PSYCHOTIC DISORDERS

Lucie Venet-Kelma*¹, Amal Abdel-Baki², Ahmed Jérôme Romain¹

¹*University of Montreal*, ²*Centre Hospitalier de l'Université de Montréal*

Background: Physical inactivity is one of the factors in the reduction of life expectancy in people with psychotic disorders. This physical inactivity occurs because of the psychotic disorders expression that leads to limitation in the daily life, poor lifestyle habits, and associated diseases. Physical inactivity is explained by barriers to physical activity (PA) and by the lack of commitment to long-term autonomous practice. PA improves overall physical and mental health, but approximately 30% of people with psychotic disorders drop out of the PA intervention in which they were engaged. The aims were to examine the long-term HIIT exercise effect among people with psychotic disorders six months after participation to an exercise intervention, and to determine which predictors could facilitate participation in PA and thus, reduce dropout.

Methods: A sample of 66 individuals included (37.9% of women, 30.73 ± 7.23 years old), with psychotic disorders were subjected to a 6-month interval training of running on a treadmill, twice 30 minutes per week, after which they had free access to the facilities used. Data from individuals who participated to the PA intervention ($n = 66$) with psychotic disorders were analyzed by a linear mixed model at three times: in baseline, after the 6-months intervention and follow-up period 6 months after the end of the intervention (12 months after baseline). The measures concern the evaluation of positive, negative, and general symptoms with the Positive And, Negative Syndrome Scale (PANSS), as well as overall functioning with the Global Assessment Functioning (GAF) and social functioning with the Social and Occupational Functioning Assessment Scale (SOFAS).

Results: After cessation of the intervention, the results showed a maintenance of benefits in negative ($p = 0.004$) and general ($p = 0.01$) symptoms. Otherwise, regarding the predictors of PA participation, results demonstrated that individuals who participated in less than 64% of the sessions were those with a lower level of global ($p=0.02$) and social ($p=0.00$) functioning and had more severe symptoms (PANSS) (negative: $p=0.02$; positive: $p=0.01$; general: $p=0.04$).

Discussion: The benefits observed were maintained in terms of negative and general psychopathology symptoms, which leads us to believe that the intervention needs to be improved in its modes of action to achieve greater maintenance of benefits. Otherwise, both global and social functioning, as symptoms severity were associated with PA participation. These elements should be considered to reduce dropout in future PA interventions, and encourage the reinvestment of good practices daily to maintain the benefits of PA.

T246. PREVENTION AND PREDICTION OF RELAPSE IN SCHIZOPHRENIC PATIENTS: RCT RESULTS ON INTEGRATIVE COGNITIVE REMEDIATION DURING 8-YEAR FOLLOW-UP

Daniel Mueller*¹, Rosa Mueller-Szer², Linda Grossenbacher¹

¹University Hospital of Psychiatry and Psychotherapy/University of Bern, ²Cantonal Hospital, Departement of Oncology and Cantonal Psychiatry Hospital (RFSM/FNPG), Fribourg

Background: Relapses are a major burden for schizophrenic patients, their relatives and caregivers. Preventing and predicting relapses is therefore a serious challenge for psychiatric treatment.

Methods: In the present RCT study, the relapse prevention potential after a psychotherapeutic intervention in addition to standard treatment was investigated over 8 years. The used psychotherapy approach was Integrated Neurocognitive Therapy (INT), a group approach with interventions in 11 neuro- and social-cognitive domains, which are partly PC-supported including therapy elements from psychoeducation, CBTp and emotion as well as stress regulation. 71 outpatients with schizophrenia (diagnosed according to ICD-10) were assigned to either an INT group (30 sessions over 15 weeks) or a standard treatment (TAU). Relapse rates were evaluated during follow-up periods of 1, 5 and 8 years. A test battery was collected before and after treatment and at the 1-year follow-up.

Results: The relapse rates for INT and TAU did not differ significantly in the first year. 5 and 8 years after the end of treatment, the relapse rates for INT (48%/52%) were significantly lower than for TAU (77.8%/82.8%). Rehospitalization days differed significantly too (8-year follow-up: INT=34.8 days; TAU=102.4 days). Predictors: During the 1-year follow-up, there was a significant correlation between higher relapse rates and lower social-cognitive performance levels (emotional processes, schemas). Relapse rates in the first year after completion of treatment predicted the course of relapses and rehospitalization days during the 5- and 8-year follow-up. At the 5- and 8-year follow-up, higher symptomatology, particularly positive symptoms, as well as higher levels of psychosocial functioning and verbal (working) memory were also found to be predictors of reduced rehospitalization days.

Discussion: There seems to be evidence that INT can significantly reduce relapses and thus the days of rehospitalization compared to TAU over a longer observation period of 8 years. Predictors for this appear to be relapse rates, positive symptoms, psychosocial functioning and working memory after a 1-year follow-up.

T247. DOES GENDER MATTERS IN THERAPEUTIC ALLIANCE? EXPLORING PATIENT-THERAPIST DYADS IN SCHIZOPHRENIA SPECTRUM DISORDER

Giovanni de Girolamo*¹, DIAPASON Consortium²

¹IRCCS St. John of God Clinical Research Centre, Brescia, ²IRCCS St. John of God Clinical Research Centre

Background: Despite the importance of therapeutic-alliance (TA), evidence regarding the impact of gender and gender correspondence in therapist-patient pairs on the alliance is limited and varied, especially for patients with severe mental disorders. This research aims to fill this gap by specifically analysing the influence of gender and gender correspondence on the levels and in TA, assessed using the Working Alliance Inventory (WAI) completed by both patients and therapists, within a sample of patients with schizophrenia spectrum disorder (SSD).

Methods: Besides a number of assessment tools covering psychopathology (BPRS and BNSS), psychosocial functioning (SLOF), time perception (ZTPI), each patient completed the Working Alliance Inventory short-form (WAI-SF) for patients (WAI-P) and was asked to

rate a specific staff member with he/she had a "one-to-one" therapeutic relationship defined as "case manager" by care setting. Similarly, each staff member completed the WAI short form for staff (WAI-T) for up to 3 different patients they were caring for. The WAI-SF includes 12 items that can be rated on a 7-point Likert scale, from 1 ("never") to 7 ("always"), with a total score ranging 12 to 84, with higher scores indicating a greater WA: three subscales measuring the three domains of WA can be computed: (a) agreement between patient and therapist about treatment goals (Goals); (b) agreement between patient and therapist on tasks to achieve these goals (Task); and (c) quality of the bond between patient and therapist (Bond). The discrepancy between therapist and patient assessments of the working alliance was computed by subtracting the therapist ratings from the patient ratings on the WAI. WAI-P and WAI-T scores, both total scores and subscales, were stratified by gender dyad groups: male patients with male therapists, male patients with female therapists, female patients with male therapists, and female patients with female therapists. We tested the differences between dyads using Anova and paired t-tests. To further understand the association of gender and gender correspondence with patient-reported scores (WAI-P) and therapist-reported scores (WAI-T), we constructed linear regression models.

Results: The WAI total score, as well as the subscale scores did not significantly differ between gender-based dyads, neither at the therapists nor at the patients' evaluations. Gender correspondence had a significant positive effect on the WAI-P task ($p = 0.030$), with a coefficient of 1.312, while no other significant associations were identified. In the complex model, the gender of patients and therapists interacted with a significant positive effect when both are male ($p = 0.013$), resulting in a coefficient of 3.893. There were no significant differences between patient and staff ratings across dyads; however, male patients had higher Goal ratings compared to both, their paired female ($M=20.4$; $SD=5.0$, vs. $M=19.5$; $SD=3.6$; $p = .022$) and male therapists ($M=21.1$, $SD=4.5$, vs. $M=19.5$; $SD=3.8$; $p = .034$). In linear regression analyses testing the effect of gender and gender correspondence on WAI scores, neither the patient nor the therapist gender was associated with the WAI-P or with the WAI-T total scores, nor with the majority of the WAI subscale scores in patients or staff evaluations after adjustment for levels of psychopathology. The only exception was the significant association between gender correspondence within the dyad and a higher WAI-P task score ($\beta=1.31$; $p=0.03$), and in particular in the case of male patient/male therapist dyad ($\beta=3.89$; $p=.013$) (Table 3).

Discussion: This study examined the relationships between gender and gender correspondence within a therapeutic dyad, and the working alliance in patients with SSD and their treating therapists. The main findings are those of no effects of gender on the levels of working alliance as assessed with the WAI by patients or therapists. Additionally, we found that gender correspondence within the dyad had limited effects on WAI ratings, with the only exception of higher scores on the Task dimension of the WAI-Patient in case of a male dyad. Similarly, gender and gender correspondence had only marginal influence on agreement in alliance between patients and therapists, with male patients scoring their alliance, and in particular their Goal levels relatively higher than their therapists. The best agreement between patients' and therapists' scores was found especially in case of female patients, and in particular in the female-female dyad, while the poorest levels of agreements appeared in case of male patients. This study is among the first to examine the role of gender and gender matching in shaping WA among patients with a diagnosis of SSD and living in a residential facility. Gender and gender correspondence seem to have only marginal effects on the task dimension of the working alliance as perceived by the patients. Although the female patient - female therapist dyad appeared to show the best agreement in alliance, male patients seemed to perceive their WA stronger than their therapists. The dimensions mostly affected by gender/gender correspondence were those of goals and tasks, suggesting that a clear

agreement on therapeutic goals and tasks is recommended, especially when working with SSD patients.

T248. WORKING ALLIANCE IN TREATING STAFF AND PATIENTS WITH SCHIZOPHRENIA SPECTRUM DISORDER LIVING IN RESIDENTIAL FACILITIES

Giovanni de Girolamo*¹, DIAPASON Consortium²

¹*IRCCS St. John of God Clinical Research Centre, Brescia*, ²*IRCCS ST. John of God Clinical Research Centre*

Background: Working Alliance (WA) is an important aspect of treatment for patients with Schizophrenia Spectrum Disorders (SSD). Establishing a therapeutic alliance in care settings with patients with SSD can be challenging due to their difficulties in building positive interpersonal relationships. A recent systematic review highlighted the role played by specific characteristics of patients with SSD in the therapeutic alliance assessments of both patients and therapists. Specifically, negative symptoms, younger age, and poor pharmacological treatment adherence seem to impact therapeutic alliance ratings. Positive symptoms, particularly paranoia, may also limit the establishment of a collaborative approach. Understanding the factors associated with better therapeutic alliance is crucial for implementing therapeutic programs and improving clinical outcomes, as well as reducing drug prescriptions and hospitalization risk. In the multicentre project on "Daily time use, Physical Activity, quality of care and interpersonal relationships in patients with SSD" (DiAPASon) data on WA were collected in people with SSD and staff members in their daily care. The present study aimed to (a) analyze the correlation between patient and staff WAI ratings; (b) identify socio-demographic and clinical variables associated with WA in patients and staff; and (c) examine factors associated with profiles of high vs. low WAI-rating discrepancy in the patient-therapist dyads.

Methods: Besides a number of assessment tools covering psychopathology (BPRS and BNSS), psychosocial functioning (SLOF), time perception (ZTPI), each patient completed the Working Alliance Inventory short-form (WAI-SF) for patients (WAI-P) and was asked to rate a specific staff member with he/she had a "one-to-one" therapeutic relationship defined as "case manager" by care setting. Similarly, each staff member completed the WAI short form for staff (WAI-T) for up to 3 different patients they were caring for. The WAI-SF includes 12 items that can be rated on a 7-point Likert scale, from 1 ("never") to 7 ("always"), with a total score ranging 12 to 84, with higher scores indicating a greater WA: three subscales measuring the three domains of WA can be computed: (a) agreement between patient and therapist about treatment goals (Goals); (b) agreement between patient and therapist on tasks to achieve these goals (Task); and (c) quality of the bond between patient and therapist (Bond). The discrepancy between therapist and patient assessments of the working alliance was computed by subtracting the therapist ratings from the patient ratings on the WAI.

Results: The final sample assessed with the WAI includes 303 patients and 165 health workers. Pearson's correlation showed a statistically significant positive correlation ($p=.314$; p LESS THAN .001) between WAI-P and WAI-T total ratings. WAI-P total ratings also correlated significantly with all WAI-T subscales [Task ($p=.332$; p LESS THAN .001); Goals ($p=.295$; p LESS THAN .001); Bond ($p=.209$; p LESS THAN .001)]. Also, WAI-T ratings were significantly and positively correlated with WAI-P subscales [Task ($p=.301$; p LESS THAN .001); Goals ($p=.249$; p LESS THAN .001); Bond ($p=.277$; p LESS THAN .001)].

Similarly, all WAI-P subscales were significantly and positively correlated with WAI-T subscales even after Bonferroni correction, except for the correlation between WAI-T Bond subscale and WAI-P Goals subscale ($p=.145$; $p=.014$). Linear regression showed that patients with higher educational levels reported significantly lower ratings at WAI-T ($\beta=-0.50$, $p=.044$): for each education year, WAI-P rating decreased by 0.5 points. As for patients' socio-demographic factors associated with WAI-T, linear regression analysis revealed that being in a not working or studying condition was associated with significant lower total WAI-T ratings ($\beta=-4.17$, $p=.015$). The severity of psychopathology, as assessed with BPRS and BNSS, was negatively associated with both WAI-T ($\beta=-0.10$, $p=.002$) and WAI-P total ratings ($\beta=-0.19$, p LESS THAN .001). The level of functioning, measured using SLOF, was positively associated with both WAI-P ($\beta=0.12$, p LESS THAN .001) and WAI-T total ratings ($\beta=0.14$, p LESS THAN 0.001).

Discussion: First, patients with higher levels of education reported significantly lower scores on the WAI-P, suggesting a possible link between the patient's level of education and successful WA. Secondly, patients who were not involved in work or study had significantly lower scores on the staff WAI (WAI-T): this may suggest that if the patient is involved in productive activities, this may facilitate a good therapeutic alliance from the therapist's perspective. Furthermore, patients with shorter hospitalizations (LESS THAN 1 year) reported higher WAI-P scores than those with longer hospitalizations (GREATER THAN 5 years), suggesting that prolonged hospitalization may be associated with a negative effect on goal sharing through tasks and the development of a valuable therapeutic alliance. Furthermore, while the severity of psychopathology was inversely correlated with both WAI-P and WAI-T scores, the level of psychosocial functioning showed a positive correlation with both scores. This highlights the contrasting roles of clinical severity and psychosocial factors in assessing the therapeutic alliance between patients and staff.

T249. PSYCHOLOGICAL AND PSYCHOSOCIAL INTERVENTIONS FOR TREATMENT-RESISTANT SCHIZOPHRENIA: SYSTEMATIC REVIEW AND NETWORK META-ANALYSIS

Nurul Salahuddin^{*1}, Alexandra Schütz², Gabi Pitschel-Walz¹, Susanna Mayer¹, Anna Chaimani³, Josef Priller¹, Stefan Leucht¹, Irene Bighelli¹

¹Technische Universität München, ²Ludwig-Maximilians-Universität München, ³Paris Descartes University

Background: Many patients with schizophrenia do not respond satisfactorily to pharmacological treatments. Additional treatment options, such as psychological and psychosocial interventions, could be useful as add-on treatments. However, their role and comparative efficacy in this population are not known. We, therefore, investigated the efficacy, acceptability, and tolerability of psychological and psychosocial interventions for individuals with treatment-resistant schizophrenia (TRS).

Methods: We included randomized controlled trials (RCTs) comparing psychological or psychosocial interventions in adults with TRS. The main outcome was overall symptoms measured with validated and published rating scales. To investigate the eligible studies from the inclusion criteria, we searched for all RCTs by performing a systematic database search on BIOSIS, CINAHL, Cochrane CENTRAL, Dissertation Abstracts, EMBASE, LILACS, MEDLINE, PsycINFO, ClinicalTrials.gov and WHO International Clinical Trials Registry Platform up to 31.01.2020, the Study registry of Cochrane Schizophrenia Group up to 31.03.2022 and PubMed and CENTRAL up to 31.07.2023. Random effects pairwise meta-

analyses and network meta-analyses have been performed to calculate standardized mean differences (SMDs) or risk ratios (RRs) with 95% confidence intervals (CIs). The study protocol was registered in PROSPERO with the number CRD42022358696.

Results: We included 60 RCTs that were eligible for qualitative synthesis after excluding 24526 records by title and abstract screening and 5540 records at full-text screening. Of these, 52 RCTs with 5812 participants comparing 20 psychological and psychosocial interventions provided data for network meta-analysis. When compared to treatment as usual with 95% CIs, we found that music therapy, integrated intervention, occupational therapy, virtual reality intervention, and cognitive behavioral therapy (CBT) were more efficacious in reducing overall symptoms. The confidence in the estimates ranged from moderate to very low. We found no indication of publication bias.

Discussion: CBT is a promising intervention to reduce the overall symptoms of TRS patients. Other psychological and psychosocial interventions could also be considered and recommendable for further investigation.

T250. COMPARING THE EFFECTS OF COGNITIVE RESTRUCTURING, COGNITIVE DEFUSION, AND THOUGHT MONITORING ON VOICE-HEARING DISTRESS IN PSYCHOSIS

Talia Leibovitz*¹, Michael Best¹

¹*University of Toronto Scarborough*

Background: Cognitive Behavioural Therapy for psychosis (CBTp) is effective to reduce symptoms of psychosis but effects are typically only moderate. To improve the efficacy of CBTp, it is critical to determine the mechanisms of change. Cognitive restructuring is a commonly used approach in CBTp and is hypothesized to generate therapeutic change. Cognitive defusion is a technique used to change the relationship an individual has with their thoughts or beliefs whereas cognitive restructuring targets the content of one's beliefs. Neither cognitive restructuring or cognitive defusion have been examined as a mechanism of CBTp, therefore it is unclear what approach to working with cognitions is most effective in psychosis. The current study evaluated the effectiveness of cognitive restructuring (CR), cognitive defusion (CD), and thought monitoring (TM) in reducing the distress of auditory verbal hallucinations (AVH).

Methods: Participants were randomly assigned to a therapeutic exercise condition: CR, CD, or TM. A graduate clinical psychology student guided participants through their assigned therapeutic exercise with an equivalent worksheet modified across conditions. The Hamilton Program for Schizophrenia Voices Questionnaire (HPSVQ) and Global Rating of distress were used to measure AVH-related distress. The Brief Mood Introspection Scale (BMIS; Mayer and Gaschke, 1988) was used to measure mood, the CHoice of Outcome In Cbt for psychosEs measure – Short Form (CHOICESF) to measure CR ability, and Cognitive Fusion Questionnaire (CFQ) to measure cognitive fusion. Following the therapeutic exercises, each participant was asked to provide feedback about the exercise to gather qualitative data.

Results: Twenty-six participants (CR = 8, CD = 9, TM = 9) with a psychotic disorder and distressing AVHs completed the study. There were no significant time by group interactions on HPSVQ distress ($F(2,23) = 0.85$, $p = .442$, $\eta^2p = .07$), global distress ($F(2, 23) = 1.18$, $p = .327$, $\eta^2p = .09$), CR ability ($F(2, 23) = 0.15$, $p = .863$, $\eta^2p = .01$), or cognitive fusion ($F(2, 23) = 1.41$, $p = .265$, $\eta^2p = .11$). There were no significant main effects of condition or time on HPSVQ distress, global distress, cognitive fusion, or cognitive restructuring ability. Exploratory paired t-tests demonstrated a significant difference between pre and post-

intervention HPSVQ distress for the CR group ($M_{diff} = 2.13$, 95% CI [1.08, 3.17], $t(7) = 4.82$, $p = .002$), however, not for the global distress ratings ($M_{diff} = 10.47$, 95% CI [-5.51, 26.45], $t(7) = 1.55$, $p = .165$). Differences between pre- and post-intervention HPSVQ and global distress scores were not significant for the CD and TM groups. Cognitive fusion pre-intervention was significantly correlated with mood ($r = -.64$, $p < .001$) and global distress ($r = .49$, $p = .012$) at baseline. CR ability (CHOICE-SF) was significantly correlated with mood (BMIS; $r = .57$, $p = .002$), however, not with HPSVQ ($r = -.10$, $p = .633$) or global distress measures ($r = -.25$, $p = .224$) at baseline. Qualitative feedback was available for 22 of the 26 (TM = 8, CD = 8, CR = 6). Positive feedback was provided by seven participants in the TM group, five participants in the CD group, and all participants in the CR group. Negative feedback was provided by one participant in the TM condition, three participants in the CD condition, and no participants in the CR condition.

Discussion: The exploratory and qualitative results suggested that CR may be effective at reducing voice-related distress; however, further examination is required. Qualitative feedback suggested that the CD milk exercise may actually increase distress for some individuals. Further research may be warranted to examine the differential effects of CBTp techniques to reduce voice-related distress.

T251. REWARD LEARNING AS A POTENTIAL MECHANISM FOR IMPROVEMENT FOLLOWING COGNITIVE REMEDIATION: A PILOT STUDY OF SCHIZOPHRENIA AND HEALTHY CONTROLS

Frances Dark^{*1}, Gabrielle Ritchie², Graham Galloway³, Matteo Cella⁴, Veronica De Monte⁵, Victoria Gore-Jones⁵, Marcus Gray³

¹*Metro South Addiction and Mental Health Services*, ²*Metro South addiction and Mental Health Service*, ³*Translational Research Institute, Brisbane, Australia*, ⁴*Institute of Psychiatry, Psychology and Neuroscience, King's College London*, ⁵*Metro South Addiction and Mental Health Services*,

Background: Cognitive remediation (CR) therapy is routinely used as a treatment for cognitive impairments and functional difficulties in people with schizophrenia. However, little is known about the mechanism of action. It is proposed that a potential mechanism of effect of CR is the engagement of the reward learning pathways with associated enhanced behavioural motivation and improved functioning.

Methods: This is a pre-post pilot study examining the impact of CR on reward learning and neurocognition. Ten participants aged between 18 to 35 years ($M = 26.1$ years, $SD = 5.30$), diagnosed with a schizophrenia spectrum disorder, completed a reward learning task with two conditions (social reward vs. non-social reward) during functional magnetic resonance imaging (fMRI) before and after 12 weeks of CR. To validate this task, reward learning was also assessed in 10 healthy controls, matched to patients for age, sex, and premorbid function. Neural differences reflecting modality (social v non-social learning) valence (reward vs loss feedback) and group (control, patients pre-CR, patients post-CR) were examined [see figure 1A]. All neural findings are corrected for inflated type 1 error reflecting multiple comparisons.

Results: Paired samples t-tests analysed the neurocognitive measures pre and post CRT intervention. The Benjamini-Hochberg correction to adjust for multiple comparisons was applied and maintain the false-discovery rate at .25. Participants improved significantly on tasks of verbal memory (adjusted $p = .014$) and executive function (adjusted $p = .028$) after

CR. Neural function clearly differentiated modality (social versus non-social learning) particularly within visual and face processing regions. Likewise neural responses clearly differed by valence (reward vs loss feedback within the default mode network and group (increased right temporal cortex responses within patients. Finally we observed a significant 3-way interaction (group x valence x mode) within the anterior cingulate and basal ganglia, with patients showing reduced responses to negative social feedback.

Discussion: Our pilot results demonstrate positive effects in people with schizophrenia spectrum disorder following Cognitive Remediation therapy, with initial results suggesting improvements in executive function and verbal working memory. Our reward learning task clearly demonstrates neural systems reflecting sensitivity to positive versus negative feedback, social versus non-social learning context, and differential cortical responses within schizophrenia spectrum disorder relative to control participants. Moreover, these neural systems appear to interact, reflecting reduced sensitivity to negative social feedback in people with schizophrenia spectrum disorder. Recruitment of participants, and further analysis of the impact of CR on patterns of neural response is ongoing.

T252. STIGMATIZATION OF PEER SUPPORT WORKERS AND ASSOCIATED FACTORS: A PARTICIPATIVE STUDY

Adrien Seguela*¹, Antoinette Prouteau²

¹*University of Bordeaux 2*, ²*University of Bordeaux, Human Sciences College and Department of Adult Psychiatry, Jonzac Hospital*

Background: Mental health practices are shifting towards a recovery-focused model, emphasizing the values and needs of individuals facing mental health challenges and employing a collaborative approach. Peer support is increasingly recognized as a valuable tool to implementing person-centered, rights-based and recovery approaches (OMS, 2021). Notably, the benefits of peer-support are mainly related to personal recovery variables such as hope, empowerment and self-efficacy (Thomas et al., 2018; Burke et al. 2019). However, qualitative data (Adams, 2020; Lynn Ng and Barlas, 2023; Wall et al., 2022) and literature addressing the barriers to peer support work (Ibrahim et al., 2020; Mutschler et al., 2022) showed that peer workers can be the targets of stigmatization in their workplace. However, this study did not describe the specific situations of stigmatization experienced by peer support worker and do not provide data on the associated lived experiences. This study aims to i) identify stigmatizing situations experienced by peer workers on their workplace ii) describe the frequency and the intensity (i.e. the level of stigma experienced) of these situations as reported by peer workers, iii) identify factors associated with these occurrences.

Methods: Initially, a focus group-like methodology was conducted with nine peer workers in order to collaboratively identify the most relevant situations of stigmatization experienced. Subsequently, based on these identified situations, an online survey will be disseminated among mental health professionals (e.g. peer workers, psychiatrists...) to quantify the frequency and the intensity of the stigmatization experienced by peer workers and explore associated factors. We hypothesize that peer workers will experience the stigmatizing situations i) more frequently and ii) with a higher degree of stigmatization than the other mental health professionals.

Results: The focus group allowed the identification of 34 situations experienced as stigmatizing by the peer workers. A collaborative work was done in order to reformulate and select the most relevant of them. Peer workers reported experiencing stigmatization at several levels such as structural (i.g. lack of access to tools, resources, and support needed to

accomplish the job), interpersonal (i.g rejection for collaboration, infantilization, skills disqualification) or internal (i.g. anticipation and self-stigma during job interview, setback during team meetings). The online survey will be disseminated among mental health professionals and results will be presented at the Schizophrenia International Research Society in 2024.

Discussion: This study will allow to identify the stigmatizing situations (and associated factors) experienced by peer workers in the mental health workplace. This contribution would highlight that stigmatization in the mental health workplace extends to peer support. This evidence could be exploited to facilitate and support the implementation of peer support workers. Finally, the identification of associated factors will provide relevant leverage to reduce the stigmatization of peer support workers.

T253. WISH LIST TO CLINICIANS AND RESEARCHERS FROM PEOPLE WITH LIVED EXPERIENCE OF BIPOLAR DISORDER

Cecilie Busch*¹, Isabel Kreis², Margrethe Collier Høegh³, Torill Ueland³, Carmen Simonsen⁴, Sofie R Aminoff⁴, Elizabeth Ann Barrett⁴, Thomas Bjella³, Ingrid Melle², Trine Vik Lagerberg³

¹Norwegian Centre for Mental Disorders Research (NORMENT), Psychosis Research Section, Oslo University Hospital, ²Norwegian Centre for Mental Disorders Research (NORMENT), Institute of Clinical Medicine, University of Oslo, ³Norwegian Centre for Mental Disorders Research (NORMENT), Psychosis Research Section, Oslo University Hospital, ⁴Early Intervention in Psychosis Advisory Unit for South East Norway, Clinic of Mental Health and Addiction, Oslo University Hospital,

Background: Despite national guidelines for the treatment of bipolar disorder and a substantial amount of research conducted in the field, we know less about what people with bipolar disorder actually want. People with lived experience can contribute to research through providing valuable input on what areas to focus on, and through increasing awareness of what is actually helpful treatment. With this in mind, we conducted an online survey asking people with lived experience of bipolar disorder what help they want from clinicians and what research questions they find important.

Methods: An online survey entitled “Wish list to clinicians and researchers from people with bipolar disorder” was distributed through posts on NORMENT’s and the Norwegian Bipolar Association’s Facebook profiles. The survey was open from the International Bipolar day 30.03.23 to 16.04.23. For the wish list to clinicians the participants were asked: “As of today: what do you wish a clinician could help you with?”. Survey alternatives included 16 pre-defined response options regarding treatment and two possibilities of not needing/wanting treatment. Each participant could tick off 1 to 3 topics. For the wish list to researchers the participants were asked: “What do you wish there was more research on?” The survey alternatives included 20 pre-defined research topics, and participants were asked to rate them on a scale from 1 (unimportant to me) to 5 (very important to me). In addition, participants were given the opportunity to provide personal comments about which topic was most important to them in both sections.

Results: There was a total of 416 responders, 80% women and 17% men, 3 % non-binary. Three of four respondents were between 26 and 55 years old. For the wish list to clinicians the following five alternatives were rated highest: a) Stabilization of depression, mania, psychosis or suicidal thoughts (27,2 %) b) Teach me to cope with, and stabilize, my emotions

(24,5 %), c) Help me to process trauma (24,5 %), d) Teach me to cope with stress (23,8 %), e) Increase my awareness of triggers and warning signs (23,3 %). For the wish list to researchers three topics were rated particularly high relative to other items: a) The association between BD and cognitive functions (M=4.58, 68.5 % of the respondents rated this item 5), b) More effective medication with less side effects (M=4.56, 73.1 % rated this item 5), c) What has been helpful to those who have recovered (M=4.54, 67.1 % rated this item 5). The remaining items were ranked M=4.21 and below. Examples of comments were: “A lot of side effects. And they reduce the quality of life”, “Knowing that I am slow because of my disorder, and not stupid, would prevent me from ruminating and becoming depressed”, “Gives me Hope!” and “The more research, the more informed we get”.

Discussion: Participants’ wishes to clinicians appear to align well with the Norwegian treatment guidelines for bipolar disorder, although the survey indicates that not everyone receives such treatment. Interestingly the participants’ top four wishes for clinical help, can be viewed as expressions of emotional suffering. With regard to research, the three most highly rated topics can be viewed as the responders need for knowledge both for themselves and for the clinicians. The wish for more effective medication with fewer side effects is well known, underlining the urgency of precision medicine. For cognition, there were many comments related to its detrimental effect on functioning and quality of life, highlighting the need for increased focus on cognition in the clinic. The fact that people with bipolar disorder want to learn from others that have recovered, can be viewed as a need for hope and inspiration in a lifetime disorder.

T254. ‘MUSIC MATTERS’ – A QUALITATIVE EVALUATION OF A NURSE-LED STRUCTURED, GROUP-BASED MUSIC PROGRAM COMPLEMENTARY TO EARLY INTERVENTION IN PATIENTS WITH FIRST-EPISODE PSYCHOSIS

Signe Marie Abild¹, Sofie Schuster¹, Julie Midtgaard*¹

¹*University of Copenhagen*

Background: Schizophrenia is a severe mental illness that exerts lasting effects on functional levels, social withdrawal, and quality of life. While music therapy has demonstrated promise in improving these areas, there is a dearth of research exploring the impact of music programs led by mental health care professionals without formal music therapy training in the context of early intervention in psychosis. This study aimed to conduct a qualitative evaluation of a once-weekly, 12-week, nurse-led music group, forming a band, offered as an adjunct to early intervention for young people experiencing first-episode psychosis. The specific objectives were to explore social interaction and the experiences of participants and instructors in relation to the music group and to provide focal points for implementation in clinical practice.

Methods: We applied an Interpretive Description methodology approach including a combination of data collection methods and sources. We combined key informant interview (n=1), group and email-based interviews (n=6), and participant observation (6 sessions x 1.5 hrs; 9 hrs in total), to ensure a comprehensive understanding reflecting the complexity of the program. The data were transcribed, thematized, and analyzed inductively using NVivo12 to facilitate deeper insight and an understanding of the music group in a clinical practice setting. Data was generated between June 2022 and February 2023.

Results: A total of ten participants, comprising eight service users and two employees, were included. The analysis resulted in three main themes: Practicalities of the music program, Restored identity, and Music as medicine, reflecting the potential of the music group to contribute to a sense of non-patient identity, decrease symptoms related to mental illness, and

create a sense of belonging to a musical community. Specifically, participants recounted enrolling in the music program to revive their musical interest and reconnect with their past. Being in a band provided them with roles like guitarist, pianist, or singer, offering a contrasting identity to their illness. Additionally, some noted that the music sessions boosted their well-being and mood regulation including provided room for a feeling of connection to their inner emotions. For some, engaging with an instrument's rhythm and beat acted as a calming distraction from anxiety.

Discussion: This study investigated the impact and delivery of an ongoing, nurse-led music group in the context of treatment of first-episode psychosis. The findings suggest that such groups could provide a structured way for patients to connect socially through a shared, non-clinical activity. Specifically, our study suggests that supervised music sessions among peers, guided by skilled mental health staff, hold promise in helping participants manage their thoughts and alleviate anxiety-related symptoms. Hence, participation in music groups can potentially promote recovery. In this regard, it is imperative that the music-setting should be promoted as a non-therapeutic, non-clinical setting, offering the participants an identity as musicians rather than patients. Moreover, to create a reliable environment, each session must be built around the same recognizable structure to decrease anxiety, but with the possibility of adapting the content of the sessions to accommodate the individual needs of the participants. However, it should be emphasized that while the current study offers suggestions on how to organize music as a complementary intervention in the treatment of early psychosis, it does not provide definitive answers related to effectiveness.

T255. CHARACTERIZATION, HEALTH CARE RESOURCE UTILIZATION (HCRU), AND COST OF US MEDICAID PATIENTS WITH NEGATIVE SYMPTOMS IN SCHIZOPHRENIA

Claudia Hastedt*¹, Theresa Cassidy², Ling Zhang²

¹Boehringer Ingelheim International GmbH, ²Boehringer Ingelheim Pharmaceuticals, Inc.

Background: Persistent negative symptoms (NS) of schizophrenia (SZ) place a significant burden on patients. Often underdiagnosed, NS have a huge impact on functioning and quality of life for people living with schizophrenia. This retrospective real-world evidence study in the US investigated if patients diagnosed with NS utilize more health care services and incur higher treatment costs compared to SZ patients without a NS diagnosis.

Methods: SZ and the NS patients were identified using administrative claims data from the Merative™ MarketScan® Multi-State Medicaid Database based on schizophrenia diagnoses (ICD10 F20, ICD9 295) and diagnoses of residual schizophrenia with negative symptoms (ICD10 F20.5, ICD9 295.60). The study included adult patients (≥18 years) with at least one year of SZ history during 2017 to 2020. The index date was determined as the first SZ diagnosis date or NS diagnosis occurring after one year of SZ history. A non-NS cohort was created that included SZ patients without any NS diagnosis during the 4-year study period to calculate more accurate cost differences between diagnosed NS patients and the overall SZ patient cohort. Propensity score matching (PSM) with a 1:1 ratio at 0.2 caliper without replacement method was used to balance the NS versus non-NS cohort based on age, sex and history of disease. Cost in USD in the year after index date was reported. After PSM, a generalized linear model with gamma distribution log link function was applied to estimate the cost difference between cohorts.

Results: The study included 81,681 SZ patients and 2,181 (2.7%) with a NS diagnosis. Among the SZ patients, 77,906 had no NS diagnosis (non-NS). The mean (standard deviation

[SD]) age of the patients in the overall SZ patient cohort was 48.8 (15.1), with mean age of 52.1 (14.9) and 48.7 (15.1) in the in NS and non-NS cohorts, respectively. Male patients accounted for 59.1% of all SZ patients, 61.5% of NS patients, and 58.9% in the non-NS cohort. After controlling for demographic differences, the mean total cost in USD (sum of medical and medication cost) during the first year of follow-up after index date, was higher in NS patients: 45,344 (60,491) compared to matched non-NS patients 40,268 (55,282). Medical costs were the main cost driver for both NS 40,109 (58,444) and non-NS patients 36,031 (53,945). Medication costs were 5,235 (12,101) and 4,237 (9,848) in NS and non-NS patients, respectively. Cost analysis from a log gamma model showed a significant difference ($p < 0.001$) in the mean total cost between NS compared to non-NS patients with adjusted risk factors. Patients diagnosed with NS generated approximately 11% higher medical cost and 24% higher medication cost compared to patients without diagnosed NS. Mean outpatient (OP) medical cost observed in NS patients were higher than in matched non-NS patients: 32,718 (55,298) versus 31,457 (52,330). The largest cost driver of OP cost was from skilled nursing facility, accounting for 54% and 46% of the total OP cost in NS patients versus non-NS patients. This corresponded to mean costs of 17,583 (51,264) in NS patients compared to 14,615 (45,344) in non-NS patients. Inpatient (IP) cost and emergency room (ER) cost were also higher in NS patients compared to non-NS patients: 5,723 (18,987) versus 3,615 (15,025) for IP costs, and 1,667 (6,573), versus 960 (3,529) for ER costs.

Discussion: Medication and medical cost in SZ patients with NS were higher compared to patients without a NS diagnosis. These results confirm the high burden of NS on patients and the economic burden on the care system, highlighting the need for innovative care approaches for these patients.

T256. LONG-TERM POOR OUTCOME IN SCHIZOPHRENIA: A SYSTEMATIC REVIEW AND META-ANALYSIS WITH META-REGRESSION OF 20-YEAR FOLLOW-UP STUDIES

Ida-Marie Mølstrøm^{*1}, Julie Nordgaard², Annick Parnas³, Rasmus Handest³, Jonas Berge⁴, Mads Gram Henriksen⁵

¹Mental Health Center Amager, ²Mental Health Centre Amager, Department of Clinical Medicine, Faculty of Health Sciences, University of Copenhagen, ³Psychiatric Center Amager, ⁴Department of Clinical Sciences, Division of Psychiatry, Lund University, ⁵Mental Health Center Amager, Department of Clinical Medicine, Faculty of Health Sciences, University of Copenhagen

Background: Schizophrenia affects individuals in different ways. Some may experience more severe symptoms than others, resulting in significant problems with both their mental and social well-being. These impairments can lead to social isolation and, in extreme cases, homelessness. How do we best support and prevent individuals with severe schizophrenia from slipping through the cracks?

Methods: We conducted a systematic review and meta-analysis on long-term follow-up studies of schizophrenia until April 21, 2021. We included only prospective studies with at least 20 years of follow-up on patients diagnosed with schizophrenia, and the studies had to include face-to-face clinical evaluation. We analyzed the outcome in three groups: 'recovery,' 'good or better' (including 'recovery'), and 'moderate or better' (including 'recovery' and 'good

or better'). We used random-effects meta-analysis and meta-regression to examine the mean estimates and possible moderators.

Results: We included 14 studies (1,991 individuals) published between 1978 and 2020. These studies used different scales and definitions to measure the outcomes, and some used the same definition to describe different outcomes. To ensure a fair comparison of outcomes across studies, we created a unified template for outcome definitions and cutoffs based on earlier recommendations from other studies. We found that 40% of people with schizophrenia live with continuous poor outcome, including poor social function. 60% had good to moderate outcome, including 22.4% in recovery. Furthermore, the outcomes were unchanged over time.

Discussion: Despite extensive treatment and research, there is a significant portion of people with schizophrenia who continue to be severely affected by the disorder. Recovery and good outcome are certainly possible; schizophrenia remains a severe and complex mental illness. Despite a century of research and efforts to improve treatment, the prognosis shows limited change.

T257. DELUSIONAL DIMENSION AND COGNITIVE FLEXIBILITY: INTEREST OF ASSOCIATED SUBJECTIVE MEASURES WITH NEUROPSYCHOLOGICAL MEASURES TO STRENGTHEN THE RECOVERY PROCESS IN A PSYCHOSOCIAL REHABILITATION PATHWAY

Marie-Cécile Bralet*¹, Alexandre Durand², Alexandre Carpentier³, Marion Feron², CRISALID-HDF Team², Claire Rascle⁴

¹Service CRISALID-HDF CHI Clermont de l'Oise, ²Service CRISALID CHI Clermont de l'Oise, ³Service SPR CHI Clermont de l'Oise/UPJV, ⁴CSN2R -(MGEC-CHU)-Université Lille

Background: Psychosocial interventions are supported by substantial evidence of efficacy in many outcome measures. Rehabilitation interventions should be considered as an evidence-based practice and need to be a part of the standard treatment of schizophrenia. To improve functional recovery an integrated and multifaceted assessment approach could be proposed using clinical, neuropsychological and self-reporting tools during rehabilitation pathway. Self-reporting can enhance a patient's feeling of involvement in the recovery process, improving metacognition, self-esteem. The objective of this presentation is: firstly to describe the motivational and metacognitive approach used at the beginning of the psychosocial rehabilitation pathway in order to allow the patient to self-determine and engage in personalized psychosocial rehabilitation care; secondly, to illustrate this approach through the dimensional exploration of delusional conviction by studying the correlation between a self-reporting tool, PDI 21 and a neuropsychological measure of cognitive flexibility, TMT B, within a rehabilitation cohort

Methods: Description of the psychosocial rehabilitation pathway at the CRISALID-HDF Rehabilitation Dsychiatric Department (Clermont de l'Oise Psychiatric Hospital, Hauts de France area, France) in a cohort of 40 patients suffering from schizophrenia (DSM 5 criteria) describing the different steps with clinical and neuropsychological tools, using quantitative/semi-structured and patient centered assessments. Correlation analysis between PDI 21 inventory delusions, sub-score conviction and cognitive flexibility measured by TMT B (level of significance p LESS THAN 0, 05)

Results: We found a significant correlation between PDI 21 sub-score conviction and TMT B : 0, 37 (p= 0, 017).

Discussion: Using self-report/subjective measures combining to neuropsychological and clinical semi-structured assessments could improve motivation and metacognitive dimensions among people with schizophrenia engaged in recovery-oriented rehabilitation program. This multifaceted assessment approach must be evaluated regarding recovery criteria outcomes. Qualitative/subjective clinical tools may be more relevant to the evaluation of rehabilitative care.

T258. THERAPISTS AS KEY FACILITATORS IN EFFECTIVE COGNITIVE REMEDIATION: A BAYESIAN NETWORK META-ANALYSIS

Anika Poppe¹, Tim Brands², Tim van Brouwershaven³, Michael Thomas⁴, Antonio Vita⁵, Elizabeth Twamley⁶, Marieke (Gerdina) Pijnenborg⁷, Lisette Van der Meer^{*7}

¹Lentis Psychiatric Institute, ²LVR-clinic Viersen, ³Lentis Psychiatric Institute, ⁴Colorado State University, ⁵University of Brescia, ⁶Department of Psychiatry, UC San Diego and Center of Excellence for Stress and Mental Health, VA San Diego Healthcare System, ⁷University of Groningen

Background: Cognitive remediation (CR) is an intervention designed to target cognitive functioning such as attention, memory, executive functions, social cognition, and metacognition, with the intention of lasting benefits and transfer to everyday life. According to a recent consensus among experts, there are four core elements necessary for CR programs to be successful: (1) targeted cognitive exercises, (2) guidance by a specially trained therapist, (3) teaching of cognitive strategies, and (4) generalization procedures to extend training gains to real-world settings. This meta-analysis aimed to identify the most effective combination of these elements in improving the everyday functioning of individuals with schizophrenia.

Methods: We conducted a systematic search in the databases PubMed, Cochrane Library, and PsycINFO, and ClinicalTrials.gov for randomized controlled trials that included participants diagnosed with schizophrenia, implemented CR, and included a functional outcome measure. We performed two Bayesian random-effects network meta-analyses to compare the effects of CR with different combinations of the four core elements on functional outcome measures and cognitive outcome measures.

Results: The network meta-analyses included 86 studies (5982 participants) and revealed that three combinations of the core elements resulted in significant improvements in everyday functioning compared to treatment as usual: cognitive exercises plus therapist ($g = 0.25$, 95% CrI [0.01, 0.49]), cognitive exercises plus therapist and generalization procedures ($g = 0.38$, 95% CrI [0.09, 0.66]), and cognitive exercises plus therapist, generalization procedures, and problem solving strategies ($g = 0.31$, 95% CrI [0.15, 0.47]). All other combinations of the four core elements did not result in significantly larger benefits in everyday functioning compared to treatment as usual. The combination of cognitive exercises, a therapist, and generalization procedures was 85.4% most likely to be the most effective treatment combination. For cognitive outcomes, the same combinations of core elements resulted in significant improvements compared to treatment as usual ($g = 0.23$ - 0.38). These results were not significantly influenced by study quality ($b = 0.08$, 95% CrI [-0.18, 0.34]).

Discussion: This meta-analysis emphasizes the crucial role of therapists in administering cognitive remediation training. When the other three core elements are combined without a therapist's involvement, the outcomes do not significantly surpass those of control interventions in enhancing cognitive and everyday functioning. The findings collectively

indicate that the most effective approach of cognitive remediation involves the combination of cognitive exercises and generalization procedures facilitated by a therapist, aiming to improve everyday functioning.

T259. INVESTIGATING THE LONG-TERM PREDICTIVE VALUE OF IMMUNE MARKERS IN PSYCHOSIS AND THE MODERATING ROLE OF CANNABIS USE

Isabel Kreis^{*1}, Kristin Fjelnseth Wold¹, Mashhood A. Sheikh², Maren Caroline Frogner Werner¹, Eivind Bakken², Nils Eiel Steen¹, Ingrid Melle¹

¹NORMENT, Institute of Clinical Medicine, University of Oslo, ²Oslo University Hospital

Background: The immune system appears to be implicated in psychotic disorders. Several cross-sectional studies have explored if markers of inflammatory and immune response could serve as biomarkers of diagnosis, symptom severity, and treatment resistance. However, very few studies have investigated them as potential predictors of psychosis outcomes and symptom development, and there are no prospective long-term studies in this area. Furthermore, inconsistencies in findings from cross-sectional and short-term prediction studies suggest the presence of moderating factors, but this has not been investigated in depth. A relevant candidate is cannabis use, which is known to impact both the immune system and psychotic relapse risk. We aim to address these research gaps by investigating to what extent immune marker levels at baseline can predict the risk of psychiatric readmission per year over a 10-year follow-up, and the role of cannabis use as a potential moderator.

Methods: 159 individuals (46% female) with first-episode psychosis (schizophrenia spectrum = 46%, bipolar spectrum = 29%, other psychosis = 25%) were included from the Norwegian Thematically Organized Psychosis (TOP) study. Data collected at the study baseline, including demographic, clinical, and cannabis use information, were linked with national health registry data prospectively, spanning a 10-year time frame. Contacts with specialized health services (inpatient care, outpatient contacts, or day treatment) due to schizophrenia spectrum diagnoses or bipolar disorder during each of the 10 follow-up years were extracted to reflect psychiatric readmission. Plasma levels of immune markers previously linked to psychotic symptoms and treatment response (CRP, IL-1Ra, sIL-2R, gp130, sTNFR-1) were measured at baseline, log- and z-transformed, and used to calculate a composite score (CSI). A logistic mixed effects model was used to assess the effect of CSI, cannabis use, follow-up year, and their interactions on readmission risk.

Results: Adjusted for covariates (age, gender, nicotine use, antipsychotic medication), preliminary results revealed a main effect of year, with readmission risk decreasing over time (OR = 0.69, p LESS THAN .001, 95% CI [0.65, 0.74]). There were no main effects of CSI or cannabis use on readmission risk. However, a two-way interaction between year and cannabis use (OR = 1.20, p LESS THAN .01, CI [1.05, 1.38]) indicated a stronger negative effect of year on readmission risk in non-users. Furthermore, a two-way interaction between CSI and cannabis use (OR = 0.53, p LESS THAN .01, CI [0.33, 0.86]) revealed a strong negative association between CSI and readmission risk in cannabis users only. Finally, as suggested by a significant three-way interaction (year*ICS*cannabis: OR = 1.09, p LESS THAN .01, CI [1.03, 1.15]), the association between year and readmission risk was moderated by CSI in cannabis users only. Specifically, among users there was a strong negative effect of year at medium-to-low CSI levels, while this effect was absent at high CSI levels. In contrast, the association between year and readmission risk was the same across all levels of CSI in non-users.

Discussion: These findings suggest that the relationship between immune markers and the course of psychosis is nuanced and influenced by cannabis use. This emphasizes the importance of considering cannabis use as a moderator of the link between immune markers and psychosis outcomes in future studies. The mechanisms underlying the complex interplay between inflammatory and immune processes, cannabis use, and the long-term course of psychosis remain to be unraveled.

T260. LEVEL OF FUNCTION ASSESSED BY CASE MANAGERS AND RELATIVES AND ITS ASSOCIATION WITH SYMPTOMATIC REMISSION SUSTAINABILITY IN SCHIZOPHRENIA

Madeleine Johansson¹, Iris van Dijk-Härd², Lars Helldin³, Lars Helldin*⁴

¹*Department of Psychiatry, NU Health Care Hospital, Department of Psychology, Karlstad University,* ²*Department of Psychiatry, NU-Hospital Groups,* ³*Department of Psychiatry, NU Health Care Hospital,* *Department of Psychology, Karlstad University,* ⁴*NU-Hospital Group, Karlstad University*

Background: General level of functioning is impaired in schizophrenia. The impairment covers several domains such as activity of daily living, social adaptation, and work ability. Patients' cognitive performance is central for their functional capacity and level of function within the society. Negative symptoms are also important for long-term functional outcome. This study addresses the influence of remission status on patients' functional performance.

Methods: Case managers and relatives rated patients' function with the Specific Level of Functioning Scale (SLOF). 147 patients were rated by case managers and of those 47 were also rated by a close relative. Patients were then followed during a period of three years with annual symptomatic remission assessments. Based on their remission status over time they were divided into three groups: Always in Remission (AwR), Altering in Remission (AnR), and Never in Remission (NiR). The six different domains in SLOF were then analyzed with a One-way ANOVA and a Tukey Post-Hoc test regarding their association to the different patterns of long-term remission status.

Results: The One-way ANOVA showed significant findings for Physical functioning, Personal care skills, Interpersonal relations, Activities, and Work skills with p-values between LESS THAN 0.001 and 0.041 for the case manager ratings. Only Social acceptability was not significant. Post-Hoc test found significant differences between all groups of remission patterns. When relatives' ratings were analyzed, the One-way ANOVA were significant for Interpersonal relations and Work skills and the Post-Hoc test revealed that the difference was between AwR and NiR.

Discussion: The study indicates that not only cognition and negative symptoms are associated with functional performance. There are also differences between different patterns of long-term remission status, in some of the domains between all groups and in others just between AwR and NiR. The differences between the ratings of case managers and relatives, may be partly due to the different sample sizes (147 vs 47). A possible conclusion is that to achieve best conditions for functioning it is necessary to reach a situation of sustainable symptomatic remission.

T261. EXERCISE INTENSITY AND EMOTIONAL AND PSYCHOPHYSIOLOGICAL FACTORS IN GYM-BASED HIGH-INTENSITY

FUNCTIONAL TRAINING COMMUNITIES FOR YOUNG ADULTS WITH SEVERE MENTAL ILLNESS – PRELIMINARY DATA FROM THE VEGA TRIAL

Victor Sørensen^{*1}, Martin F. Andersen², Bolette S. Rafn³, Bjørn H. Ebdrup⁴, Julie Midtgaard⁵

¹*Centre for Applied Research in Mental Health Care (CARMEN) and Center for Neuropsychiatric Schizophrenia Research (CNSR), Mental Health Center Glostrup, University of Copenhagen,* ²*Centre for Applied Research in Mental Health Care (CARMEN), Mental Health Center Glostrup, University of Copenhagen, Department of Physiotherapy, University College of Northern Denmark,* ³*Centre for Applied Research in Mental Health Care (CARMEN), Mental Health Center Glostrup, University of Copenhagen, Danish Cancer Society National Cancer Survivorship and Late Effects Research Center (CASTLE), Department of Oncology, Copenhagen University Hospital Rigshospitalet,* ⁴*Center for Neuropsychiatric Schizophrenia Research (CNSR), Mental Health Centre Glostrup, University of Copenhagen, Faculty of Health and Medical Sciences, Department of Clinical Medicine, University of Copenhagen,* ⁵*Centre for Applied Research in Mental Health Care (CARMEN), Mental Health Center Glostrup, University of Copenhagen, Faculty of Health and Medical Sciences, Department of Clinical Medicine, University of Copenhagen*

Background: Exercise is a beneficial and cost-effective adjunctive treatment in people with severe mental illness (SMI), with potential for improving multiple outcomes. Furthermore, exercise may induce acute and short-term improvements of emotional and psychophysiological factors, such as mood and physical well-being. High-intensity functional training (HIFT), utilizing constantly varied functional exercises and various activity durations that does not necessarily include rest intervals, has become increasingly popular as community-based exercise. HIFT holds the potential to facilitate personal recovery through its pronounced emphasis on skill acquisition, and when delivered in communities, it may also support other recovery aspects of the connectedness, hope, and optimism about the future, identity, meaning in life, and empowerment (CHIME) framework. To our knowledge, we here provide the first preliminary data on the acute effects of HIFT on emotional and psychophysiological factors in people with SMI.

Methods: This analysis is derived from the ongoing Vega trial investigating the value of gym-based group exercise versus usual care for young adults (18-35 years) with SMI (ClinicalTrials.gov ID: NCT05461885). Training sessions were supervised by certified Vega instructors at three commercial HIFT-gyms across Denmark. Each session lasted one hour and was divided into warm up, part A (resistance training), part B (workout of the day), and cooldown. Heart rate (HR) was monitored on chest straps at random sequential occasions where participants were blinded to the HR output during the sessions. Rate of perceived exertion (RPE) of each session part was collected with the Borg scale, ranging from 6-20, at the end of each session part. Physical well-being, mood, and mental energy was collected before and after each training session on 10cm VAS-scales, and differences was analysed with paired t-tests.

Results: Data was collected during 16 sessions with a mean attendance per session of 3.0 ± 0.8 (mean $\pm$ SD) with a total of 46 measurements (18 unique participants) from May to November 2023 across the three sites. Each part of the exercise sessions lasted 8.2 ± 2.7 , 14.8 ± 4.7 , 17.8 ± 4.2 , and 6.2 ± 1.8 minutes for warm up, part A, part B, and cooldown, respectively. Average %HR relative to age-predicted maximal HR (%HR_{max}) was 67.3 ± 7.9 (12.3 ± 1.9 RPE), 71.2 ± 7.8 (14.4 ± 2.2), 81.3 ± 5.7 (17.2 ± 1.5), and 68.3 ± 6.0 (9.7 ± 2.4) for warm up, part A, part B, and cooldown, respectively. Further, the average and maximally achieved

%HRmax was 74 ± 5.8 and $93.9 \pm 6.3\%$ across the entire training session, respectively. Acute changes were not observed for physical well-being ($P=0.190$), however, average mood increased with 1.5cm (0.8, 2.1 0.95CI; $P < 0.001$), corresponding to a relative change of 46.2% (28.3, 64.0 0.95CI), and average mental energy increased with 1.6cm (0.9, 2.3 0.95CI; $P < 0.001$), corresponding to a relative change of 62.4% (32.5, 92.2 0.95CI). Changes in mood and mental energy was not correlated with training intensity.

Discussion: The present preliminary analysis shows that the exercise communities in the Vega trial induce acute improvements in mood and mental energy. Additionally, the intensity of the HIFT training sessions results in elevations in HR and RPE corresponding to high-intensity exercise. Thus, the intended exercise intensity of HIFT is achievable and tolerable for people with severe mental illness. Future research in exercise communities should consider exploring predictive markers for acute changes in emotional and psychophysiological factors to identify meaningful values for persons with SMI to improve physical activity offers and engagement.

T262. CULTURAL AGREEMENTS ABOUT ETIOLOGY OF SCHIZOPHRENIA AND EXPRESSED EMOTION IN MEXICAN FAMILIES

Ricardo Audiffred-Jaramillo*¹

¹*Universidad de Guadalajara*

Background: Schizophrenia is a severe and persistent mental disorder that affects around 21 million people worldwide. The etiology of schizophrenia is currently understood as heterogeneous and multifactorial. Genetic and environmental factors are the most common explanations to the onset of schizophrenia, but along with these, hybridized cultural ideas coexist between medical, superstitious, or religious paradigms. Objective: To identify the relation between cultural beliefs about schizophrenia, etiology and Expressed Emotion. Method: The present study used a mixed-method design, with an analytical approach for ethnographic research. The sample was confirmed by 40 people, relatives of patients diagnosed with schizophrenia, selected with a simple random probabilistic sampling. Results A valid cultural consensus was found with statistical significance ($p \leq 0.05$). Emotional trauma in childhood was identified as the leading cause of schizophrenia, followed by hereditary factors, emotional problems, head trauma, mistreatment, and divine will. Best-informed relatives showed less Emotion Expressed than those with less cultural competence Conclusion: Mexican families in this study were closer to scientific knowledge about etiology of schizophrenia, but religious ideas and compassionate explanations were part of this hybridized model.

Methods: This research used the tools of cognitive anthropology to analyze through semantic structures, the cultural consensus of relatives of individuals with schizophrenia on the etiology of schizophrenia, and its relation with the EE. This study has a mixed design with an analytical method used in ethnographic research.

Results: The sample consisted of 40 relatives of individuals with schizophrenia from 18 different families in the Area Metropolitana de Guadalajara. Emotional trauma in childhood was identified as the first cause of schizophrenia described by family members (16%). The next factor was heredity with 15% and was followed by emotional problems (12%), head trauma (7%), mistreatment (5%), and divine will (5%), among others. It should be noted that variables related to neural problems and brain substances (4%) occupied the last places on the list but were still part of the valid cultural consensus. A single valid cultural consensus was

found, with a variability ratio of 39,130 and a statistical significance lower than ($p \leq 0.05$), which included 95.4% of all possible variations of the model items, with a multidimensional diagram with stress of 0.01.

Therefore, it resulted that 55% of the sample in this study had a low EE and the remaining 45% had a high EE. Based on the single-factor ANOVA, there was no significant difference between gender ($p = .898$), marital status ($p = .839$), religion ($p = .473$), schooling ($p = .382$), occupation ($p = .479$), or family relationship ($p = .170$) with the expressed emotion. Participants with adequate cultural competence (good informants) who provided answers attached to the valid cultural consensus on etiology of schizophrenia and people with inadequate cultural competence (bad informants) were categorized in order to analyze a possible association with high EE. Subjects with inadequate cultural competence showed a high EE ($p = \leq .05$) ($t = -9.15$; 95% CI [64.50-40.66]).

Discussion: This research studied the cultural consensus about etiology of schizophrenia and its possible relation with high EE. The hypothesis of this study sustained that there is a link between the cultural beliefs about schizophrenia etiology and high EE. And, as it has been shown, the comprehension about etiology has an impact on family expression of EE. Best-informed relatives express less EE. Being directly involved with a person with a mental disorder allows people to understand the reality of this illness in a deeper way. However, relationship or closeness does not exempt any individual from having a deficient understanding of this mental condition. The lack of knowledge resulting from the absence of information or misinformation about schizophrenia, usually generates negative attitudes or social rejection against people who live with it. The attitude of rejection or acceptance towards people with a mental disorder will depend on how people understand their condition. As for the EE, 45% of relatives with the role of caregivers of the person with schizophrenia presented a high EE and it was precisely this percentage of people who provided an understanding of the etiology that did not match the cultural consensus of this study. The percentage of relatives identified with high EE, matches with the data found in another research in Mexico, (19) where 42% of the people showed high EE. The fact that a significant association has been found between EE and those who live with the person with schizophrenia, confirms the theory of EE, which states that this phenomenon falls on those who spend more time with the patient and have bigger responsibilities in his or her caregiving. This study also corroborates the statement of Barrowclough and cols; and Cozolino and cols., which argues that relatives with high EE seem less informed about schizophrenia.

T263. ECOLOGICAL VALIDATION OF ATTACHMENT STATES AS MEDIATORS OF THE RELATIONSHIP BETWEEN CHILDHOOD ADVERSITY AND SUBCLINICAL PSYCHOTIC AND AFFECTIVE PHENOMENA IN DAILY LIFE

Pilar Torrecilla^{*1}, Tamara Sheinbaum², Thomas R. Kwapił³, Neus Barrantes-Vidal⁴

¹Universitat Autònoma de Barcelona, ²Instituto Nacional de Psiquiatria "Ramón de la Fuente Muñiz", ³University of Illinois at Urbana-Champaign, , ⁴Departament de Psicologia Clínica i de la Salut, Facultat de Psicologia, Universitat Autònoma de Barcelona

Background: It is well established that childhood adversity is associated with psychotic phenomena at both clinical and nonclinical levels. In the last few years, increased attention has been given to the psychological mechanisms that may underlie this association. In particular, insecure attachment styles have been shown to mediate the associations between childhood adversity and psychosis expression. However, only a few studies have examined attachment in naturalistic daily-life conditions, that is attachment states, in relation to psychosis. More so, most of these studies do not distinguish between the dismissing and fearful styles. The present study aimed at testing the ecological validity of four attachment states (secure, preoccupied, dismissing, fearful) assessed in daily life using Experience Sampling Methodology (ESM) by examining their association to trait-like attachment styles. Secondly, and following previous studies supporting the role of insecure attachment trait-like styles as an explanatory mechanism of the pathway from childhood adversity to psychosis, we examined whether insecure attachment states mediated the effects of childhood adversity on subclinical psychotic phenomena in the flow of daily life.

Methods: The study comprised a total of 159 nonclinical college students (mean age=28, sd=2.3) with a wide distribution of schizotypy traits belonging to the Barcelona Longitudinal Schizotypy Study (BLISS). Participants were assessed with a self-report measure of childhood adversity and trait-like attachment and completed Experience Sampling Methodology (ESM) over 7 days. First, multilevel structural equation models were used to examine whether state attachment styles were predicted by trait-like attachment styles, and whether attachment states predicted subclinical psychotic-like experiences (PLE), paranoia, negative and positive affect. Second, multilevel mediation models were conducted to examine the indirect effect of childhood adversity on subclinical experiences via insecure attachment states (preoccupied, dismissing and fearful) in daily life.

Results: Secure attachment state was positively associated with secure trait-like attachment, and negatively associated with dismissing, fearful and disorganized attachment styles. Preoccupied attachment state was positively associated with preoccupied trait-like style, dismissing state with dismissing trait-like and the fearful state with the fearful trait-like attachment style. Individuals with higher secure attachment state reported decreased paranoia, PLE, and negative affect, and increased positive affect, whereas the fearful attachment state showed the opposite pattern of associations. Multilevel mediation analyses revealed a significant indirect pathway of childhood adversity to paranoia, positive PLE and negative affect through preoccupied and fearful attachment states, but not through dismissing state. The fearful attachment state also mediated the association of adversity and decreased positive affect.

Discussion: The present study i) ecologically validated four attachment states suggesting that stable trait-like attachment styles may translate to daily life fluctuations, and ii) showed that childhood adversity impacts the expression of psychosis-like and affective subclinical symptoms through increased levels of insecure attachment states in the flow of daily life. The findings are consistent with previous studies and support psychological models of psychosis expression, which may inform ecological momentary interventions based on attachment-informed approaches.

T264. DIVERGENT TRAJECTORIES OF INTRACORTICAL MYELIN CONTENT DURING THE EARLY PHASE OF SCHIZOPHRENIA SPECTRUM DISORDERS

Filip Spaniel¹, Tereza Nekovářová¹, Jana Kopřivová¹, Lea Jakob*¹, Antonín Škoch¹, Marián Kolenič¹, Petra Fürstová¹, Markéta Fialová¹, Kristina Hakenová¹, Václav Čapek¹

¹*National Institute of Mental Health, Czech Republic*

Background: The distinctive phylogenetic characteristics of the human brain is marked by abundant myelin and an extended period of developmental myelination. Maladaptive myelination is implicated in various neurodegenerative and neuropsychiatric disorders, including schizophrenia. This study specifically examines intracortical myelin content (ICM) in schizophrenia, delving into its deviant ontogenetic trajectories.

Methods: Using T1w/T2w MRI, we compare the longitudinal development of ICM in patients at the early stage of schizophrenia (n=265) to a healthy ontogenetic database.

Results: Preliminary findings reveal deviations in ICM trajectories within four years post-onset, leading to the identification of two distinct clusters: a hypermyelination cluster (comprising 75% of all cases) and a hypomyelination cluster (25% of cases).

Discussion: Notably, persistent negative symptoms, as assessed by PANSS, are observed in the hypomyelination cluster, remaining stable since the first visit and persisting across all four years of follow-up.

T265. HELPING AND IMPEDING FACTORS IN ACHIEVING PERSONAL RECOVERY 2 YEARS AFTER THE FIRST EPISODE OF PSYCHOSIS: A QUALITATIVE STUDY

Inge Heijden-Hobus^{*1}, Bram-Sieben Rosema², Manna Alma², Iris Sommer³, Nynke Boonstra⁴

¹*Janssen Cilag, Johnson and Johnson SIO*, ²*UMCG*, ³*University Medical Center Groningen, Department of Neuroscience and Department of Psychiatry*, ⁴*NHL Stenden University of Applied Science, Leeuwarden, the Netherlands/ University of Utrecht*

Background: Experiencing a first episode of psychosis (FEP) can be a distressing and life-altering event for individuals and their families. It is still widely assumed that schizophrenia is a chronic disease for which recovery is not possible.. However, the concept of recovery can be explained in different ways. A traditional focus in research and clinical care is clinical recovery (Wilken et al., 2006)., while people with lived experience usually focus on the concept of personal recovery. Other used concepts entail functional, occupational, and social recovery. Personal recovery in the context of first psychosis refers to the process through which individuals regain a sense of control, purpose, and meaning in their lives despite the challenges posed by their condition. It goes beyond symptom reduction and encompasses various aspects of an individual's well-being, including psychological, social, and emotional dimensions. Personal recovery emphasizes the importance of hope, self-determination, and empowerment for individuals to live fulfilling lives beyond the confines of their illness (van Eck et al., 2018). To date, little is known about the most important helping and/or hindering factors in a personal trajectory of recovery after a first episode of psychosis.

Methods: The current qualitative study used a descriptive, interpretative phenomenological approach to gain insight into the factors that helped or hindered individuals in their trajectory toward personal recovery. Interviews with participants who were 24 months in remission of a FEP were conducted by a female and a male researcher, the latter being an expert with lived experience.

Results: Thirty-one FEP patients who were in remission for 24 months were interviewed (mean age: [sd]; 16 male, 15 female). Of all participants, 19 had a paid job when 24 months in remission after their first psychosis. Working hours varied between 5 and 40 hours a week. Six main themes could be distinguished from the analyses of the transcripts of

interviews: balance, self-understanding, existential and fundamental conditions, support, prospect, and remaining symptoms. Sub-themes emerged within each theme. Having meaningful daily activities helped individuals to find their balance. These activities also acted as a fundament for existential conditions or the pursuit of prospect. Support came from significant others and professionals, the latter not always perceived as helping. Stigma or self-perceived stigma was a hindering factor in achieving personal recovery.

Discussion: The current study found six themes emerging out of qualitative interviews with individuals who were in 24 months after recovery of their first episode of psychosis. Participants were able to indicate which factors either helped or hindered them during their trajectory towards achieving personal recovery. Having meaningful activities emerged throughout all themes, which may be one of the main goals to act upon in clinical practice when helping individuals recover from their first episode of psychosis. More insight and research are needed to address the leverage points for addressing the right trajectory toward personal recovery. In rebuilding their lives again, personalized paths must be drawn.

T266. THE RELATION OF FORMAL THOUGHT DISORDER WITH SOCIAL COGNITION AND THEIR EFFECTS ON SOCIAL FUNCTIONING IN SCHIZOPHRENIA PATIENTS AND FIRST DEGREE RELATIVES

Background: Formal thought disorder (FTD) is considered to be one of the core symptoms of schizophrenia and a possible risk indicator as they are seen in milder forms in first-degree relatives of patients. Social cognition deficits in schizophrenia have been shown in many studies and its relation with other symptoms such as FTD is an important area of research. This study aims to determine FTD and social cognition deficits including theory of mind (ToM), emotion recognition and social knowledge in schizophrenia patients and their first degree relatives (siblings), to examine the relation between FTD and social cognition domains, to examine the effects of FTD and social cognition skills on social functioning and quality of life in patients.
