Methods: Participants consisted of N=100 patients diagnosed with schizophrenia according to DSM-5, N=41 siblings of schizophrenia patients without psychiatric disorders, and N=60 healthy controls. The sociodemographic characteristics of all participants were noted in detail, as well as the clinical information of schizophrenia patients. All participants were administered the Turkish version of Thought and Language Disorder Scale (TALD), the Reading the Mind in the Eyes Test, the Hinting Task, the Facial Emotion Identification Test, the Facial Emotion Discrimination Test and the Situational Features Recognition Test-2 as social cognition tests, the Digit Span Test, the Verbal Fluency Test and the Auditory Consonant Trigram Test (ACT) for neurocognitive assessment, and the Personal and Social Performance Scale (PSP) to assess social functioning. Additionally, in schizophrenia patients, the Positive and Negative Syndrome Scale (PANSS) and the Clinical Global Impression Scale (CGI) were administered to determine the severity of illness, and the Quality of Life Scale was administered to assess quality of life.

Results: The results of the study revealed that schizophrenia patients had higher scores in all domains of TALD (p LESS THAN 0.05) and significant impairments in all social cognition tests compared to controls (p LESS THAN 0.05), while siblings' group had only more positive FTD than controls (p LESS THAN 0.05), and did not differ from controls in terms of

social cognition skills. In schizophrenia patients, negative FTD was negatively correlated with ToM ($r(100) = -0.471$, $p < 0.001$) and emotion recognition ($r(100) = -0.329$, $p = 0.001$) among social cognition domains, whereas in healthy controls, the presence of symptoms related to negative FTD was negatively correlated with ToM ($r(60) = -0.368$, $p = 0.004$) and social knowledge performance which are SFRT-2 hit action recognition ($r(60) = -0.452$, $p < 0.001$) and SFRT-2 hit goal recognition scores ($r(60) = -0.437$, $p < 0.001$). In schizophrenia patients, negative FTD was found to be associated with lower social functioning ($r(100) = -0.447$, $p < 0.001$) and deterioration in quality of life ($r(100) = -0.513$, $p < 0.001$), whereas ToM skills were found to be associated with an increase in quality of life ($r(100) = 0.296$, $p = 0.003$). In schizophrenia patients, social functioning and quality of life were best predicted by negative FTD and social knowledge performance, whereas in healthy controls, social functioning was best predicted by symptoms related to negative FTD and ToM skills.

Discussion: The results of this study suggest that among FTD in schizophrenia patients, mainly negative FTD is associated with social cognition deficits, and negative FTD and social knowledge performance have substantial effects on social functioning and quality of life of schizophrenia patients. It is important to better understand negative FTD and negative symptoms in general and social cognition deficits in schizophrenia patients and to prioritize the development of treatment approaches targeting these areas in order to improve the social functioning and quality of life of patients.

T267. NEUROIMAGING BIOMARKERS OF ANTIPSYCHOTIC TREATMENT RESPONSE – A REVIEW OF THE LITERATURE, AND PRELIMINARY FINDINGS SURROUNDING THE UTILITY OF EEG ASSESSMENTS FOR TREATMENT STRATIFICATION

Magdalene de Rozario^{*1}, Emily Painter², Tahnee Bridson³, Sarah Herniman³, Andrew Thompson³, Ilvana Dzafic³, Stephen Wood³

¹University of Melbourne, ²Orygen, ³Orygen and Centre for Youth Mental Health, University of Melbourne

Background: Up to a third of patients with schizophrenia do not experience sufficient improvement of symptoms and functioning on their first two trials of antipsychotic medications. This is concerning as ineffective antipsychotic treatment early in psychotic illness can lead to exacerbations of psychotic symptoms that impair daily functioning – leading to worse long-term outcomes. Given the considerable burdens associated with psychosis, there is a clear need to identify successful treatments, earlier in the course of illness. Numerous efforts have been made to identify different biomarkers for predicting antipsychotic treatment responses for patients with psychotic disorders. However, there are no known published systematic reviews pulling available evidence on this topic together. This systematic review is currently in preparation, and aims to identify any previously studied neuroimaging biomarkers proposed to be potential predictors of antipsychotic treatment response in individuals presenting with First Episode Psychosis (FEP) or a psychotic disorder.

Methods: The study is being conducted in accordance with the updated Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines. A systematic search of three electronic databases (MEDLINE, PsycINFO, and EMBASE) was conducted in May 2022. Data synthesis is currently in progress.

Results: Relevant data from selected studies has been extracted, and the narrative synthesis is currently underway to consolidate all available research on neuroimaging biomarkers that have potential to predict antipsychotic treatment response in individuals presenting with FEP or a psychotic disorder. The clinical utility of the different neuroimaging biomarkers in the prediction of antipsychotic treatment response will be discussed.

Discussion: Through identifying the most efficacious treatments as early into a patient's treatment as possible, clinicians can avoid the prescription of ineffective drugs and enable more rapid treatment responses. This can enhance patient welfare, while also bringing a considerable economy to the healthcare system.

T268. THETA-BURST RTMS IN SCHIZOPHRENIA TO AMELIORATE NEGATIVE AND COGNITIVE SYMPTOMS: A DOUBLE-BLIND, SHAM-CONTROLLED, RANDOMIZED CLINICAL TRIAL

Boglarka Orbán-Szigeti^{*1}, Karolin Suri², Kinga Farkas², János Réthelyi², Gábor Csukly²

¹*Semmelweis University*, ²*Semmelweis University*

Background: Schizophrenia, a prevalent mental disorder affecting around 1% of the global population, is characterized by significant challenges in social cognition and the presence of negative symptoms, such as blunted affect and emotional withdrawal. These factors substantially contribute to the psychosocial functioning deficits and long-term disability associated with schizophrenia. Both the state-like and trait-like aspects of social cognition are compromised in individuals with this condition. Traditional approaches to treatment, including antipsychotic medications and psychosocial interventions, have shown limited effectiveness in alleviating negative and cognitive symptoms in schizophrenia. While there is emerging clinical evidence suggesting that new therapeutic protocols based on theta-burst stimulation can significantly enhance the efficacy of repetitive transcranial magnetic stimulation (rTMS) in depression, the available data on similar augmented therapies for schizophrenia remain scarce. The variability in network impairments among individuals may explain why some patients respond positively to specific stimulation sites while others do not.

Methods: In light of this, we propose an augmented theta-burst stimulation protocol for individuals with schizophrenia, targeting two regions associated with negative symptoms: the vermis of the cerebellum and the left Dorsolateral Prefrontal Cortex (DLPFC). We plan to randomize ninety participants with schizophrenia who exhibit negative symptoms, aged between 18 and 50 years, into two groups in a 1:1 ratio—active stimulation and sham stimulation. The TBS parameters we will employ adhere to standard TBS protocols, featuring 3-pulse bursts at 50 Hz, administered every 200 ms (at 5 Hz), with an intensity set at 100% of the active motor threshold. Over a four-week period, we intend to administer 1800 stimuli to the vermis and 1800 stimuli to the left DLPFC daily, split into two 9.5-minute sessions.

Results: The primary outcome measure will be the change in the severity of negative symptoms, as assessed by the Positive and Negative Syndrome Scale (PANSS). Secondary efficacy endpoints will encompass changes in cognitive flexibility, evaluated through the Wisconsin Card Sorting Test, as well as improvements in social cognition, measured by the 'Reading the Mind in the Eyes' test, facial emotion recognition, and the 'Faux pas' test. The safety assessment will focus on monitoring the occurrence of serious adverse events.

Discussion: In summary, the objective of our study is to establish the safety and effectiveness of theta-burst stimulation as a treatment modality for alleviating negative symptoms in schizophrenia.

T269. TRANSDIAGNOSTIC CHARACTERISTICS OF ANTICIPATORY AND CONSUMMATORY AFFECTIVE RESPONSES IN SCHIZOPHRENIA AND DEPRESSION SPECTRUM DISORDERS

Lei Shen^{*1}, Chi Xie¹, Yi Wang², Chao Yan³

¹East China Normal University, ²Institute of Psychology Chinese Academy of Sciences, ³Key Laboratory of Brain Functional Genomics (MOE and STCSM), Shanghai Changning-ECNU Mental Health Center, School of Psychology and Cognitive Science, East China Normal University

Background: Anhedonia is a multidimensional construct encompassing anticipatory and consummatory pleasure, and it manifests across a range of psychiatric disorders. However, the common and unique mechanisms that underlie these affective difficulties between schizophrenia and depression spectrum disorders remain unclear. This study aimed to apply the network approach to explore the characteristics and interplay between anticipatory and consummatory affective responses among individuals within the schizophrenia and depression spectrums.

Methods: A total of 762 participants were recruited, including a healthy control group (HC, $n = 394$), clinical patients comprising schizophrenia (SCZ, $n = 115$) and major depressive disorder (MDD, $n = 60$), as well as a subclinical group comprising individuals with schizotypal traits (ST, $n = 83$) and subclinical depression (SD, $n = 110$). All participants completed the Monetary Incentive Delay (MID) task, designed to investigate momentary affect during the anticipation and consumption of rewards. Partial correlation networks were constructed using anticipatory and consummatory affective responses, calculated by averaging the valence subjective rating scores as nodes. Separate network comparisons were conducted to examine differences in network structure, global strength, and edge weights within the schizophrenia and depression spectrum.

Results: The linear mixed-effects model on the valence ratings during the anticipatory and consummatory phases revealed that a consistent pattern of diminished affective responses in clinical patients (vs. HC), encompassing individuals with SCZ and MDD, in relation to both the anticipation and consumption of reward gain and loss. However, the subclinical individuals including SD and ST showed similar affective response characteristics to HC, but their negative affect significantly increased under reward loss conditions ($p = .007$). Network analysis indicated that the global strength of the network for anticipatory and consummatory affective responses in the subclinical group was significantly lower than that of clinical patients ($S = 1.509$, $p = .049$; $GS_{clinical} = 4.838$, $GS_{subclinical} = 3.329$) and HC ($S = 1.561$, $p = .013$; $GSHC = 4.890$, $GS_{subclinical} = 3.329$), suggesting a less consistent and more fluctuating pattern of response in the subclinical group. Within-spectrum comparisons further highlighted that the commonly impaired affective pattern was predominantly concentrated on a noticeable attenuation in pleasure to reward anticipation and outcome among the clinical SCZ and MDD. Moreover, the individuals within the depression spectrum displayed higher levels of negative affect in response to reward loss compared to those within the schizophrenia spectrum. Importantly, there were significant differences in the network structure of affective responses between the schizophrenia and depression spectrum ($M = 0.551$, $p = .0005$). In contrast to the depression spectrum, the schizophrenia spectrum demonstrated stronger connections in pleasurable affective responses during both reward anticipation and consumption (i.e., Anticipatory_Gain--Consummatory_Gain; $t = 0.304$, $p = .032$; edge weights: the schizophrenia spectrum = 0.658, the depression spectrum = 0.354).

Discussion: The present study unveiled common abnormal affective patterns in patients with schizophrenia and depression. Our findings suggested that the diminished interplay of affective response functions in subclinical individuals might serve as a risk factor for progressing to clinical levels of anhedonia. The inter-relationship between anticipatory and consummatory pleasure may elucidate distinct mechanisms underlying anhedonia in the schizophrenia and depression spectrum.

T270. ESTABLISHMENT OF A DIGITAL THERAPEUTIC ALLIANCE IN PATIENTS LIVING WITH NEGATIVE SYMPTOMS OF SCHIZOPHRENIA

Abhishek Pratap^{*1}, Cornelia Dorner-Ciossek², Cassandra Snipes³, Brendan D. Hare⁴, Olya Besedina³, Thomas Mick³, Eehwa Ung⁵, Alankar Gupta⁶, Shaheen E. Lakhan³

¹*Boehringer Ingelheim Pharmaceuticals, Inc.; King's College London; University of Washington*, ²*Boehringer Ingelheim International GmbH*, ³*Click Therapeutics, Inc.*, ⁴*Boehringer Ingelheim Pharmaceuticals, Inc.; Click Therapeutics, Inc. (at time of study)*, ⁵*University of California, San Francisco (UCSF); Click Therapeutics, Inc. (at time of study)*, ⁶*Click Therapeutics, Inc. (at time of study)*

Background: There are no approved pharmacotherapies for treating experiential negative symptoms (ENS) of schizophrenia. While treatment guidelines recommend psychosocial interventions for this population, access to these treatments is limited. Prescription digital therapeutics (PDTs), which are evidence-based digital therapeutics that receive regulatory authorisation and require a prescription for utilisation, may be able to deliver psychosocial interventions to people with schizophrenia. One of the critical success factors of face-to-face therapy is the effective establishment of a therapeutic alliance between the patient and healthcare professional. A similar bond established between a patient and PDT, which could be referred to as a digital working alliance (DWA), may also help to improve treatment outcomes. Two studies determined whether patients with moderate–severe ENS of schizophrenia could form and maintain an effective DWA with beta versions of CT-155. CT-155 is a PDT in development for the treatment of ENS of schizophrenia. Additionally, it was determined if the strength of the DWA varied by patient demographics or ENS symptom severity.

Methods: Two exploratory, single-arm, multi-centre studies lasting 3 (Study 1) or 7 (Study 2; NCT05486312) weeks included adults with schizophrenia and self-reported ENS. Patients were receiving stable antipsychotic medication for ≥ 12 weeks and had on-demand access to beta versions of CT-155. Patient demographics were captured at screening, and negative symptoms were evaluated using the Motivation and Pleasure Scale-Self-Report (MAP-SR) at screening and the clinician-administered Clinical Assessment Interview for Negative Symptoms Motivation and Pleasure Scale (CAINS-MAP) at baseline. The overall strength of the DWA at Weeks 1 and 3 in Study 1 and at Week 3 in Study 2 was assessed using the mobile Agnew Relationship Measure (mARM); a score ≥ 5 represented a positive alliance. A post hoc analysis assessed correlations between the strength of the DWA (mARM scores) and patient age and ENS severity (MAP-SR and CAINS-MAP scores) using Spearman's correlation coefficients. mARM scores were compared across Race (Black or African American versus Other) using an F test.

Results: In Studies 1 (N=49) and 2 (N=50), patients had a median (range) age of 46 (18–64) and 53.5 (23–64) years and 71% and 80% of patients were male, respectively. The mean (standard deviation; SD) overall MAP-SR score at screening was 22.6 (6.8) in Study 1 and

14.9 (8.9) in Study 2. ENS were moderate–severe at baseline as determined by a mean (SD) overall CAINS-MAP score of 2.37 (0.76) in Study 1 and 2.28 (0.92) in Study 2. A positive DWA was established and maintained between patients and the PDT in Study 1 (mean [SD] mARM: 5.15 [0.74] at Week 1 and 5.16 [0.77] at Week 3). In Study 2, a positive DWA was observed at Week 3 (mean [SD] mARM: 5.36 [1.06]). In the post hoc analysis (Study 1: n=40, Study 2: n=45), there was no statistically significant correlation between mARM scores and either age (Study 1: $r=0.31$, $p=0.054$; Study 2: $r=0.15$, $p=0.32$), MAP-SR scores at screening (Study 2: $r=0.11$, $p=0.48$) or baseline CAINS-MAP scores (Study 1: $r=-0.16$, $p=0.36$; Study 2: $r=-0.13$, $p=0.41$). mARM scores were not significantly affected by Race (Study 1: F-test=1.193, $p=0.719$; Study 2: F-test=1.162, $p=0.747$).

Discussion: Establishing a positive DWA may be critical for the successful treatment of patients using a PDT. These early findings demonstrate that patients with moderate–severe ENS of schizophrenia were able to consistently establish a positive DWA with beta versions of CT-155, which overall, was not affected by age, race or negative symptom severity.

Funding: Boehringer Ingelheim and Click Therapeutics.

T271. CASE REPORT OF TREATMENT OF NEUROLEPTIC MALIGNANT SYNDROME IN CHILD AND ADOLESCENT

Moon Doo Kim^{*1}, Won-Myong Bahk², Bo-Hyun Yoon³, Kwanghun Lee⁴, Sang-Yeol Lee⁵, Young Jun Kwon⁶

¹*School of Medicine, Jeju National University*, ²*Yeouido St. Mary's Hospital, The Catholic University of Korea*, ³*Naju National Hospital*, ⁴*Dongguk University Hospital*, ⁵*Wonkwang University School of Medicine and Hospital*, ⁶*Soonchunhyang University*

Background: Neuroleptic Malignant Syndrome (NMS) is a rare clinical syndrome occurring due to idiosyncratic reaction after use of neuroleptics. Recently, the use of antipsychotics has been increasing in psychosis, mood disorder, and destructive behavior disorder in the field of child and adolescent psychiatry. We report a case of neuroleptic malignant syndrome in a patient with acute schizophrenia after treatment with antipsychotics.

Methods: Case Report.

Results: A 14-year-old male patient, diagnosed with schizophrenia in May of 2021, was admitted to the psychiatric closed ward due to worsening of psychotic symptoms on October of 2020. Pineal cystoma and pituitary microadenoma were detected incidentally on MRI conducted after hospitalization, and consultation with the department of pediatrics recommended close observation. Because 7 mg of risperidone monotherapy, initiated after hospitalization, caused akathisia, it was reduced to 6 mg. Even though akathisia subsided slightly, risperidone was combined alternatively with aripiprazole, ziprasidone, and quetiapine due to residual symptoms. Treatment effects were closely evaluated for more than 4 weeks while slowly increasing dosages. After treatment with 6mg of risperidone in combination with 300 mg of quetiapine, 80 mg of propranolol for prevention of akathisia, and 1.5 mg of benzodiazepine, psychotic symptoms and difficulties in communication improved enough to be discharged. However, while preparing for the discharge, the patient showed worsening of psychotic symptoms including auditory hallucination. Quetiapine was increased to 600 mg, and symptoms, when severe, were controlled with IM injection of 2.5 mg of haloperidol and 2 mg of lorazepam. Since March 25th of 2021, due to manifestation of

paralytic ileus from worsening of underlying constipation, all the oral medications were stopped along with NPO for treatment; in addition, IM injection of haloperidol was only allowed for the symptom control. Mental symptoms were worsened within 3 days after termination of oral medications while using IM injections of 10 mg of haloperidol and 8 mg of lorazepam per day. The day before the onset of neuroleptic malignant syndrome, IM injection of 15 mg of haloperidol and 10 mg of lorazepam resulted in vomiting, headache, fever of 39°C, systemic tremor and stiffness, confusion in consciousness, tachycardia and sweating. On April 1st of 2021, with suspicion of neuroleptic malignant syndrome, the patient was transferred to ICU at our institution. Blood work-up performed on day of admission at ICU indicated CPK 2836 IU/L and myoglobin 337.2 ng/ml, and CPK, after peaking at 4493 IU/L, continuously decreased and was normalized by the 18th day at ICU. Diazepam (IV), dantrolene, domperidone, L-Dopa/benserazide and cold blanket were applied because the patient continuously screamed due to fever, stiffness, tremor, and psychotic symptoms. Even though confusion improved after 3 days, nausea and vomiting persisted for 8 days. Tremor, stiffness, and fever were stabilized after 3 days, but aspiration pneumonia occurred on the 8th day and recovered on the 15th day at ICU. Tachycardia improved after 17 days. Recovery of hematologic abnormalities such as increased CPK and myoglobin and leukocytosis were followed by stabilization of tremor, stiffness, and high fever on the 18th day.

Discussion: Known risk factors of NMS are 1) male, 2) combination of more than two antipsychotic, 3) history of previous EPS symptoms or NMS, 4) psychiatric disorders such as severe agitation, mood disorder, or delirium, 5) recent initiation or increasing dose of antipsychotics, 6) IM injection of antipsychotics, 7) poor physical conditions like dehydration, infection, malnutrition, brain tumor, encephalitis, or AIDS, 8) use of zuclopenthixol acetate (clopixol acuphase), and 9) substance abuse. In this case, because the patient had 6 of the risk factors described above, which are biological vulnerabilities due to pineal cystoma and pituitary micro adenoma, dehydration and malnutrition caused by paralytic ileus, and sudden change in IM antipsychotics and dosage, it was critical to consider more carefully in medication injection and changes in dosage. Although the patient showed both fever and muscular stiffness, it is common not to present with both fever and muscular stiffness as required by diagnostic criteria of DSM-IV in child and adolescent NMS while using atypical antipsychotics. In addition, it is difficult to diagnose because atypical antipsychotics takes twice longer incubation time until the disease manifestation than typical antipsychotics. However, the increase in CPK, as shown in all cases of child and adolescent NMS, provides diagnostic specificity. Once diagnosed with NMS, immediate hydration and efforts to lower body temperature are critical to prevent complications like acute renal failure, and use of dantrolene, bromocriptine, and benzodiazepine is helpful in shortening the treatment period. In cases of NMS in patients who cannot terminate use of neuroleptics due to underlying mental disorders, ECT is an effective method to treat both NMS and mental disorders. Safety and efficacy of ECT have been already proven, and it is highly recommended when needed.

T272. SCHIZOMICS: A CIBER MULTIDISPLINARY DESIGN TO OPTIMIZE SCHIZOPHRENIA TREATMENT BASED ON MULTI-OMICS DATA AND SYSTEMS BIOLOGY ANALYSIS

Background: Schizophrenia is a severe and chronic mental disorder which onset typically occurs in late adolescence to young adulthood. The keystone of schizophrenia treatment is antipsychotic medications. Newer or second-generation antipsychotics (SGAs) widely used to treat psychosis may improve positive symptoms and are quite often associated to weight gain, metabolic changes and increased risk of cardiovascular diseases. Individual response and side effects profiles associated to these drugs are highly variable, and identifying the optimal treatment for any patient is often a trial and errors process that can span many years and even then, response is often poor. In this regard, the use of combined multi-omics approaches might constitute a diagnostic tool for personalizing the treatment since the first psychotic episode. To enable the implementation of mainstream precision medicine to improve the sightlessness traditional symptom-driven practice in schizophrenia treatment, allowing treatment selection or approach using predictive biomarkers of clinical response and toxicity to tailoring better-personalized treatments. We propose a multidisciplinary prospective study to deciphering the heterogeneity in clinical response and hepatic-metabolic side effects in schizophrenia. We rely on: (1) a carefully designed multicenter (11 CIBERSAM centers) prospective randomized clinical trial on first episode schizophrenia-spectrum individuals; and (2) a wide implementation of high-throughput technologies (omics) and systems biology approaches to elucidating biological mechanisms related to clinical response and appearance of metabolic side effects.

Methods: This project will be formed by five work packages (WP):

WP1: To set up a randomized open-label clinical trial to compare effectiveness and security of aripiprazole and paliperidone.

WP2: To collect and identify multiomics profiles in schizophrenia to characterize new mechanisms related to treatment response and thus, clustering a priori individuals with higher or lower like hood of respond to specific antipsychotics.

WP3: To phenotyping the effect of antipsychotics on blood glycemic, lipidic and hepatic outcomes at 1 year to characterize molecular mechanisms related to clinical and side effects outcomes at medium term.

WP4: Using bioinformatic and computational techniques for delivering highly relevant models of personalized treatment response and side effects.

WP5: Project Management and Organization.

Results: Understanding patient's biological heterogeneity at baseline in conjunction with thorough prospective clinical data will significantly lead to determining predisposition and predictive biomarkers and pathways eventually providing optimal and personalized care for schizophrenia individuals. We hypothesize that multi-omics data and systems biology analysis will permit clustering schizophrenia individuals and tailoring the most beneficial therapeutic option for each person at the right time.

Discussion: SchizOMICS assembles a team with a breadth of interdisciplinary excellence in the clinical milieu of schizophrenia and hepatic, glycemic and lipidic diseases, as well as in high-throughput omic approaches to analyze biological samples and integrating these multi-dimensional omics data into biologically meaningful context challenging.

The application of data-driven systems biology and machine learning approaches could provide a predictive understanding of schizophrenia treatment response, and pave the way to the development of novel biomarkers and rational design of schizophrenia therapeutics.

T273. A LONGITUDINAL ASSESSMENT OF GYRIFICATION PATTERNS AND SULCAL MORPHOLOGY IN ADOLESCENTS AT FAMILIAL RISK FOR SCHIZOPHRENIA AND BIPOLAR DISORDER

Simon Poortman^{*1}, Louise ten Harmsen van der Beek¹, Jakub Jamárik², Nikita Setiaman¹, Manon Hillegers¹, Neeltje Van Haren¹

¹Erasmus MC, ²Erasmus MC, Masaryk University

Background: Early diagnosis and intervention are essential for managing and improving long-term outcomes of severe mental illness, highlighting the need for reliable early biomarkers. This longitudinal study explores cortical folding development in offspring of parents with schizophrenia or bipolar disorder (SZo and BDo, respectively). Cortical gyrification, the remodeling of brain surface morphology to create sulci and gyri and thereby expanding the cortical surface area, has emerged as a promising endophenotypic marker for psychosis and risk of SZ and BD. The gyrification index (GI), which is the ratio of the pial and outer hull perimeters from structural T1-weighted magnetic resonance imaging (MRI) images, can be used to quantify this marker and has been shown to be a more stable marker of neurodevelopment than gray matter volume-based measures. Other measures that are of interest are sulcal length, depth, and width which have not yet been investigated in offspring at familial high-risk for schizophrenia or bipolar disorder.

Methods: We obtained 286 T1-weighted MRI scans of 184 offspring (aged 8–18 years at baseline) of at least one parent diagnosed with bipolar disorder (n=78) or schizophrenia (n=52) and offspring of parents without severe mental illness (n=54); 102 offspring underwent a follow-up scan (on average 3.9 years between scans). Local Gyrification Index (LGI; FreeSurfer) and sulcal morphological measures (i.e., sulcal depth, length, and width; BrainVisa) were computed and analyzed using linear mixed-effects models. To correct for multiple comparisons, we applied a Benjamini-Hochberg false discovery rate (FDR) correction (q=0.05).

Results: At baseline, no significant differences in LGI and sulcal depth, length, and width were found. A significant effect of age on both LGI and sulcal measurements was found, with decreasing LGI, sulcal depth and length and increasing sulcal width. The effect of age on LGI and sulcal trajectories was not significantly different in SZo and BDo as compared to control offspring, nor between SZo and BDo.

Discussion: This research emphasizes that cortical folding is not static but rather evolves over time. The decrease in IGI potentially reflects synaptic pruning during adolescence, where unnecessary neural connections are eliminated. We found no indication for aberrant age-related brain developmental changes in cortical folding that could precede the onset of schizophrenia or bipolar disorder.

T274. ASSOCIATIONS BETWEEN SOLUBLE UROKINASE PLASMINOGEN ACTIVATOR RECEPTOR (SUPAR) CONCENTRATION AND PSYCHIATRIC DISORDERS – A SYSTEMATIC REVIEW AND META-ANALYSIS

Jennifer Murphy^{*1}, Anna Zierotin², David Mongan³, Colm Healy², Subash Raj Susai¹, Brian O'Donoghue², Mary Clarke², Karen O'Connor⁴, Mary Cannon¹, David Cotter¹

¹Royal College of Surgeons in Ireland, ²University College Dublin, Ireland, ³Queen's University Belfast, United Kingdom, ⁴University College Cork, Ireland

Background: There is some evidence that suggests that inflammation is associated with the pathogenesis of psychiatric disorders. Soluble urokinase plasminogen activator receptor (suPAR) is a biomarker of chronic inflammation, which is thought to provide a more stable index of systemic inflammation than more widely used biomarkers. This review aims to synthesise studies that measured suPAR concentrations in individuals with a psychiatric disorder, to determine if these concentrations are altered in comparison to healthy participants.

Methods: Comprehensive literature searches from inception to June 2023 were conducted of five relevant databases (PubMed, Web of Science, Embase, Scopus and APA PsychInfo). Random-effects meta-analyses were performed to compare the standardised mean difference of suPAR levels for individuals with any psychiatric disorder relative to controls. Separate meta-analyses of suPAR levels were conducted for individuals with schizophrenia or other psychotic disorder and depressive disorder. Risk of bias was assessed using the Newcastle Ottawa Scale. Post-hoc sensitivity analyses included excluding studies at high risk of bias, and analyses of studies that measured suPAR concentrations in serum or plasma separately.

Results: The literature search identified 115 records. Eleven full-text studies were screened for eligibility and 9 studies were included for review. No significant difference was observed in suPAR levels between individuals with any psychiatric disorder compared to controls (SMD = 0.42, 95% CI [-0.20, 1.04]). However, those with depressive disorder had elevated suPAR levels relative to controls (SMD = 0.61, 95% CI [0.34, 0.87]). Similarly, there was no evidence of a significant difference in suPAR levels in individuals with any psychiatric disorder when studies at high risk of bias were excluded, but elevated suPAR concentrations for those with schizophrenia or other psychotic disorder were found (SMD = 0.98, 95% CI [0.39, 1.58]). Furthermore, studies that analysed plasma suPAR concentrations found elevated plasma suPAR levels in individuals with any psychiatric disorder relative to controls (SMD = 0.84, 95% CI [0.38, 1.29]), while studies measuring serum suPAR levels in any psychiatric disorder did not find a difference (SMD = -0.61, 95% CI [-1.27, 0.04]). For plasma, elevated suPAR concentrations were also identified for those with schizophrenia or other psychotic disorder (SMD = 0.98, 95% CI [0.39, 1.58]).

Discussion: When studies measuring either serum or plasma suPAR were considered, no significant difference in suPAR levels were observed between psychiatric disorder groups, although significantly elevated suPAR levels were detected in those with moderate to severe depressive disorder. However, plasma suPAR levels were significantly elevated in those with any psychiatric disorder relative to controls, while no difference in serum samples was found.

A similar finding was reported for schizophrenia or other psychotic disorder. The findings suggest that suPAR could represent a plasma transdiagnostic marker for these disorders and support the hypothesis that chronic inflammatory dysregulation contributes to the pathology of schizophrenia and depressive disorder. Future longitudinal studies are required to fully elucidate the role of this marker in the psychopathology of these disorders.

T275. FIRST EPISODE PSYCHOSES IN OVER-35 YEARS OLD: UNCOVERING POTENTIAL ACTIONABLE TARGETS FOR EARLY INTERVENTION SERVICES

Maria Ferrara*¹, Ilaria Domenicano¹, Aurora Marchi¹, Lorenzo Benini², Cristina Sorio², Elisabetta Gentili³, Martino Belvederi Murri¹, Spyridon Zotos², Franca Emanuelli², Luigi Grassi¹

¹*Institute of Psychiatry, University of Ferrara*, ²*Integrated Department of Mental Health and Pathological Addictions*, ³*Department of Engineering, University of Ferrara*,

Background: Early Intervention in Psychosis programs (EIS) have been historically designed around the care needs of young individuals. Since 2012, Ferrara (Italy) has successfully implemented an EIS dedicated to FEP and individuals at risk for psychosis, between the age of 15 and 35 years old. However, it has been shown that a significant group of individuals, especially women, have their onset later in life, but are excluded from EIS based on their age. The aim of this study is to compare the sociodemographic and clinical characteristics of patients who had their FEP treatment earlier than 35 years old with those of individuals who had theirs later, in order to uncover actionable clinical targets for a potentially vulnerable group of FEP individuals.

Methods: In this retrospective study individuals, aged 18-65, with a primary diagnosis of affective and non-affective, non-organic FEP, were identified in the FEPSY dataset, which includes data on who had access to community psychiatric services in Ferrara province since 1991, selecting only those who were admitted between 2012 and 2021. Patients were compared for sociodemographic, clinical, and pathway-to-care characteristics based on their age of access (under-35 and over-35) with bivariate analysis. Chi-squared tests and t-tests were performed to compare categorical variables and normally distributed variables, respectively. Mann-Whitney tests were used to analyze skewed continuous variables.

Results: A total of 854 individuals were identified, most of whom were over 35 years old (61.8%). Compared to the under-35 group, the over-35s were significantly more represented by women (55.7% vs 32.5%, $p < 0.01$), married (27.8% vs 6.1%, $p < 0.01$), living with their own family (28.8% vs 10.4%, $p < 0.01$), more frequently diagnosed with affective psychoses (21.6% vs 13.5%, $p < 0.01$) and delusion disorders (22.2% vs 19.0%, $p < 0.01$). Compared to the under-35 group, a lower proportion of those over-35 were hospitalized (47.2% vs 63.5%, $p < 0.01$). Antipsychotics were the psychotropic category most frequently prescribed in both groups, while the long-acting formulation (LAI) was less frequently prescribed in the over-35s (6.3% vs 9.0%, $p=0.36$). Antidepressants were more prescribed in the over-35s (15.3% vs 8.0%, $p < 0.01$). In the under-35s, affective psychosis was twice as frequent in women compared to men (22.6% vs 9.1%, $p < 0.01$). In both age groups, women were less frequently prescribed LAI compared to men (1.7% vs 12.3% in under-35s, $p=0.04$; 3.7% vs 10.0% in over-35s, $p=0.07$).

Discussion: This study confirmed that there is indeed a significant segment of the older population suffering from FEP and this vulnerable group mainly includes women. These

findings support the need to expand the age criteria for extant EIS, to reorient the clinical service offered to accommodate older people's care needs, and more specifically to tailor such services for women with FEP.

T276. THE ASSOCIATION BETWEEN EXECUTIVE FUNCTIONING AND SOCIETAL RECOVERY IN PEOPLE WITH A PSYCHOTIC DISORDER

Ruth Rietveld^{*1}, Bernice van Aken¹, Andre Wierdsma¹, Yolande (Y) Voskes², Marieke Pijnenborg³, Jaap van Weeghel⁴, Niels Mulder⁵

¹Erasmus MC, ²Amsterdam UMC/GGz Breburg, ³University Groningen, ⁴Phrenos/Tilburg University, ⁵Erasmus MC/Parnassia Groep

Background: Societal recovery (SR) is one of the most valued forms of recovery in people with psychotic disorders. Often, people with psychotic disorders report wanting to go back to work, study, or wanting to participate in society differently, like being a friend, brother or sister. However, very few clients succeed in taking on the roles they value. It is known that these clients often experience severe cognitive impairments, especially in the executive functions. These functions are important for how we interact with the world. Therefore, it is thought that these executive functions - might play a key role in SR.

Methods: This study is cross-sectional, and part of a cohort of 323 people with a psychotic disorder (the UP'S study). SR was measured using the World Health Organization - Disability Assessment Schedule 2.0 (WHO-DAS). This was divided into two subscales: the Daily Functioning (DF) scale and the Social Functioning (SF) scale. FR was measured using the Behavior Rating Inventory of Executive Functioning Adult version (BRIEF-A) and the Tower of London (TOL). Employment status was divided in 'Not active', 'Otherwise active' (e.g. volunteer work) and 'Active'. Model selection was based on the Wald-test.

Results: 323 participants with a mean age of 41,5 years are part of the UP'S cohort study. The mean disability score on DF was 30.3, whereas the mean SF disability score was 43.2. The BRIEF-A showed to have an effect on both the DF (= 5.1) and SF (= 5.1), whereas the TOL only had an effect on the DF (= -1.8). Furthermore, for employment status only being 'Otherwise active' had an influence on DF (= -4.5). There was no influence of employment status on SF.

Discussion: There is an important difference between self-reported and performance-based measured executive functioning in relation to Daily and Social Functioning. Furthermore, being 'Otherwise active', i.e., being a volunteer or looking for a job, has a positive influence on perceived disabilities in Daily Functioning.

T277. UNVEILING THE NRN1 GENE EPIGENETIC-EXPRESSION BRAIN CORRELATES IN SCHIZOPHRENIA

Carmen Almodóvar-Payá^{*1}, Marcos Moreno², Mariona Latorre-Guardia³, Edith Pomarol-Clotet³, Luis F. Callado⁴, Carme Gallego², Mar Fatjó-Vilas⁵

¹FIDMAG Research Foundation, Barcelona; CIBERSAM (Biomedical Research Network in Mental Health); Faculty of Biology, University of Barcelona (UB), ²Molecular Biology Institute of Barcelona (IBMB-CSIC), ³FIDMAG Research Foundation, CIBERSAM (Biomedical Research Network in Mental Health), ⁴Department of Pharmacology, University

of the Basque Country (UPV/EHU), CIBERSAM (Biomedical Research Network in Mental Health), ⁵FIDMAG Research Foundation, CIBERSAM (Biomedical Research Network in Mental Health), Department of Evolutionary Biology, Ecology and Environmental Sciences (BEECA), Faculty of Biology, University of Barcelona (UB),

Background: Schizophrenia (SZ) is characterised by neuroanatomical and synaptic plasticity alterations (Berdens et al., 2020; Keshavan et al., 2020). The *Neuritin1* gene (*NRN1*) has emerged as a pivotal gene central to these processes. Firstly, *NRN1* is associated with SZ susceptibility and cognitive performance (Fatjó-Vilas et al. 2016; Chandler et al. 2010). Secondly, *NRN1* ranks among the most differentially methylated genes in the prefrontal cortex when comparing patients and controls (Pidsley et al. 2014). Lastly, its expression exhibits sensitivity to neurotherapeutic agents (Dyrving et al. 2014; Alme et al. 2007). Our goal was to provide a comprehensive understanding of the interplay between methylation and gene expression within the *NRN1* locus. In post-mortem brain samples, we aimed to compare the methylation and mRNA levels between patients diagnosed with SZ and healthy controls and to analyse the correlation between *NRN1* methylation and expression patterns.

Methods: We used post-mortem brain tissue samples, both from the prefrontal cortex and the hippocampus. The samples came from 30 healthy subjects (HS) and 20 subjects with schizophrenia (SZ). Patients were classified based on the presence of clozapine (SZ-Clz) or the absence of antipsychotic drugs (SZ-Free) in their bloodstream at the time of death. The obtained molecular data included i) *NRN1* mRNA expression using qRT-PCR, and ii) methylation levels across the three previously identified differentially methylated islands between HS and SZ using EpiTYPER™ methodology. The statistical analyses comprised i) assessing expression level differences between groups using ANOVA, ii) examining methylation differences through Partial Least Square Discriminant Analysis (PLS-DA; R package “mixOmics”), and iii) exploring the correlation between expression and methylation components. All analyses were adjusted by sex, age, post-mortem delay, and samples' ph.

Results: *NRN1* expression was altered in patients with SZ, specifically those treated with clozapine, with a significant decrease in mRNA levels in both the prefrontal cortex and hippocampus. The PLS-DA analyses revealed that *NRN1* methylation, whether in the prefrontal or hippocampal regions, did not distinguish between HS and SZ-Free. Nevertheless, the hippocampal *NRN1* methylation effectively stratified between HS and SZ-Clz and correlated with hippocampal *NRN1* mRNA levels.

Discussion: These findings provide evidence that both *NRN1* expression and epigenetic changes are associated with SZ, especially in patients treated with clozapine. In addition, the observed correlation between epigenetic and mRNA profiles in the hippocampus suggests *NRN1*'s potential role as a molecular effector of this antipsychotic drug, deepening our understanding of the underlying mechanisms. Our results add to existing animal models detailing *NRN1* expression and epigenetic modifications post-antipsychotic treatment (Dyrvig et al. 2014; Park et al. 2014), emphasizing its pivotal role in the response to such pharmacological intervention.

T278. GLUTAMATE AND GABA-RELATED ANTERIOR CINGULATE CONNECTIVITY IN SCHIZOPHRENIA: ASSOCIATION WITH SYMPTOM DOMAINS

Jonas Persson*¹, Simon Cervenka², Linda Steinholtz², Jan Weis³, Robert Bodén²

¹*Uppsala University*, ²*Department of Medical Sciences, Psychiatry, Uppsala University*,

³*Department of Surgical Sciences, Radiology, Uppsala University*

Background: Both glutamate and gamma-aminobutyric acid (GABA) are implicated in the pathophysiology of schizophrenia. Previous studies have shown associations between altered levels of these neurotransmitters and prefrontal functional connectivity patterns in patients with schizophrenia, but less is known of how these effects relate to major symptom domains of the disorder.

Methods: Patients with longterm schizophrenia (n=27) and healthy controls (n=34) underwent resting-state functional magnetic resonance imaging (fMRI) and 1H Mescher-Garwood point-resolved spectroscopy (MEGA-PRESS) to measure glutamate and GABA levels within the anterior cingulate cortex (ACC). Positive, negative, and affective symptoms were measured with the Brief Psychiatric Rating Scale (BPRS). Seed-based connectivity was used to assess group differences in voxel-wise whole-brain ACC-connectivity and its relationship to GABA and glutamate. Summary measures from these analyses were in turn correlated to the three symptom domains.

Results: Glutamate, but not GABA, was reduced in patients compared to controls. A voxel-wise group comparison revealed reduced connectivity in patients compared to controls encompassing the ACC and bilateral insula. Overall, ACC glutamate levels were positively associated with ACC-connectivity to left insula, thalamus, midbrain, and left cerebellum. When correlating the average connectivity within this glutamate-related network to symptoms in patients, a significant relationship was found with negative symptoms only ($r=.45$, $p=.018$).

Discussion: The results are consistent with reduced prefrontal glutamate levels leading to reduced connectivity among salience processing regions, in turn contributing to negative symptoms in patients with schizophrenia. These findings add to our mechanistic understanding of this debilitating set of symptoms.

T279. THE DEVELOPMENT AND VALIDATION OF A MEDICINES OPTIMISATION TOOL TO PROTECT THE PHYSICAL HEALTH OF PEOPLE WITH SEVERE MENTAL ILLNESS (OPTIMISE)

Aoife Carolan*¹, Dolores Keating¹, Stephen McWilliams¹, Caroline Hynes¹, Mary O'Neill², Fiona Boland³, Sharon Holland⁴, Judith Strawbridge³, Cristin Ryan⁵

¹*Saint John of God Hospital Ltd.*, ²*Tallaght University Hospital*, ³*Royal College of Surgeons in Ireland*, ⁴*Northumberland, Tyne and Wear NHS Foundation Trust, Newcastle upon Tyne*,

⁵*Trinity College Dublin*

Background: The life expectancy of people with Severe Mental Illness (SMI) is shorter than those without SMI, with multimorbidity and poorer physical health contributing to health inequality. Screening tools could potentially assist the optimisation of medicines to protect the physical health of people with SMI. The aim of our research was to design and validate a

medicines optimisation tool (OPTIMISE) to help clinicians to improve physical health in people with SMI.

Methods: A review of existing published guidelines, PubMed and Medline was carried out. Literature was examined for medicines optimisation recommendations and also for reference to the management of physical illness in people with mental illness. Potential indicators were grouped according to physiological system. A multidisciplinary team with expertise in mental health and the development of screening tools agreed that 83 indicators should be included in the first draft of OPTIMISE. The Delphi consensus technique was used to develop and validate the contents. A 17-member multidisciplinary panel of experts from the UK and Ireland completed 2 rounds of Delphi consensus, rating their level of agreement to 83 prescribing indicators using a 5-point Likert scale. Indicators were accepted for inclusion in the OPTIMISE tool after achieving median score of 1 or 2, where 1 indicated strongly agree and 2 indicated agree, and 75th centile value of ≤ 2 . Interrater reliability was assessed among 4 clinicians across 20 datasets and the chance corrected level of agreement (kappa) was calculated. The kappa statistic was interpreted as poor if 0.2 or less, fair if 0.21-0.4, moderate if 0.41-0.6, substantial if 0.61-0.8, and good if 0.81-1.0.

Results: Consensus was achieved after 2 rounds of Delphi for 62 prescribing indicators where 53 indicators were accepted after round 1 and a further 9 indicators were accepted after round 2. Interrater reliability (IRR) of OPTIMISE between physicians and pharmacists indicated a substantial level of agreement with a kappa statistic (κ) of 0.75.

Discussion: OPTIMISE is a 62 indicator medicines optimisation tool, developed using Delphi consensus methodology, to assist decision making in those treating adults with SMI. IRR of OPTIMISE is substantial with an overall level of agreement (κ) of 0.75. This means that when physicians and pharmacists have access to the same medical information relating to people with SMI, they reliably achieve a substantial level of agreement when applying the various indicators within the tool. Validation of other medicines optimisation demonstrated similar levels of agreement in IRR studies. A high level of IRR improves the utilisation and reliability of OPTIMISE among different healthcare professionals in clinical settings. OPTIMISE has the potential to improve medicines optimisation by ensuring preventative medicines are considered when clinically indicated. Further research including wider validation and implementation of OPTIMISE is required to demonstrate its true benefit.

T280. SAFETY DATA OF ICLEPERTIN (BI 425809) FROM PHASE 1 HEALTHY VOLUNTEERS AND PHASE 2 PATIENTS WITH COGNITIVE IMPAIRMENT ASSOCIATED WITH SCHIZOPHRENIA

Fredrik Gruenenfelder¹, Peter Nagy*¹, Yury Shatillo², Michael Desch², Eric Fu³, Corey Reuteman-Fowler³

¹Boehringer Ingelheim International GmbH, ²Boehringer Ingelheim Pharma GmbH and Co. KG, ³Boehringer Ingelheim Pharmaceuticals, Inc.

Background: Iclepertin (BI 425809) is a potent and selective inhibitor of GlyT1 in Phase 3 clinical development for cognitive impairment associated with schizophrenia (CIAS). The Phase 1 development so far includes 330 healthy volunteers (HV, 278 on iclepertin; 52 on placebo). In Phase 2, 709 patients with CIAS were treated (438 on iclepertin; 271 placebo).

Methods: This is a descriptive abstract and no methodology was used/required.

Results: In Phase 1, 162 HV on iclepertin (58.3%) and 17 on placebo (32.7%) participants reported any adverse events (AEs) across all the dosing, 2 (0.7%) were severe in intensity and

14 (26.9%) were defined drug-related by the investigator. 5 (1.9%) AEs lead to treatment discontinuation, and 5 (1.9%) AEs were significant according to ICH E3. No AE of special interest (AESI) and serious AE (SAE) were reported. The most common Preferred terms in HVs compared to placebo were headache (50 [18%] vs 5 [9.6%]), Dizziness (28 [10.1%] vs 3 [5.8%]), Nasopharyngitis (15 [5.4%] vs 3 [5.8%]), Back Pain (15 [5.4%] vs 2 [3.8%]), Nausea [23 (8.3%) vs 1 [1.9%]]; Fatigue [18 (6.5%) vs 3 [5.8%]], Vomiting [15 (5.4%) vs 1 [1.9%]]. No Suicidal ideation or behavior was reported. No notable decrease in hemoglobin or hematocrit compared to placebo treatment was observed.

In Phase II, 204 (46.6%) patients with CIAS on iclepertin versus 131 (48.3%) on placebo reported any AEs. 10 (2.3%) treated participants versus 3 (1.1%) placebo-controlled patients had AEs of severe intensity and 76 (17.4 %) versus 50 (18.5%) were defined drug-related by the investigator. 14 (3.2%) versus 8 (3.0%) patients discontinued treatment due to an AE, and 11 (2.5%) versus 7 (2.6%) AEs were significant according to ICH E3. One (0.2%) AESI occurred on iclepertin versus 0 on placebo. 13 (3.0%) vs 6 (2.2%) SAEs have been reported. The most common Preferred terms were Headache [40 (9.1%) vs 20 (7.4%)], Somnolence [17 (3.9%) vs 7 (2.6%)], Dizziness [17 (3.9%) vs 6 (2.2%)] and Nasopharyngitis [29 (6.6%) vs 14 (5.2%)]. The SAE Schizophrenia was reported in 2 (0.5%) patients on iclepertin and 1 (0.4%) patient on placebo. Suicidal ideation was reported in 1 (0.2%) patient on iclepertin and 3 (1.1%) patients in the placebo group.

Discussion: Iclepertin was well tolerated by both HVs and CIAS patients. No dose-dependent trends were observed for the overall number of AEs. The well-known class effect, hemoglobin decrease, showed dose-dependency in one of the phase II trials in CIAS patients, however none of the changes were considered to be clinically relevant. No meaningful changes were observed in the analyzed ocular safety parameters compared to placebo treatment.

T281. MOTIVATIONAL INTERVIEWING FOR ACUTE PSYCHOSIS: A FEASIBILITY STUDY

Rahel Horisberger*¹, Janani Panchalingam¹, Claudio Corda¹, Nicolas Kleisner¹, Achim Burrer¹, Tobias Spiller¹, Erich Seifritz¹, Philipp Homan¹

¹*University Hospital of Psychiatry/University of Zurich*

Background: While guidelines recommend combining pharmacological therapy with psychotherapeutic methods already during the acute phase of schizophrenia spectrum disorders, few therapeutic interventions are available. In addition, low therapeutic adherence and resistance to treatment altogether are common obstacles during the acute phase. Motivational interviewing, a directive, client-centered counseling style for eliciting behavior change, is well suited to address these challenges. Here, we conducted a pilot study in acutely ill individuals with schizophrenia spectrum disorders to test the feasibility and effectiveness of Motivational Interviewing. We hypothesized that Motivational Interviewing is a feasible intervention in acutely ill individuals with schizophrenia spectrum disorders.

Methods: The primary objective was to investigate the impact of a brief intervention with Motivational Interviewing in an acute psychiatric inpatient setting on factors that impact treatment outcome including therapeutic alliance, changes in symptom severity, adherence to treatment, motivation for further psychotherapy and others. Inpatients with a diagnosis of

psychosis, aged between 18 and 65 years, were randomized to receive four sessions of Motivational interviewing (treatment condition) or four sessions of supportive counseling (control condition) in a single-blinded, within-therapist, parallel-group design. Speech was recorded during the sessions.

Results: Within a year, thirty-four participants were included of which 23 completed the whole study (11 in the treatment group, 12 in the control group), clearly demonstrating the feasibility of the study. While we did not formally test for statistical significance due to the pilot design, the raw data showed that therapists rated therapeutic adherence as improved in both conditions. Similarly, we saw a reduction in positive symptoms in both conditions.

Discussion: This study demonstrated the feasibility of Motivational Interviewing for acutely ill individuals with schizophrenia spectrum disorders. The study also showed that therapeutic alliance as well as psychotic symptoms improved but this awaits formal testing in a prospective clinical trial.

T282. THE PROCESSING OF FACIAL EXPRESSIONS USING MOVEMENT KINEMATICS IN SCHIZOPHRENIA PATIENTS – AN FMRI STUDY

Anastasia Pavlidou^{*1}, Evin Demir², Sofie von Känel², Sophie Sowden³, Jennifer Cook³, Sebastian Walther²

¹University of Bern, University Hospital of Psychiatry and Psychotherapy, Translation Research Centre, ²University of Bern, University Hospital of Psychiatry and Psychotherapy, Translation Research Centre, Bern, Switzerland, ³Centre for Human Brain Health, School of Psychology, University of Birmingham

Background: Understanding and recognizing facial expressions is crucial for successful social interactions. While schizophrenia patients often exhibit deficits during the recognition of different facial expressions, most stimuli used are either pictures or videos of different faces that lack ecological validity, and require the processing of multiple cues at once. In recent years, movement kinematics which refers to the detailed analysis of the speed, coordination and timing of the facial muscles involved in conveying emotions, have become an integral part in understanding the complexities of how facial muscles contribute to the recognition of various facial expressions. To this end, the current study utilized movement kinematics of facial expressions together with functional Magnetic Resonance Imaging to compare the neural correlates involved during the recognition of these facial expressions between schizophrenia patients and healthy controls.

Methods: We included 11 schizophrenia patients and 13 healthy controls matched for age and gender and measured their BOLD responses during the visual processing of the movement kinematics of four different facial expressions (angry, happy, sad and neutral) across multiple trials. Each trial started with a fixation cross (3-6 seconds), followed by a facial expression stimulus (~5 seconds), after which participants were asked to rate how 'angry/happy/sad' each stimulus was using a 1 (not angry/happy/sad) – 5 (very angry/happy/sad) Likert scale. Thus, each stimulus was rated three times; once for how angry the participants thought the stimulus appeared, once for how happy, and once for how sad. Group effects for the facial expression vs rest contrast were tested using between sample t-tests separately for each emotion (angry, happy, sad and neutral) and the results were corrected for multiple comparisons (pFDR LESS THAN 0.05). Brain images were acquired using a 3T Siemens Prisma scanner.

Results: Between group analyses revealed higher BOLD activation in schizophrenia patients' vs healthy controls during the processing of angry, happy and sad facial expressions in bilateral anterior cingulate gyrus, superior frontal gyrus, precuneus, as well as right angular gyrus. In contrast, healthy controls exhibited higher BOLD activation during the processing of happy and sad facial expressions in bilateral inferior/middle frontal gyrus, as well as, right anterior insula, supramarginal gyrus and supplementary motor area. We observed no group differences for the neutral facial expressions.

Discussion: Our results suggest that schizophrenia patients and healthy controls recruit different neural areas during the processing of the movement kinematics of different facial expressions. These differences might be crucial in unraveling the complexities of emotional processing impairments in schizophrenia patients and can help in developing novel targeted interventions that can improve their emotional processing. We expect greater differences as more participants are included in the study.

T283. IMMUNOMODULATORY EFFECTS OF PSYCHOTROPIC AGENTS: BETA DEFENSIN 2 LEVEL ASSOCIATED WITH ANTIPSYCHOTICS USE

Monica B. E. G. Ormerod^{*1}, Mashhood A. Sheikh², Thor Ueland³, Gabriela Hjell⁴, Linn Sofie Sæther³, Synve Hoffart Lunding³, Ingrid Torp Johansen³, Linn Rødevand³, Torill Ueland³, Trine V. Lagerberg³, Ingrid Melle³, Srdjan Djurovic⁵, Ole A. Andreassen³, Nils Eiel Steen⁶

¹Section for Precision Psychiatry, Oslo University Hospital, ²NORMENT, Centre, Division of Mental Health and Addiction, Oslo University Hospital, Oslo, Norway, ³Oslo University Hospital, University of Oslo, ⁴Oslo University Hospital, University of Oslo, Østfold Hospital, ⁵Oslo University Hospital, University of Oslo, University of Bergen, ⁶Oslo University Hospital, University of Oslo and Diakonhjemmet Hospital

Background: Immunomodulatory effects of psychotropic agents used to treat severe mental disorders (SMDs) have been suggested. This includes effects of antipsychotics (AP) on pro- and anti-inflammatory cytokines and markers of immune activation, as well as immunomodulatory effects of antidepressants (AD) and mood stabilizers (MS). However, findings are inconsistent and there is a need for well-adjusted studies. In the current cross-sectional study, we investigated the immunomodulatory effects of psychotropic agent use and dosage in a large sample of individuals with SMDs, applying comprehensive adjustments for potential confounders.

Methods: Participants with SMDs [N = 852, including schizophrenia spectrum (N = 588), and bipolar disorders (N = 264)] were included from the major hospitals in Oslo, Norway. We also recruited a healthy control group (HC, N=645) from the same catchment area for comparison of immune marker levels. We analyzed a panel of forty-four immune markers with use and dosage of AP, AD and MS using linear regressions with adjustments for age, sex, body-mass index (BMI), C-reactive protein (CRP), diagnosis and the Positive and Negative Syndrome Scale (PANSS) score. P-values LESS THAN 0.001 were considered significant. Participants with CRP GREATER THAN 10.0 were excluded to prevent impact from acute infections on immune marker levels.

Results: Plasma levels of human beta defensin 2 (BD-2) was positively associated ($\beta = 0.19$, p LESS THAN 0.001) with AP use in the fully adjusted model, while a similar positive trend was observed for soluble tumor necrosis factor receptor 1A (sTNF-R1) ($\beta = 0.07$, $p = 0.004$), and between MS use and sIL-2R ($\beta = 0.11$, $p = 0.004$). There were no other significant

associations between immune marker levels and psychotropic agent use, and no significant associations with psychotropic agent dose.

Discussion: The study revealed that antipsychotic agent use was associated with increased levels of BD-2. Beta defensins have broad innate immune functions including antimicrobial effects but may be immunomodulating and act as a chemoattractant for TNF activated neutrophils which could enhance disruption of blood-brain barrier function. The current results suggest that studying the effects of antipsychotics on release of beta-defensins from relevant cells and effects on neutrophils could be relevant in SMD. Lack of significant dose-dependent associations and the cross-sectional design are limitations to our findings. Identifying effects on specific immune factors might potentially help improve antipsychotic treatment strategies in SMDs.

T284. SUBSTANCE USE AND PSYCHOTIC-LIKE EXPERIENCES IN ADOLESCENCE DURING THE COVID PANDEMIC: A POPULATION BASED CROSS-SECTIONAL STUDY OF ADOLESCENTS IN IRELAND

Ronan Fleury^{*1}, Lorna Staines², Jessica Ohland³, Emmet Power³, Colm Healy⁴, Mary Cannon⁵

¹Royal College of Surgeons in Ireland, ²Royal College of Surgeons in Ireland, Department of Health Psychology, ³Royal College of Surgeons in Ireland, Department of Psychiatry, ⁴University College Dublin, School of Medicine, ⁵Royal College of Surgeons in Ireland, Department of Psychiatry,

Background: Evidence has shown adolescence as a developmentally sensitive period, characterised by biopsychosocial changes. Given this sensitivity, adolescence can be vulnerable to maladaptive behaviours, including substance use, with the potential to cause mental health concerns e.g., psychotic like experiences (PLE). This study aimed to investigate the association between substance use and PLE in Irish youth during this time period. We secondarily examined gender differences in the association.

Methods: This cross-sectional study is based on the 2021 Irish Planet Youth Programme. This school-based survey incorporated North Dublin, Cavan, and Monaghan, and included 40 schools, targeting 15–16-year-olds. The outcome of interest is PLEs, measured using the Adolescent Psychotic Symptom Screener (APSS). This self-reported seven-item tool assesses several PLEs e.g., hallucinations, grandiosity, and delusions. For the purposes of this analysis we used both a continuous score and a binary measure whereby PLE was defined as APSS score GREATER THAN 2. Primary exposure variables included cannabis use, alcohol use, and smoking within the past 30 days. Covariates included gender, rural vs urban living and ethnicity. Analysis using STATA included descriptives, mean differences and binary logistic regressions (BLR).

Results: The sample size was 4,404, with males accounting for 51%, females 44% and gender-diverse 4.5%. 7.5% (n=302) reported using cannabis, 35.4% (n=1433) reported drinking alcohol, and 12.3% (n=514) reported smoking tobacco. We found a significant mean difference in APSS scores between cannabis (N=282) and non-cannabis users (N=3,536), ($\chi^2(1) = 16.2$, $p = 0.0001$); between alcohol (N=1,330) and non-alcohol users (N=2,435), ($\chi^2(1) = 16.2$, $p = 0.0001$) and between smokers (N=470) vs non-smokers (N=3,421) ($\chi^2(1) = 58.01$, $p = 0.0001$). We found an increased risk of PLE as a categorical variable (i.e., score of GREATER THAN 2 on APSS) among cannabis users vs non users of cannabis (OR=2.36, 95% CI [1.85,3.02] and this effects remained significant following adjustment for covariates

(aOR=2.31, 95% CI [1.80,2.96]). Male users had an increased adjusted odds of PLE compared to male controls (aOR=2.15, 95% CI [1.51,3.05]). Likewise, female cannabis users had an increased adjusted odds compared to controls (aOR=2.58 95% CI [1.76,3.78]). Gender-diverse individuals using cannabis had an increased adjusted odds (aOR=2.8 95% CI [0.76,10.31]) compared to non-cannabis using controls. We found a significant association between PLE and alcohol use (OR=2.33, 95% CI [1.15,3.54]) which remained significant following adjustment (aOR=1.57, 95% CI [1.35,1.82]). Male alcohol users had an increased adjusted odds of PLE compared to non-alcohol using control males (aOR=1.43, 95% CI [1.14,1.8]). Female alcohol users had an increased adjusted odds compared to female controls (aOR=1.63 95% CI [1.31,2.03]). Gender-diverse individuals had an increased adjusted odds compared to controls (aOR=1.74 95% CI [0.84-3.61]). There was a significant association between PLE and smoking (OR=1.95, 95%CI [1.56,2.32]) which remained significant following adjustment (aOR=1.57, 95%CI[1.35,1.82]). Male users had an increased adjusted odds of PLE compared to male controls (aOR=2, 95% CI [1.46,2.76]). Female smokers had an increased adjusted odds compared to female controls (aOR= 1.9 95% CI [1.43,2.5]). Gender-diverse had an increased adjusted odds compared to controls (aOR=2.89 95% CI [0.99,8.45]). The interaction between all three substances reported an increased adjusted odds ratio of PLE (aOR=3.7, 95% CI[2.6,5.2], relative to those to who use none of the substances.

Discussion: These results highlight a significant association between all three substances explored and PLE. Cannabis is associated with the largest increased odds of PLE in comparison to alcohol and smoking. This effect did not markedly differ by gender. This survey was carried out during the pandemic. Covid-19 posed a series of new challenges to young people, such as increased isolation and lack of social services. In Ireland, schools were closed for 6-months, with two additional lockdowns for 8-months restricting access to sports, clubs, and after school activities. Within this context, the rates of substance use increased substantially within this age group in Ireland. These results have highlighted the need for further monitoring of mental health effects of the pandemic on youth. It would also be important to monitor the persistence of PLE in these young people and the associations with other mental health problems. This research was funded by the Health Research Board (Ireland).

T285. DO NEGATIVE SYMPTOMS CAUSE COGNITIVE IMPAIRMENTS, OR DO COGNITIVE IMPAIRMENTS CAUSE NEGATIVE SYMPTOMS: CAUSAL INFERENCE OF THE RELATIONSHIP BETWEEN NEGATIVE SYMPTOMS AND COGNITION OVER TIME

Christy Au-Yeung^{*1}, Keita Christophe¹, Martin Lepage²

¹*McGill University*, ²*McGill University, Douglas Mental Health University Institute*

Background: Both negative symptoms (NS) and cognitive impairments, notably verbal memory, are key predictors of functioning and remain a crucial therapeutic need. They appear during illness prodrome, highlighting their relevance to the etiology. In addition, cross-sectional and longitudinal links between NS and cognition have been firmly established, suggesting a common underlying foundation. Given their clinical significance, there have been separate advances in their treatment, including psychological treatments like cognitive remediation and pharmacotherapies for NS. However, enhancing treatment planning and development necessitates elucidating the directionality and potential causal links in their relationship, which are currently understudied and inconclusive.

Conflicting evidence for the directionality of the relationship has been demonstrated, with some suggesting poorer cognition leads to more severe NS, while others suggest that more severe deficits in NS lead to cognitive impairments. These studies primarily rely on mediation models which have been criticized for their inability to detect robust causal mediators, instead being contingent on assumed causal models. The current study seeks to overcome past methodological limits to understand which symptom predicts and potentially causes the other, within the first two years of psychosis onset, using a cross-lagged panel model design.

Methods: The Recovery After an Initial Schizophrenia Episode Early Treatment Program Data collected between 2010-2017, held in the NIMH Data Archive was used. In the study, those experiencing their first episode of psychosis received one of two early treatment interventions. The current analysis focuses on a subset of the population aged 20+, as there exist reliable cognitive norm scores in this age group (N=338). Participants had a mean age at baseline of 24.6 (SD= 4.9) and were 73% males to females. Assessments of cognition (BACS, Verbal Memory) and NS (PANSS) were conducted at baseline, 12 and 24 months. A nested random-intercept autoregressive cross-lagged panel design was used to examine whether NS predict future cognitive abilities, and/or whether cognitive abilities predict future NS levels. The model with the best fit was selected using chi-square differences test.

Results: In the best fitting model, it was observed that all paths from baseline to 12 months and from 12 months to 24 months were equal ($\chi^2(df) = 22.638(9)$, CFI = 0.96, RMSEA= 0.067). Cognition, assessed by verbal memory, significantly predicted future NS ($\beta = -0.77$, $p = 0.000$). Specifically, decreases in cognitive abilities predicted greater NS severity. On the other hand, the relationship that NS had in predicting future NS was non-significant ($\beta = -0.02$, $p = 0.78$). Cognition significantly predicted future cognition ($\beta = 0.63$, $p = 0.000$), such that better cognition at baseline predicts improved cognition at future timepoints. NS did not significantly predict cognition ($\beta = -0.018$, $p = 0.071$).

Discussion: This study employs a novel method enabling causal inference, revealing that cognition predicts future NS within two years of psychosis onset. These findings support the neurocognitive model of schizophrenia, which posits that cognitive deficits primarily contribute to the development of the disorder. In addition, these findings have implications on treatment development, for instance in the development of NS treatments that leverage cognitive approaches. Findings that NS do not predict future NS severity add to the literature highlighting the lack of stability in NS during early stages of psychosis. In summary, these findings further our understanding of these core dimensions of schizophrenia and in better understanding of symptoms in early stages of psychosis.

T286. THE EFFECT OF ADVERSE CHILDHOOD EXPERIENCES AND DIFFERENT TYPES OF BULLYING ON ATTENUATED PSYCHOTIC SYMPTOMS IN YOUNG ADULTS

Donncha Hanna^{*1}, Callum Urquhart², Ciaran Shannon³

¹Queens University Belfast, ²Queens University, ³IMPACT Research Centre, Northern Health and Social Care Trust

Background: Associations have been found between Adverse Childhood Experiences (ACEs) and attenuated psychotic symptoms (APS). However there is a lack of consensus on the potential relationships between traditional bullying (indirect, physical and verbal) or

cyber bullying and APS. This study explored the relationship between traditional forms of bullying and cyberbullying on APS when controlling ACEs.

Methods: 1528 adults (18-35) completed a range of measures including the Adverse Childhood Experience Questionnaire, Retrospective Bullying Questionnaire and Prodromal Questionnaire (PQ16) through Amazon's online crowdsourcing service Mechanical Turk (MTurk). Hierarchical multiple regression models explored the effects of demographics, ACEs, traditional bullying and cyberbullying on APS as measured by the PQ16.

Results: Responses on the PQ16 indicated that 84.1% of the sample experienced at least one APS, while 28.4% experienced 6 or more items which may be suggestive of at At Risk Mental State (ARMS). Participants reported experiencing high levels of verbal bullying, especially in Middle/High School (75.5%), and lower levels of cyber bullying (2.2-16.5%). The final regression model, which included ACEs and all forms of bullying explained 15% of variance in relation to the number of items endorsed on the PQ16. Traditional forms of bullying made a unique contribution of 4.6% to the regression model which increased by 0.6% when cyberbullying was included.

Discussion: The presence of bullying during childhood significantly contributes to the prediction of the presence of APS, even when other adverse childhood experiences are controlled for; in addition, cyberbullying has been shown to make a very small but significant contribution to APS, over and above more traditional forms of bullying.

T287. THE ASSOCIATION OF STIGMA AND RESILIENCE WITH TREATMENT DELAY IN PATIENTS DIAGNOSED WITH SCHIZOPHRENIA

Nataliia Maronchuk^{*1}, Kie Takahashi², Yuya Mizuno³, Jean Paul⁴, Fabienne Post⁴, Timo Schurr⁴, Ellen Rubinstein⁵, Hiroyuki Uchida², Alex Hofer⁴

¹Medical University Innsbruck, Department of Psychiatry and Psychotherapy, ²Keio University School of Medicine, ³Institute of Psychiatry, Psychology and Neuroscience, King's College London, ⁴Medical University of Innsbruck, ⁵North Dakota State University

Background: Schizophrenia affects approximately 0.7% of the world population and is associated with considerable morbidity as well as a 3- to 4-fold increased risk of death in contrast to the general population. A promising strategy for mitigating the negative consequences of this disorder is to encourage early help-seeking and the use of medical resources. Knowledge of the factors contributing to treatment delay among individuals diagnosed with schizophrenia is currently limited. By identifying treatment barriers, such as internalized stigma or a low degree of resilience, measures can be taken to reduce the burden of untreated illness and improve treatment outcomes. This can be achieved through shortening the duration of untreated illness (DUI).

Methods: In this ongoing study, stigma and resilience are assessed by means of the Social Impact Scale (SIS) and the Resilience Scale for Adults (RSA), respectively. In addition, various demographic and clinical data are collected.

Results: So far, 20 individuals have been included into the study. Preliminary findings indicate that there is no significant association between DUI and stigma ($r=0.187$, $p=0.443$). Additionally, the degree of resilience failed to demonstrate a significant correlation with DUI ($r=-0.080$, $p=0.744$). Accordingly, we did not find any evidence for an association between stigma, resilience, and DUI in individuals living with schizophrenia. However, a significant negative correlation was observed between resilience and stigma ($r=-0.504$, $p=.028$),

indicating that higher levels of resilience are associated with a lower perception of stigmatization.

Discussion: These preliminary results have to be seen with caution as a larger sample size is clearly needed to get insight into patients' outlooks and encounters in seeking help for mental health issues. Further research into the relationship between DUI, stigmatization, resilience, perceived quality of life, religiosity, and social engagement may be crucial for public health interventions aiming to mitigate the impact of mental disorders and reduce the global burden of schizophrenia.

T288. BEHAVIORAL ASSESSMENT OF COGNITIVE MODELS OF SCHIZOPHRENIA USING NOVEL MOUSE CANTAB-LIKE TEST BATTERY

Konstantin Andrianov*¹, Jenan Azaizah¹, Inna Gaisler-Salomon¹

¹*University of Haifa*

Background: Cognition is among the first domains to be affected in schizophrenia, and can predict the onset of psychosis. Measuring cognitive changes in schizophrenia is a complex process, which often involves a battery of multiple tests, where individual performance is compared to the average performance of the healthy population. Animal models are often used to probe into mechanisms of cognitive dysfunction. However, animal models of cognitive dysfunction in schizophrenia and other disorders usually focus on a single cognitive domain using a limited number of cognitive assays. In addition, behavioral analysis is performed at the group level without reference to individual variability.

Methods: In the present study, we designed a battery of cognitive tests equivalent to the schizophrenia relevant human CANTAB battery. This battery included multiple relevant assays per animal such as learning, memory, social behavior tests, problem solving and extra dimensional set shifting. To assess the relevance of the battery to schizophrenia research, we tested glutamate dehydrogenase (Glud1)-deficient mice, previously shown to mimic schizophrenia-like phenotypes (Lander et al. 2019). The performance of each animal in each assay was compared to the average performance of a control group, and the classification of animals into levels of cognitive vulnerability was based on abnormal performance in several assays. Animals were categorized into three groups: High-, Average- or Low-cognitive performers.

Results: We found an unequal distribution of cognitive performance in the different genotypes tested.

Discussion: This indicates that the novel mouse CANTAB-like battery may be a useful tool for the assessment of cognitive abnormalities in schizophrenia.

T289. IMPORTANCE OF CHILDHOOD TRAUMA IN SUICIDAL BEHAVIOR IN FIRST-EPISODE PSYCHOSIS

Regina Vila-Badia*¹, Alicia Colomer-Salvans¹, Clara Serra-Arumí¹, Anna Butjosa², Núria Del Cacho¹, Helena Escobedo-Pareras¹, Judith Usall¹

¹*Parc Sanitari Sant Joan de Déu*, ²*Hospital Sant Joan de Déu*

Background: Suicidal behavior and childhood trauma are two relevant variables in individuals experiencing a first-episode psychosis (FEP) and should be considered during

treatment. However, the majority of studies have examined these variables separately. Therefore, our goals were to investigate the prevalence of suicidal behaviors and childhood trauma, as well as to examine the impact of childhood trauma on suicidal risk controlling for covariates of interest.

Methods: This research was part of a longitudinal observational study called 'PROFEP Group' in Catalonia. The patients belong to Mental Health Parc Sanitari Sant Joan de Déu and Hospital Germans Trias i Pujol (for adults) and Hospital Sant Joan de Déu (for children and adolescents) health care sector. 129 participants with FEP (39♀; 90♂) were included. The Childhood Traumatic Questionnaire (CTQ), which is divided into emotional abuse, physical abuse, sexual abuse, emotional neglect and physical neglect subscales, was used to evaluate childhood trauma and the Plutchik suicide risk scale was used to assess suicide ideation, suicide attempts and suicide risk. The statistical analysis was conducted using frequencies, the Mann-Whitney U test, and linear regression models controlling for the following variables: THC consumption, perceived stress, and psychotic and depressive symptoms.

Results: Patients with FEP reported 51.2% experiencing suicidal ideation, 17.8% having made suicide attempts, and 45.7% being at suicidal risk. Regarding childhood trauma, 53.5% reported some form of CT; specifically, 16.3% reported sexual abuse, 30.2% emotional abuse, 11.6% physical abuse, 17.1% emotional neglect, and 20.2% physical neglect. Finally, after controlling for covariates, greater levels of emotional abuse, increased perceived stress, more symptoms of depression, and higher THC consumption were predictive variables for elevated scores of suicide risk.

Discussion: There was a higher prevalence of suicidal behavior and childhood trauma in FEP patients, and the relationship between these two variables, especially with emotional abuse, was evident. For this reason, it is important to consider both variables in the evaluation and treatment to improve the prognosis, quality of life, and well-being of these patients.

T290. BIO-COMPARABILITY OF LONG-ACTING ORAL WEEKLY RISPERIDONE LYN-005 TO DAILY RISPERIDONE (STARLYNG-1 STUDY)

Nayana Nagaraj¹, Anna Legedza², Elan Cohen³, David P. Walling⁴, Richard Scranton^{*2}
¹Lyndra Therapeutics Inc., ²Lyndra Therapeutics, ³CenExel Hassman Research Institute, ⁴CNS Network, LLC

Background: LYN-005 is a long acting, once weekly formulation of risperidone that aims to reduce the pill burden and improve treatment adherence in individuals with schizophrenia and schizoaffective disorders. The LYN-005 capsule consists of 6 polymeric arms that are connected to a flexible core and encapsulated as a folded star shaped formulation. The coated drug arms ensure a sustained release of the drug over the course of the week. In the pivotal STARLYNG-1 study, the pharmacokinetics of the 15 and 45mg doses were compared to the 2mg and 6mg once daily Risperdal.

Methods: In this open label, parallel group study, clinically stable participants with schizophrenia or schizoaffective disorder on a stable dose of antipsychotic drug were eligible to participate in the study. Participants received a total daily 2mg or 6mg (as 1mg twice daily / 2mg once daily or 3mg twice daily / 6mg once daily doses) Risperdal based on the participants' current antipsychotic dose. Following a run-in with daily Risperdal for 7 days, participants received 5 doses of once weekly (OW) LYN-005. In addition to LYN-005, participants also received half dose of the IR run-in as supplemental in week 1. Primary

endpoints included comparison of C_{min}, C_{max} and C_{avg} of LYN-005 at week 5 to that of Risperdal on the last day of run-in (Day -1). Secondary endpoints included change in PANSS from baseline to week 5 and treatment emergent adverse events (TEAEs) from week 1 to week 5. A total of 90 completers were planned for the study, with an interim analysis (IA) after 46 subjects completed the final PK visit. The IA allowed for the study to be either stopped for success or continued with sample size re-estimation. Pharmacokinetic parameters were calculated using non-compartment analysis.

Results: Approximately 83 subjects were enrolled in the study with 47 subjects completing the study. Dropout rate in Risperdal (n=16 over 1 week) and LYN-005 (n=18 over 5 weeks) periods were similar. Following LYN-005 administration, sustained release of risperidone was noted across all 5 doses. At the IA, GMR (90% CI) of C_{min} [1.02 (0.86, 1.22)], C_{max} [0.84 (0.77, 0.92)], and C_{avg} [1.03 (0.94, 1.15)] met the prespecified primary endpoint criteria of C_{min} (90% CI >0.8), C_{max} (90% CI <1.25), and C_{avg} (90% CI between 0.8-1.4). No notable change was observed in the positive and negative symptom scale (PANSS) scores from baseline to week 5.

LYN-005 was generally safe and well tolerated. Most common TEAEs were in the gastrointestinal (GI) system organ class, majority of which were mild (75%) and transient. GI AEs longer than 3 days included dyspepsia, GERD, and constipation. The incidence of GI AEs on LYN-005 decreased week over week. Two serious AEs (esophagitis and worsening of psychosis) were reported in the study with participants having recovered fully shortly thereafter.

Discussion: The study demonstrated bio-comparability of LYN-005 at 2 dose levels (15mg and 45mg) to Risperdal (2mg and 6mg respectively) with drug concentrations maintained above the therapeutic threshold across the dosing period and well below the peak concentrations of immediate release Risperdal. Both high and low doses were well tolerated. The new oral weekly risperidone LYN-005 formulation has the potential to reduce pill burden, as well as improve medication compliance and quality of life in individuals with schizophrenia or schizoaffective disorder.

T291. Brilaroxazine Phase 3 Recover Trial in Acute Schizophrenia Supports Efficacy, Safety, and Effects on Neuroinflammation

Laxminarayan Bhat^{*1}, Seema Bhat², Arulprakash Ramakrishnan², Wasim Khan², Amardeep Neburi², Simeen Khan²

¹Reviva Pharmaceuticals Holdings Inc, ²Reviva Pharmaceuticals Holdings Inc.

Background: Brilaroxazine, a serotonin-dopamine signaling modulator, displays partial agonist activity at D₂/3/4 and 5-HT_{1A}/2A receptors and antagonist activity at 5-HT_{2B}/7 receptors with binding affinity for 5-HT_{2B} > D₂. It also reduces proinflammatory cytokines, an underlying disease driver. Phase 1 studies in healthy volunteers and stable schizophrenia patients have established its safety and pharmacokinetic profile. Phase 2 investigation has confirmed efficacy and safety in acute schizophrenia or schizoaffective disorders. This experience set the foundation for the pivotal Phase 3 RECOVER trial to investigate brilaroxazine's safety and efficacy and explore its effects on neuroinflammation and sexual dysfunction.

Methods: This study involved a randomized, double-blind, placebo-controlled, multicenter design. It evaluated brilaroxazine (15 mg or 50 mg daily) in acute schizophrenia patients (N=411) for 28 days. Brilaroxazine 15 mg and 50 mg and placebo administered were in 140, 134, and 137 patients, respectively. PANSS total score vs. placebo, baseline to Day 28, was

the primary endpoint. Positive and negative symptoms, PANSS social cognition, excitement/agitation, personal and social performance (PSP), and clinical global impression severity (CGI-S) were secondary endpoints. Changes in Sexual Function Questionnaire (CSFQ) examined the effect on disease-related dysfunction. Analysis of neurotrophin BDNF and inflammatory cytokines (IL-6, IL-8, MCP-1, MIP-1beta) explored brilaroxazine's effects in mediating neuroinflammation.

Results: Brilaroxazine 50 mg produced a 10.1-point greater reduction vs. placebo (-23.9 vs. -13.8, $p < 0.001$) for the primary study endpoint, PANSS total score. It also resulted in significant and clinically meaningful Positive ($p < 0.001$), Negative ($p = 0.003$), and Negative Marder Symptoms ($p = 0.002$); PANSS Social Cognition ($p < 0.001$) and Excitement/Agitation ($p < 0.001$); PSP ($p < 0.001$); and CGI-S ($p < 0.001$), compared with placebo. The 15 mg dose was numerically superior for all endpoints and significant for social cognition ($p = 0.024$) and PSP ($p = 0.022$) vs. placebo. Treatment-emergent adverse events (TEAEs) rates for brilaroxazine 15 mg, 50 mg, and placebo were 34.5%, 35.5%, and 30%, and discontinuation rates were 19%, 16%, and 22%, respectively. The most frequent TEAEs included headache $< 6\%$ and somnolence $< 7.5\%$. Adverse events of special interests (AESIs) included weight gain $< 5.9\%$ and 2.1% with 50 and 15 mg doses, and akathisia and extrapyramidal symptoms $< 1\%$ with the 50 mg dose. Prolactin levels decreased in both doses, and thyroid hormone changes mirrored placebo. Brilaroxazine improved BDNF levels, decreased proinflammatory cytokines IL-6, IL-8, MCP-1, and MIP-1beta, and enhanced sexual function ($P < 0.05$) in females versus placebo.

Discussion: Brilaroxazine achieved significant efficacy at 50 mg and activity at 15 mg vs. placebo for multiple symptom domains in acute schizophrenia. Both doses were well tolerated. Improvement in inflammatory cytokine biomarker levels vs. placebo offers insight into this agent's effect on mitigating neuroinflammation, a contributing pathology to schizophrenia. Enhancement of sexual function (e.g., desirability) represents another significant finding that may relate to negative symptom improvement. These findings highlight that brilaroxazine appears to be a novel addition to the treatment armamentarium for schizophrenia and suggests potential application to other schizoaffective disorders.

T292. RL-007, A NOVEL ORAL NEUROMODULATOR BEING DEVELOPED TO TREAT COGNITIVE IMPAIRMENT ASSOCIATED WITH SCHIZOPHRENIA – A NON-CLINICAL AND CLINICAL OVERVIEW

Sarah McEwen^{*1}, Matt Pando¹, Gary Walker¹, Srinivas Rao², John Donello¹
¹*Recogify Life Sciences*, ²*atai Life Sciences*

Background: Schizophrenia is a severe mental illness and considered a complex polygenic and multifactorial disorder, involving abnormalities in neurotransmission, including the GABAergic and cholinergic synaptic pathways. Cognitive impairment associated with schizophrenia (CIAS), arising from aberrant neuromodulation, is observed in approximately 80% of schizophrenia patients and viewed as having the strongest influence on everyday functioning. These cognitive deficits are a critical target for new treatment development, as there are currently no approved therapies for CIAS. This will be the first presentation of the novel oral neuromodulator, RL-007, to provide the scientific and clinical evidence of RL-007 to potentially become a first in class therapy to improve cognition in schizophrenia patients.

Methods: Data will be summarized from preclinical studies of RL-007 that have explored the role GABAergic and cholinergic neuromodulation play in the compound's unique pharmacology. Data will be presented from a translational model of cognitive

impairment (scopolamine challenge) that was used to test the pro-cognitive effects in a series of animal and human studies. Safety and tolerability data will be summarized from over 500 participants from 10 clinical trials who have been administered RL-007. Lastly, we will present data from clinical trials that measured cognitive performance, including a Phase 2 pilot study conducted in CIAS.

Results: RL-007 enhances GABAergic signaling and hippocampal synaptic plasticity (long-term potentiation, LTP), via GABAB receptor dependent neuromodulation. RL-007 also acts synergistically with acetylcholine to enhance cholinergic signaling. RL-007 was found to be safe and well-tolerated, including in a CIAS population, and without typically observed GABAergic or cholinergic side effects. RL-007 reverses scopolamine-induced learning and memory deficits across species. Clinical studies of RL-007 found improved cognitive performance, specifically for verbal learning and memory and processing speed. Additionally, a correlation between cognitive performance and functional outcome was observed.

Discussion: RL-007 has shown a unique pharmacological profile that could assist in restoring neurotransmission abnormalities in CIAS, including GABAB modulating properties and enhanced cholinergic pathway activity through excitatory signaling. RL-007 is a safe and well-tolerated compound in humans and does not produce sedating or parasympathetic side effects. Furthermore, we have found consistent evidence for improving cognition in non-clinical and clinical studies, specifically learning and memory abilities, making RL-007 a promising compound to potentially treat CIAS. A Phase 2, placebo-controlled clinical trial in CIAS is currently underway to explore the cognitive and functional benefits of RL-007.

T293. Glutamate Modulation by Evenamide as an Add-On to TRS Patients Not Responding to Their Current Antipsychotics is Associated With Clinically Important Improvement Across Outcome Measures: Results From 1-Year, Open-Label Trial

Ravi Anand*¹, Alessio Turolla², Giovanni Chinellato³, Francesca Sansi², Arjun Roy⁴, Richard Hartman⁵

¹Anand Pharma Consulting, ²Newron Pharmaceuticals SpA, ³Newron pharmaceuticals, ⁴CliniRx, ⁵NeurWrite LLC

Background: The management of schizophrenia with 1st/2nd generation antipsychotics has led to >30% of the patients becoming treatment resistant schizophrenics (TRS). Preclinical, neurometabolic and mechanistic studies suggest that TRS is associated with excess glutamatergic [Moghaddam et al 2012], but normal dopaminergic transmission: this may explain why 5HT2/D2 blockers are ineffective in TRS. Studies in rodents, primates, and humans have demonstrated that the use of glutamate antagonists is suggestive of benefit in patients with schizophrenia. [Demjaha et al 2014]

In vivo microdialysis studies in rats demonstrated that evenamide was devoid of any effect on basal glutamate levels but attenuated the excessive glutamate release. Evenamide, a NCE, structurally unrelated to any existing/in development AP is highly selective for sodium channels, not interacting with any other CNS receptors, neurotransmitters, enzymes, or transporter. Animal studies indicated the efficacy of evenamide in ameliorating behavioral disturbances induced by dopamine/cholinergic/glutamatergic antagonists. [Bortolato et al 2018]

A pilot, placebo controlled study in patients with schizophrenia inadequately responding to aripiprazole/risperidone provided a statistically significant signal of efficacy on PANSS positive and CGI-C further supporting its benefits in TRS patients. [Anand et al 2018]

Methods: The tolerability and the long term benefits of glutamate modulation by evenamide was assessed in study 014/015, a phase 2, multinational, randomized trial with an initial 6 week, followed by 46 week extension phase with evenamide administered at 3 fixed doses (7.5, 15, 30 mg bid) as an add on treatment in patients with TRS not responding to their current AP.

Patients on a stable dose of an AP, who met criteria for TRS [Howes et al 2017], with PANSS total ≥ 70 and predominant positive symptoms (score of 4 or more on ≥ 2 core symptoms and a PANSS positive total score ≥ 20), a CGI-S rating from 4 to 6 (moderately to severely ill) were enrolled.

Efficacy, assessed by a trained psychiatrist blinded to treatment, was based on PANSS, CGI-S/C, and functioning (LOF) ratings. Changes from baseline and categorical analyses within each dose group were analyzed for the PANSS and CGI S/C using a paired t-test.

Results: 161 patients with TRS (males= 69%; mean age= 37.7 year; mean duration of illness= 6.8 year; baseline PANSS= 79.4; CGI-S= 4.5) were randomized, of whom 153 completed 6 weeks of treatment, and 144 of these patients continued into 46 week extension with 85% of them completing 1 year of treatment. [Anand et al 2023]

At week 6, the PANSS mean change from baseline was -11.9% improving to -20% at 1 year. The proportion of patients with a clinically meaningful improvement in symptoms (PANSS $\geq 20\%$ [Meltzer et al 2008; Rosenheck et al 1997]) doubled from 6 week (15.4%) to 6 month (34.0%) and increased further at 1 year (41.8%) with the vast majority (~90%) of the patients who met this level of improvement preserving their response at 1 year. In addition, ~30% of patients improved by at least 2 categories in disease severity (CGI-S), and 45% were rated at least 'much improved' (CGI-C).

The high completion rate, the low number of patients with treatment related adverse events (9.4%), discontinuation for adverse events (1.9%), and the absence of psychotic relapses, confirmed the good tolerability of evenamide.

Discussion: These results indicate a unique pattern of gradual, but sustained efficacy across all efficacy measures up to 1 year at all doses, supporting the role of glutamate release inhibition in the therapy of TRS. These encouraging results support the hypothesis that patients with TRS may have excess glutamatergic transmission that would respond to glutamate but not 5HT₂/D₂ modulation.

T294. CLINICAL DEVELOPMENT OF EMRACLIDINE FOR PSYCHOSIS IN SCHIZOPHRENIA AND ALZHEIMER'S DISEASE

Erica Koenig^{*1}, Matthew Leoni¹, Ih Chang¹, Koji Takahashi¹, Zheng Ren¹, Meera Tugnait¹,
Lillian Frohlich¹, Raymond Sanchez¹

¹Cerevel Therapeutics, LLC

Background: Emraclidine is a novel, highly selective, positive allosteric modulator of M4 muscarinic acetylcholine receptors (mAChRs), the activation of which may reduce psychotic symptoms by reducing excess dopamine signaling in the striatum. Recent data confirm target engagement of emraclidine in healthy adults (~60% M4 receptor occupancy across plasma concentrations of 350-900 ng/mL [Duvvuri et al., ACNP Meeting, 2023]). Emraclidine is currently under investigation for the treatment of schizophrenia and Alzheimer's disease psychosis (ADP). Here, we summarize emraclidine clinical data and ongoing clinical trials.

Methods: Part B of a two-part phase 1b trial (NCT04136873; Krystal et al., Lancet. 2022;17;400:2210-2220) was a 6-week, randomized, double-blind, placebo-controlled trial in adults with schizophrenia experiencing acute exacerbation of symptoms that evaluated the

safety, tolerability, pharmacokinetics (PK), and pharmacodynamics (change from baseline in Positive and Negative Syndrome Scale [PANSS] and Clinical Global Impression-Severity [CGI-S] score) of emraclidine doses identified in Part A (ie, 30 mg once daily [QD], 20 mg twice daily [BID]). A subsequent 8-week, phase 1 trial (NCT05245539) evaluated change from baseline in ambulatory blood pressure in participants with stable schizophrenia receiving emraclidine 10 mg or 30 mg QD.

EMPOWER-1 (NCT05227690) and EMPOWER-2 (NCT05227703) are ongoing phase 2, 6-week randomized trials evaluating fixed doses of emraclidine in adults with schizophrenia experiencing an acute exacerbation of psychosis (CGI-S ≥ 4 , PANSS total score 85-120). Participants are randomized 1:1:1 to placebo or 1 of 2 doses of emraclidine (30 mg or 10 mg QD [EMPOWER-1]; 30 mg or 15 mg QD [EMPOWER-2]). The primary endpoint is change from baseline to Week 6 in the PANSS total score; secondary endpoints include the CGI-S, PANSS responders, extrapyramidal symptoms, suicidality, metabolic parameters, and safety. EMPOWER-1/EMPOWER-2 participants (and de novo participants) may be eligible for EMPOWER-3 (NCT05443724), a 52-week, open-label extension trial evaluating safety and tolerability of emraclidine 30 mg QD in adults with schizophrenia. An ongoing phase 1, multiple-ascending-dose trial (NCT05644977) is evaluating the safety, tolerability, and PK of emraclidine in healthy elderly adults.

Results: In Part B of the phase 1b trial (N=81), the most common adverse events were similar across placebo, emraclidine 30-mg QD, and 20-mg BID cohorts (headache: 26%, 30%, 26%, respectively; nausea: 4%, 7%, 7%, respectively). Modest increases in supine blood pressure and heart rate observed with emraclidine treatment initiation decreased over time and were not clinically meaningful vs placebo by treatment end. At Week 6, emraclidine 30 mg QD and 20 mg BID were associated with 19.5-point (difference vs placebo -12.7, nominal P=0.023) and 17.9-point (difference vs placebo -11.1, nominal P=0.047) reductions from baseline in the PANSS total score, respectively, with associated reductions across PANSS subscales. In the ambulatory blood pressure monitoring trial, the least squares mean change from baseline at Week 8 for systolic blood pressure was -2.7 mm Hg and -0.4 mm Hg for the emraclidine 10-mg and 30-mg QD groups, respectively.

Discussion: Current data support further investigation of emraclidine as a once-daily treatment for schizophrenia without the need for titration, leading to initiation of the phase 2 EMPOWER program and the phase 1 trial evaluating the safety, tolerability, and PK of emraclidine in elderly adults to support clinical development for treatment of ADP. The emraclidine program aims to establish selective targeting of M4 mAChRs as a novel treatment approach for schizophrenia and ADP.

T295. A RANDOMIZED, DOUBLE-BLIND, ACTIVE COMPARATOR-CONTROLLED, PHASE 3 STUDY TO EVALUATE THE LONG-TERM SAFETY AND TOLERABILITY OF ULOTARONT IN PATIENTS WITH SCHIZOPHRENIA

Leslie Citrome¹, Heather Dworak², Kenneth S. Koblan³, Robert Goldman³, Hailong Cheng³, Alison Fitzgerald³, Antony Loebel³, Armin Szegedi³, Nicholas DeMartinis^{*4}

¹New York Medical College, Valhalla, NY, ²Sumitomo Pharma America, Inc., ³Sumitomo Pharma America, Marlborough, MA, ⁴Sumitomo Pharma America

Background: Ulotaront is a trace amine-associated receptor 1 (TAAR1) agonist with 5-HT1A agonist activity that lacks direct D2 and 5-HT2A receptor antagonism. Ulotaront is in clinical development for the treatment of schizophrenia. The pharmacological, safety and

tolerability profile of ulotaront appears to be distinct from atypical antipsychotics based on preclinical [Dedic et al., Int J Mol Sci 2021; Dedic et al., Mol Metab 2024] and clinical [Koblan et al., N Engl J Med 2020; Correll et al., NPJ Schizophr 2021; Kane et al., Neuropsychopharmacology 2023] data demonstrating minimal to no association with extrapyramidal symptoms (EPS), no prolactin effects, and a potentially favorable metabolic profile. The current study was designed to evaluate the long-term safety and tolerability of ulotaront, for ulotaront as a novel treatment for schizophrenia. Exploratory analyses were included to compare ulotaront to an atypical antipsychotic (quetiapine XR).

Methods: This was a multicenter, randomized (in a 2:1 ratio), double-blind, parallel-group, 52-week, flexible-dose study evaluating the safety and tolerability of ulotaront (50-100 mg/d) versus quetiapine XR (QXR; 400-800 mg/d), in adult patients with a DSM-5 diagnosis of schizophrenia who were clinically stable for ≥ 8 weeks prior to screening and had a PANSS total score ≤ 80 at study entry. Patients who were treatment resistant to antipsychotic medication or who had a history of inadequate response or intolerability to quetiapine or quetiapine XR were excluded from study entry. The primary study outcomes were safety related, including incidence of overall adverse events (AEs), serious adverse events (SAEs), AEs leading to discontinuation, change from Baseline in body mass index (BMI) and waist circumference, clinical laboratory tests, and ECG parameters.

Results: In the safety population treated with ulotaront (N=201) and QXR (N=102), total discontinuations were 47.8% vs. 44.1%, respectively, and AEs leading to study discontinuation were 22% vs. 21%. The most common AEs for ulotaront vs. QXR ($\geq 10\%$ in either group) were somnolence (6.0% vs. 20.6%), insomnia (14.9% vs. 10.8%), schizophrenia (14.4% vs. 5.9%), anxiety (13.9% vs. 9.8%), constipation (3.5% vs. 11.8%), and weight increase (4.0% vs. 10.8%). Mean changes from Baseline to Week 52 in weight-associated parameters for ulotaront vs. QXR were as follows: weight (-1.2 vs. +1.4 kg; p LESS THAN 0.001), BMI (-0.4 vs. +0.5 kg/m²; p LESS THAN 0.001), and waist circumference (-1.4 vs. +1.4 cm; p LESS THAN 0.05). There was no clinically-significant Baseline to Week 52 changes in either treatment group in laboratory (including glycemic indices, lipids, prolactin) or vital sign parameters. In secondary effectiveness measures (PANSS total and subscale scores), there were no significant differences in change from Baseline to Week 52, or to any intermediate time-point, between ulotaront and QXR.

Discussion: The results of this study extend the findings from a previously-reported 6-month Phase 2 study to 52 weeks [Correll et al. 2021], demonstrating that long-term treatment with ulotaront is safe and well-tolerated with no unexpected adverse effects for this novel TAAR1 agonist class drug. The notable lack of adverse effects of ulotaront on lipids and glycemic indices, and the significant reduction in weight and waist circumference, are consistent with preclinical research suggesting that ulotaront improves glycemic control and reduces body weight in rodent models of diabetes, obesity, and iatrogenic weight gain [Dedic et al., 2024].

T296. TRAJECTORIES OF PSYCHOTIC-LIKE EXPERIENCES AND AUTISTIC TRAITS ACROSS EARLY ADOLESCENCE AND THEIR ASSOCIATION WITH BASELINE WHITE MATTER ALTERATIONS

Grace Jacobs*¹, Suheyra Cetin-Karayumak², Nora Penzel³, Johanna Seitz-Holland⁴, Hajer Nakua⁵, Lindsay Oliver⁶, Nikos Makris², Steve Pieper², Fan Zhang², Lauren J. O'Donnell², Yogesh Rathi⁴, Stephanie Ameis⁵

¹Brigham and Women's Hospital, Harvard Medical School, ²Brigham and Women's Hospital, Harvard Medical School, ³Massachusetts General Hospital, Harvard Medical School,

⁴Brigham and Women's Hospital, Massachusetts General Hospital, Harvard Medical School, ⁵Centre for Addiction and Mental Health, University of Toronto, ⁶Centre for Addiction and Mental Health

Background: During childhood, psychotic-like experiences (PLEs) and autistic traits may co-occur, with the presence of one increasing the risk of the other. At the individual level, both PLEs and autistic traits show variable trajectories with persistent symptoms associated with poor cognition, brain alterations, and elevated risk for developing psychiatric disorders. However, co-occurring PLEs and autistic trait trajectories are poorly understood, and potential underlying structural brain features remain unknown. Childhood and adolescence are an important period of maturation for brain white matter, and alterations during this time may be related to or predictive of emerging symptoms. We investigated whether childhood white matter features are associated with trajectories related to persistent or increasing PLEs and/or autistic traits in a pediatric population-based sample.

Methods: The Prodromal Questionnaire Brief and a subset of 15 items from the Child Behavior Checklist were used to measure PLEs and autistic traits, respectively, at baseline (ages 9-10), year 1, year 2, and year 3 in 9965 (48% female) children from the Adolescent Brain Cognitive Development (ABCD) Study. Latent Class Growth Analysis (LCGA) was used to identify trajectory groups separately for PLEs and autistic traits. Goodness of fit measures AIC, BIC, log likelihood and entropy, as well as posterior probabilities of class membership were used to determine optimal models. Harmonized diffusion imaging white matter tractography measures of fractional anisotropy (FA) in 57 white matter tracts were examined in a subset of 7892 participants. ANCOVAs assessed baseline FA differences between trajectory groups (covarying for age, sex, and head motion).

Results: The LCGA models identified three trajectory groups for PLEs: 1) persistent low (89.5% of the sample), 2) increasing (3.7% of the sample), and 3) decreasing (6.8% of the sample); and three trajectory groups for autistic traits: 1) persistent low (87.3% of the sample), 2) increasing (6.8% of the sample), and 3) decreasing (5.9% of the sample). Among the trajectory groups, a greater number of females had increasing PLEs (60.3%), while a greater number of males had decreasing PLEs over time (60%, $X^2=29.7$, $df=2$, $p < 0.001$). A greater number of males also had decreasing autistic traits over time (62%, $X^2=26.8$, $df=2$, $p < 0.001$). Compared to children with both persistent low or no PLEs and autistic traits ($n=7721$): i) children with increasing PLEs only ($n=261$) featured lower baseline FA in 19 tracts, with the largest effects in the left inferior longitudinal fasciculus (ILF, $F=10.7$, $df=1$, $p=0.001$), left thalamo-parietal ($F=10.6$, $df=1$, $p=0.001$), and middle longitudinal fasciculus ($F=9.1$, $df=1$, $p=0.002$); ii) children with increasing autistic traits only ($n=527$) featured lower baseline FA in 8 tracts, with the largest effects in the right posterior limb of the internal capsule ($F=12.8$, $df=1$, $p < 0.001$), right striato-frontal ($F=6.9$, $df=1$, $p=0.008$), and left thalamo-parietal ($F=6.5$, $df=1$, $p=0.01$); iii) children with both initially high or increasing PLEs and autistic traits ($n=247$) featured lower baseline FA in 7 tracts with the largest effects in the left corona-radiata-frontal ($F=13.3$, $df=1$, $p < 0.001$) and left ILF ($F=10.1$, $df=1$, $p < 0.001$).

Discussion: PLEs and autistic trait trajectories across adolescence were associated with lower baseline white matter FA. Different tracts were associated with the presence of co-occurring persistent/increasing PLEs and autistic traits, versus only PLEs or autistic traits. Examining changes in both PLEs and autistic traits over time can help improve our understanding of this critical developmental period and important variables that may alter risk for worsening trajectories.

T297. THE TIMING AND SEVERITY OF CLOZAPINE-ASSOCIATED NEUTROPENIA: IS THE RISK OVERSTATED?

Allison Brandt^{*1}, Frederick Nucifora¹, Peter Zandi¹, Russell Margolis¹

¹*Johns Hopkins University School of Medicine*

Background: Treatment-resistant schizophrenia (TRS), defined by lack of response to two or more antipsychotic trials, is highly disabling. Clozapine has been shown to be superior to all other antipsychotics for TRS. However, the agent remains underutilized in the United States, in part due to concerns about potentially dangerous clozapine-associated neutropenia and the need for long-term hematologic monitoring and registry requirements. This study investigates patient demographics, rates of neutropenia, and the timing of neutropenia in those who started clozapine at a large academic medical system.

Methods: Data was collected from Johns Hopkins Medicine (JHM) electronic medical record between 2013 and 2023, accessed using the Schizoaffective Disorders Precision Medicine Center of Excellence registry on the Precision Medicine Analytics Platform. The registry includes demographic characteristics, medical history, medications, and lab results. Those whose first prescription for clozapine in the system was for 50mg or less were considered to be starting clozapine. Absolute neutrophil counts (ANC) prior to starting clozapine were reviewed, and patients with two ANC counts LESS THAN 2000 cells/ μ L, more than 30 days apart, without other explanation, were presumed to have Duffy-null Associated Neutrophil Count (DANC). Based on ANC counts during clozapine use and presumed DANC status, patients were divided into groups who experienced no neutropenia (ANC $\geq$ 1500 cells/ μ L or $\geq$ 1000 cells/ μ L if DANC), mild (1000 – 1499 cells/ μ L), moderate (500 – 999 cells/ μ L), and severe neutropenia (LESS THAN 500 cells/ μ L). Neutropenia for those with DANC was defined as ANC LESS THAN 1000 cells/ μ L and severe if ANC LESS THAN 500 cells/ μ L. Demographics were compared between groups and timing of first neutropenia was explored.

Results: Out of 308 patients started on clozapine, ANC data were available for 287 patients, of whom 38% were female, 62% male, 5% were Asian, 45% white, and 46% Black, 2% were Hispanic. The mean age was 39.2 years. The mean ANC before starting clozapine was 4640 cells/ μ L and the mean ANC while taking clozapine was 4600 cells/ μ L. Nineteen patients met clinical criteria for presumed DANC, and none developed neutropenia while taking clozapine. Fourteen patients (4.9%) developed neutropenia, 12 (4.2%) had mild neutropenia and two (0.7%) had moderate neutropenia. No patients developed severe neutropenia. Out of the 14 patients who developed neutropenia, 10 did so within eight months of starting clozapine, and one of the remaining four developed neutropenia only during COVID infection. Both patients who developed moderate neutropenia did so in the first 35 days of clozapine use. There were no significant differences in age, gender, race, or ethnicity among neutropenia groups, except that all patients with presumed DANC identified as Black. Three patients stopped receiving clozapine at JHM after developing neutropenia. The rest were continued on clozapine after neutropenia and neutropenia resolved.

Discussion: While ANC monitoring is required indefinitely in the US for patients taking clozapine, these results suggest that the risk of neutropenia after eight months is low and the risk of severe neutropenia during clozapine use is minimal. These findings suggest a need for careful reconsideration of current ANC monitoring requirements. Excessive and indefinite ANC monitoring may limit the most effective use of clozapine.

T298. DYNAMIC BRAIN ALPHA CONNECTIVITY IN RESTING-STATE EEG: QUANTIFYING BRAIN NETWORK STATE EVOLUTION IN INDIVIDUALS WITH PSYCHOSIS

Romain Aubonnet^{*1}, Mahmoud Hassan², Paolo Gargiulo³, Stefano Seri⁴, Giorgio Di Lorenzo¹

¹Laboratory of Psychophysiology and Cognitive Neuroscience, Department of Systems Medicine, University of Rome Tor Vergata, Rome, Italy, ²School of Engineering, University of Reykjavik, Reykjavik, Iceland, ³Institute of Biomedical and Neural Engineering, Reykjavik University, Reykjavik, Iceland, ⁴College of Health and Life, Wellcome Laboratory for MEG Studies, Aston Brain Centre, Aston University, Birmingham, West Midlands, United Kingdom

Background: Schizophrenia is a multifaceted disorder that presents a complex challenge, demanding a nuanced understanding of its neurophysiological underpinnings for effective treatment. Traditional static connectivity analyses fall short in capturing the dynamic intricacies of the brain, prompting the exploration of innovative methodologies. Our project addresses this gap by delving into dynamic connectivity analysis using electroencephalography (EEG) signals. Our aim is to unveil the nuanced dynamics of brain connectivity states in individuals with schizophrenia, shedding light on the intricate interplay of neural networks.

Methods: We conducted a study involving 78 individuals with psychosis and 60 control subjects from the OpenNeuro database. Participants underwent 5-minute resting-state EEG recordings with eyes open, utilizing a 60-channel setup. Source reconstruction was executed using eLORETA, defining 68 regions of interest (ROIs) based on the Desikan-Killiany atlas. A power spectral density (PSD) analysis was performed in the alpha band (7-13Hz). Then, functional connectivity in the alpha band was estimated using the weighted phase lag index (wPLI). Adapting methods from the classical EEG microstate approach, we performed clustering with modified k-means to identify distinct brain network states (BNS). Backfitting and smoothing were applied to each subject's data, and BNS metrics (coverage, duration, occurrence, and transition matrices) were extracted. Additionally, the dominant function of each BNS was evaluated using graph theory metrics. Statistical analyses were performed on these metrics to discern differences between control and psychosis subjects. A correlation analysis was conducted between these metrics and the scores of the cognitive domains of MCCB, as well as psychopathological scales (SANS, SAPS, GAFAS).

Results: The PSD analysis revealed significant differences in almost every ROI, with a lower power in individuals with psychosis. Correlation analysis demonstrated a Pearson coefficient between 0.2 and 0.3 (p-value LESS THAN 0.02) between speed of processing and working memory scales and PSD values, as well as a correlation of -0.3 (p-value LESS THAN 0.01), with PSD and SANS scales. The clustering analysis identified seven distinct BNS. Statistical analyses revealed significant differences (p LESS THAN 0.01, effect size GREATER THAN 0.3), in transitions between BNS, underlining the dynamic nature of neural interactions. These transitions, mostly in regions associated with visual and default mode network (DMN) cortices, emerged as main points of divergence when comparing BNS in psychosis and control subjects. Correlation analysis showed a Pearson coefficient of 0.3 (p-value LESS THAN 0.002) between transition probabilities and reasoning and problem-solving scales for patients with schizophrenia, and a Pearson coefficient around 0.2 (p-value LESS THAN 0.02) between speed of processing, visual learning, and verbal learning scales and the transition probabilities for all Control and Psychosis subjects.

Discussion: The observed disparities in BNS, particularly during transitions, suggest an intricate interplay of neural dynamics in individuals with psychosis. The prominence of

visual and DMN cortices in these differences implicates specific brain regions in the pathology of schizophrenia, which is also confirmed by the correlation between those results and cognitive scales.

Our findings pave the way for a deeper understanding of dynamic brain connectivity alterations in psychosis, providing potential avenues for targeted therapeutic interventions. Further exploration of these dynamic network states holds promise for refining diagnostic approaches and tailoring treatment strategies for individuals with schizophrenia.

T299. LATENT CLASSES BASED ON CLINICAL SYMPTOMS OF MILITARY RECRUITS WITH MENTAL HEALTH ISSUES AND THEIR CLINICAL RESPONSES TO TREATMENT

Jeongwon Eo*¹, Duk-In Jon¹, Eun Hee Park¹, Hyun Ju Hong¹

¹*Hallym University Sacred Heart Hospital*

Background: In South Korea, all men at the age of 18 or older are required to serve at military for a certain period as an obligation. These recruits should be able to withstand psychological stress and pressures of rapid adaptation of the unique and new environment in military. The number of military recruits facing adaptation issues has been on the rise, necessitating an evaluation for active service. In our previous study (Park et al., 2023), we classified the military recruits with mental issues according to latent profile analysis (LPA) and examined the treatment response during six months. In this study, we further examined clinical characteristics over the next six months.

Methods: Ninety-two participants were analyzed with LPA using MMPI-2 clinical profiles in the previous study. The three classes were identified: mild maladjustment (Class 1, n=14), neurotic depression and anxiety (Class 2, n=36), high vulnerability and hypervigilance (Class 3, n=42). At 12 months, Clinical Global Impression-Severity and Global Assessment of Functioning were assessed to test their long-term changes.

Results: While Class 1 and 2 significantly improved over 6 months, Class 3 showed little or no improvement even with more medications in our previous study. During the 6-month follow-up period, 50% of Class 1, 38.9% of Class 2, and 41.5% of Class 3 were dropped. It was during this period that their level of military service was decided. Class 1 and 2 which showed marked improvement up to initial 6 months, did not demonstrate substantial further improvement during follow-up period with a considerable portion stopped visiting hospital. Subjects in Class 3, who showed little or no improvement during initial 6 months, demonstrated continued improvement in this study, although their symptoms still appeared relatively severe.

Discussion: This study suggests clinical implications for treatment plan and intervention of each subgroup classified based on MMPI-2 clinical profiles of military recruits who might show maladjustment to serve. The long-term continuous treatment for Class 3 patients will be needed, even after exemption from active duty.

T300. THE EFFECTS OF DISTINCT ENVIRONMENTAL ENRICHMENT PROTOCOLS ON MEMORY AND/OR LEARNING IN SCHIZOPHRENIA RODENT MODELS: A SYSTEMATIC REVIEW

Sinem Güneri*¹, Emine Ilgın Hoşgelen², Köksal Alptekin³

¹Dokuz Eylül University, Graduate School of Health Sciences, ²Dokuz Eylül University, Graduate School of Health Sciences, Department of Neuroscience, ³Dokuz Eylül University, Faculty of Medicine, Department of Psychiatry

Background: Memory and learning deficits are prominent cognitive markers for schizophrenia, which may be evaluated in schizophrenia animal models through several behavioral tasks. Environmental enrichment (EE) protocols are thought to have a positive impact on memory and learning deficits, encompassing a range of interventions designed to enhance sensory, cognitive, and social stimulation in laboratory animals (Vaquero-Rodríguez et al., 2023). As EE interventions are multimodal and multifactorial, there is no evaluation determining which components of EE protocols are essential for the positive impact on cognitive domains in schizophrenia animal models. This review, therefore, focuses on the effects of different EE protocols' components on memory and learning deficits in schizophrenia rodent models.

Methods: In accordance with Preferred Reporting Items for Systematic Reviews and Meta-Analysis (PRISMA) guidelines, a search was conducted in two academic databases, Web of Science (WoS) and PubMed, by two independent researchers (SG and EIH) in January 2024. Articles meeting the following eligibility criteria were included: (1) studies solely involving rodents, (2) studies presenting a schizophrenia model, (3) environmental enrichment (EE) as an only intervention, (4) studies utilizing standard housing as a comparator, (5) studies assessing changes in memory and/or learning through relevant parameters (e.g., discrimination index), and (6) studies published in English. Exclusions were applied for (1) studies with a different protocol of EE and/or a different rearing condition as comparators, (2) studies lacking a clear specification of their research approach as a schizophrenia model, and (3) studies categorized as letters, reviews, comments, editorials, or duplicates. The SYRCLE's strategy was used for quality assessment of the involved studies.

The parameters extracted encompassed various factors such as the type of species, strain, gender, age, number of animals at the commencement of housing, the start of the behavioural experiment, the enrichment category (whether social, cognitive, or physical), the average behavioural outcome parameter, and the specific behavioural test utilized.

Results: The systematic search identified 169 records of articles, of which 60 duplicates were excluded. Afterwards, 109 articles were screened and subjected to the eligibility criteria, leading to the exclusion of 86 articles via abstract reading. After full-text reading of 23 studies, 7 of these were excluded. Therefore, 16 studies were included in this systematic review. Among these studies, the types of schizophrenia model were as follows: 8 pharmacological, 3 neurodevelopmental, and 5 genetic. While 11 studies used rats, the rest of the studies used mice. The time intervals and onsets of EE protocols are quite diversified. 5 of the studies enhanced social interaction, but all studies adopted physical activity and cognitive stimulation. Among behavioral tasks, Morris Water Maze (n=6) and Novel Object recognition tests (n=3) were most used to evaluate these deficits. EE protocols failed to ameliorate the memory and/or learning deficits in 7 out of 16 studies. 3 out of 4 studies presented no reversal of these symptoms with EE in females, while this ratio is 4 out of 12 studies in males.

Discussion: There are some contradictions regarding to which components of EE are more effective in treatment. In rodents, the onset, duration, and time intervals of EE protocols may be the reason of failure in improving some types of memory and/or learning deficits. Due to limited number of studies and divergence in EE protocols, affecting components and gender differences are elusive. Therefore, it is obvious that additional research is needed in both genders for considerable interpretation and comparison. To ensure the credibility and

widespread acceptance of EE's positive impact, it is imperative to implement a valid standardization process.

T301. MONOCYTE/LYMPHOCYTE RATIO (MLR) AS A PROXY FOR INFLAMMATION IN A SAMPLE OF CHILD AND ADOLESCENT PSYCHIATRIC INPATIENTS

Maria Gariup^{*1}, Guillermo Muñoz Sánchez², Azucena González², Carles Serra-Pagés³, Astrid Morer⁴

¹OPUS YOUNG Study, Child and Adolescent Psychiatric Center Glostrup, ²Immunology Service, Hospital Clínic, ³Immunology Service - Hospital Clínic, Barcelona University, ⁴Child and Adolescent Psychiatry Dept., Hospital Clínic and Barcelona University

Background: Research shows increased inflammatory state in subgroups of psychiatric patients through the diagnostic spectrum. Most data regard CRP and certain proinflammatory cytokines (CK), as interleukin-6 (IL-6), IL-1beta, TNF-alfa and the chemokine MCP-1 (Monocyte chemoattractant protein-1). Cytokines have shown complex actions both in the peripheral system and in the central nervous system (CNS), but their measurement is not part of the standard laboratory tests.

In search of more inexpensive and reproducible inflammation markers, recent psychiatry research has focused on monocyte/lymphocyte ratio (MLR), neutrophil/lymphocyte ratio (NLR), and platelet/lymphocyte ratio (PLR), predictors of cardiovascular, autoimmune and other systemic diseases. These markers have been found elevated among adult patients with psychotic and mood disorders versus healthy controls (HC), especially in acute phases of diseases (Cheng et al., 2022; M.G. Mazza et al., 2019; Mario Gennaro Mazza et al., 2018), and in preliminary studies in children and adolescents (C and A) with depression, psychosis and ADHD (Gędek et al., 2023; Henry Taylor et al., 2023; Özyurt and Binici, 2018). Our group has described higher cytokines (IL-1beta, IL-6, IL-8, MCP-1 and IP-10) and monocyte count in a transdiagnostic group of C and A acute inpatients, vs. a control group in the same age range (8-17) (Gariup et al., 2015). Here we compare MLR, NLR and PLR between the two groups and analyze their correlation with cytokines and clinical scales.

Methods: 77 consecutive Child and Adolescent inpatients and 34 Healthy Controls (HC) were recruited. Mean age (SD) were 15.1 (2.4) and 15.7 (2.7), male ratio 52% and 41% respectively (p GREATER THAN 0.05 for both). MLR, NLR and PLR were compared between the two groups, and between HC and 5 diagnostic clusters of inpatients (U- Mann Whitney). Spearman correlations between MLR, NLR and PLR with cytokines, CRP, age, BMI, and stressful-life events (SLE), anxiety (SCARED), global assessment of functioning (GAF), Autism Spectrum Screening Questionnaire (ASSQ) and Conners Parent Rating Scales Revised (CPRS) were assessed for the whole sample.

Results: MLR was higher in the whole patient group (p=0.049) and in the subgroup of anxiety and OCD disorders (p=0.015) vs HC. We found no significant differences in NLR and PLR distribution between patient group/subgroups and HC.

CONTROLS	(n=34)	PATIENTS	(n=77)	ADJUSTMENT
(n=5)	ANXIETY and OCD (n=17)	DEPRESSION	(n=19)	BAD
MANIA or MIXED (n=14)	PSYCHOSIS and SAD (n=22)			

MLR mean (SD)	0.17 (0.07)	0.20 (0.08)	0.20 (0.07)	0.21 (0.05)	0.19 (0.09)
	0.18 (0.06)	0.21 (0.12)			
	p=0.049*	p=0.223	p=0.015*	p=0.584	p=0.370
	p=0.140				

MLR, NLR and PLR correlated significantly with each other and with CRP. Moreover, MLR correlated with IL-1beta, IL-2, IL-8, IP-10, and ASSQ, with a trend for IL-6, IFN-gamma and GAF; NLR with IL-2, IL-6, with a trend for BMI and IL-4; PLR with IP-10.

Spearman's Rho

	MLR	NLR	PLR	CRP	BMI	IFNg	IL1b	IL2	IL4	IL6	IL8	IP10
ASSQ												
MLR		.584**	.585**	.389**		0.159	.221*	.199*		0.164	.193*	
	.196*	.343*	-0.163									
		0,000	LESS THAN	.001	0.001		0.096	0.02	0.036			
	0.086	0.042	0.047	0.01	0.088							
NLR	**		.606**	.510**	0.174		.256**	0.181	.190*			
			LESS THAN	.001	LESS THAN	.001	0.093					
	0.007	0.057	0.045									
PLR	**	**		.326**								
	.237*											
				.008								.016

Discussion: Results show higher MLR in a cohort of acute C and A psychiatric inpatients with described higher inflammatory cytokines vs HC. Of the three parameters, MLR showed the most correlations with cytokines.

Despite mutual correlations between the three markers, and with CRP, no difference was found for NLR and PLR between patients and controls, in contrast with adult literature and with some previous studies on C and A population. This may be due to sample size, young age and/or heterogeneity of diagnosis.

Results support a possible role of MLR as an inexpensive biomarker of the inflammatory profile in C and A psychiatric population.

To our knowledge this is the first work in psychiatric population relating MLR, NLR and PLR to cytokine levels.

T302. PSYCHOLOGICAL DISTRESS OF SCHIZOPHRENIA AND AT-RISK PSYCHOSIS UPON PANDEMIC ASSOCIATED WITH HIPPOCAMPUS ALTERATIONS: A LONGITUDINALLY MIXED-METHOD STUDY

Qian Guo^{*1}, Lihe Chen¹, Hao Hu¹, Dan Zhang¹, Zexin Zhao², Yao Hu¹, Xiaohua Liu¹, Guanjun Li¹, Jijun Wang¹

¹Shanghai Mental Health Center, Shanghai Jiao Tong University School of Medicine,
²Zhongshan Hospital, Fudan University

Background: Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) has caused a global pandemic in 2019 and induced extensively negative effects on long-term outcomes of mental health worldwide. It is widely accepted that impact might be more overwhelming on vulnerable population with severe mental disorders such as schizophrenia (SCZ). Hippocampus, one of core subcortical nuclei to modulate stress response, plays a unique role in psychopathological mechanism in SCZ. So far, there is no study investigating neuroimaging alterations of SCZ or at-risk psychosis in response to the stress of pandemic. In present research, we aimed to investigate the longitudinal impact of the COVID-19 pandemic on psychological distress and hippocampus features in individuals with first-episode schizophrenia (FES) and clinical high risk for psychosis (CHR).

Methods: Current study was based on existing cohorts of FES and CHR in Shanghai Mental Health Center. A total of 49 FES, 92 CHR, and 73 HC were recruited during the period of the pandemic (from August 2020 to March 2022). At baseline, participants underwent assessments including scales of PHQ-9, GAD-7, PSS-10, PCL-5, Coronavirus Impact Scale (CIS) and T1-weighted imaging on a 3.0 T S Verio MRI scanner. Nine patients were volunteered to participate semi-interview. During the large-scale outbreak of the epidemic in Shanghai (from April to May 2022), 20 FES, 42 CHR, and 43 HC were followed up with above scales and additional scales related to coping strategy (perceived social support scale, simplified coping style questionnaire, and Rosenberg self-esteem scale). Characteristics of hippocampal subfields was preprocessed by FreeSurfer (v6.0). Variance analysis, principal component analysis, and multiple linear regression analysis were applied to compare differences among three groups. Content analysis was used to encode qualitative data of semi-interviews.

Results: Demographic data among three groups showed no differences in age and gender, while HC showed higher level of education. Results of variance analysis demonstrated that levels of psychological distress were significantly elevated in FES and CHR. And the total scores of CIS was significantly higher in FES when compared to the CHR ($P=0.019$) and HC ($P=0.003$). Differences were observed in volume of bilateral hippocampal fissure ($F=4.46$, $P=0.013$; $FL=3.56$, $P=0.031$), right parasubiculum ($F=3.64$, $P=0.029$) and right hippocampus-amygdala transition area (HATA) ($F=3.30$, $P=0.040$) among three groups. Of note, psychological distress at baseline positively correlated to right parasubiculum volume in FES ($r=0.37$, $P=0.036$). Semi-interviews demonstrated that the negative coping strategies of FES patients were prominent.

At follow-up, the inter-group differences disappeared among three groups. The degree of psychological distress decreased in FES after large-scale outbreak of the epidemic, while the degree of COVID-19 impact was significantly increased in CHR ($P=0.018$) and HC ($P<0.001$). Additionally, differences in the total scores of PSSS ($F=3.81$, $P=0.026$) and SCSQ-Active ($F=3.73$, $P=0.028$) were observed across groups, with decreased PSSS scores in CHR ($P=0.033$) and lower scores of SCSQ-Active in FES ($P=0.029$). Multiple linear regression showed that passive coping strategy was related to elevated psychological distress at follow-up for FES, while positive factor was associated with lower psychological distress at follow-up for CHR and HC. Finally, volume of left hippocampal fissure at baseline was negatively correlated with the change of PSS scores ($R=-0.65$, $P=0.012$) and CIS scores ($R=-0.59$, $P=0.033$) in FES.

Discussion: The outbreak of COVID-19 pandemic has prominent effects on individuals with FES and CHR. Negative coping strategy is a risk factor for psychological distress of FES,

while positive factors such as social support, positive coping strategies, and self-esteem are protective factors for CHR and HC. Notably, alterations in hippocampal subfields of FES patients are highly correlated to their psychological distress and can predict long-term stress symptoms.

T303. PREVALENCE OF PSYCHOTIC SPECTRUM ILLNESS IDENTIFIED BY SYSTEMATIC SCREENING IN GENERAL PSYCHIATRIC SETTINGS: A META-ANALYSIS

Cheryl Y. S. Foo*¹, Jacqueline A. Clauss¹, Catherine J. Leonard¹, Katherine Dokholyan¹, Corinne Cather¹, Daphne Holt¹

¹*Massachusetts General Hospital*

Background: The absence of systematic detection strategies within general psychiatric services contributes to substantial treatment delays for individuals with psychosis. We conducted a meta-analysis to estimate rates of psychotic symptoms and likely psychotic disorders identified by screening treatment-seeking samples to inform the implementation of routine psychosis screening in outpatient psychiatric settings.

Methods: PubMed and Web of Science databases were searched to identify empirical studies that contained information on the point prevalence of psychotic symptoms, psychotic disorders, or clinical high-risk for psychosis syndrome (CHRS) identified by screening in outpatient samples aged 12-64 receiving general (i.e., not specialized) psychiatric care. Included studies were published between 2006 and 2023. Psychotic symptoms were identified by validated self-reported questionnaires (e.g., Prodromal Questionnaire), and psychotic disorders and CHRS by gold-standard structured interview assessments (e.g., Structured Interview for Psychosis-Risk Syndrome, Comprehensive Assessment of At Risk Mental States). A meta-analysis of each outcome was conducted using the DerSimonian and Laird method of estimating effect sizes in a random effects model, which accounts for between-sample heterogeneity by weighting each sample by sample size and variance.

Results: 36 independent samples from 13 countries involving n=24,979 outpatients were included in the meta-analysis. Among a general outpatient psychiatric population, the prevalence rate for screening for supra-threshold psychotic symptoms was 42.2% (95% CI: 30.1-52.7%; 25 samples, n=22,114). The prevalence rate for psychotic disorders was 8.7% (95% CI: 6.5-10.8%; 25 samples, n=15,903). The prevalence rate of CHRS was 24.3% (95% CI: 20.4-28.2%; 23 samples, n=15,991).

Discussion: High rates of psychotic spectrum illness in general psychiatric settings underscore the need for psychosis screening. These base rates in clinical settings can be used to estimate positive screen rates and resources required to conduct assessments to accurately identify and triage individuals with psychotic disorders and CHRS.

T304. A LONGITUDINAL STUDY OF BIDIRECTIONAL CAUSAL RELATIONSHIPS BETWEEN PSYCHOTIC EXPERIENCES AND PSYCHOLOGICAL DISTRESS: MODERATING EFFECT OF GENDER

Feten Fekih-Romdhane*¹, Lilia Houissa¹, Ahmad Abu-Akel², Alexandre Andrade Loch³, Majda Cheour¹, Souheil Hallit⁴

¹Tunis El Manar University, Faculty of Medicine of Tunis, ²University of Haifa, ³Universidade de Sao Paulo, ⁴Holy Spirit University of Kaslik

Background: Although the co-occurrence of psychotic experiences (PEs) and psychological distress symptoms is growingly recognized in several major previous studies, there is still a lack of literature which clearly outlines how these two psychopathological entities affect each other over time. This study is intended to add to the literature by examining: (a) the longitudinal, bidirectional associations between PEs and psychological distress in a sample of Tunisian adolescents, and (b) whether these associations are moderated by sex.

Methods: A total of 510 Tunisian adolescent students (mean age of 16.05 ± 1.01 years, 61.2% females) took part in a prospective longitudinal study. PEs and psychological distress were measured at three occasions over a one-year period. The cross-lagged panel modeling approach was adopted.

Results: The current results showed that the experience of PEs at baseline triggered later psychological distress (at 6 months), which had in turn led to further exacerbation of psychological distress at 12 months of follow-up. Temporally primary psychological distress symptoms were not a significant predictor for the development of later psychotic symptoms in the whole sample. However, temporal patterns between adolescent distress and psychotic symptoms differed for girls and boys. Adolescent girls who initially presented with PEs had an elevated risk of developing later psychological distress, and adolescent boys who firstly endorsed psychological distress were at higher risk of experiencing new onset psychotic symptoms over time.

Discussion: Findings suggest that patterns of associations between PEs and distress differ across sex in adolescent populations. Depending on sex, one factor can be an early marker for the other, and routine screening for one outcome is warranted when the other is present. This also implies that prevention and intervention strategies for adolescents who present with PEs or psychological distress need to be tailored to sex in order to reach maximum effectiveness. In particular, psychological distress could potentially serve as a primary target for decreasing and mitigating PEs in boys, and vice versa for girls. As for research perspectives, long-term follow-up studies (e.g., birth cohorts) still need to study the different possible pathways by which the two constructs could influence each other over longer periods of time. It is also crucial to investigate and better understand factors other than sex, such as a wider age range (adolescence versus early adulthood), that may moderate the relationships between psychosis and distress. Finally, the field may benefit from future experimental research testing whether targeting one of the two conditions (i.e., PEs and psychological distress) could reduce the incidence of the other in adolescents.

T305. PSYCHOTIC AND DISSOCIATIVE SYMPTOMS IN THE GENERAL POPULATION: A LATENT PROFILE ANALYSIS

Ho-wang Bryan Yu*¹, Chui-de Chiu¹, Suzanne Ho-wai So¹

¹The Chinese University of Hong Kong

Background: Psychiatric patients presenting with co-occurring positive psychotic symptoms and dissociative symptoms, compared to those with only either spectrum of symptoms, exhibit more severe symptomatology and poorer functioning. While existing literature has also corroborated the interrelatedness between psychotic and dissociative symptoms in non-clinical samples, further understanding of the frequency and pattern of their co-occurrence among the general population is limited. By using a large community sample, the current

study aimed to identify the distinct profiles of individuals demonstrating varying levels of psychotic and dissociative symptoms, using multidimensional measures that reflect their heterogeneity. The identified profiles were then compared on various outcomes (depression, anxiety, and daily functioning).

Methods: Samples were recruited through mass mail advert in local universities, snowball sampling, social media platform, and distribution of pamphlets in local communities. Participants completed a cross-sectional online survey battery encompassing the Community Assessment of Psychic Experiences-Positive scale (CAPE-P), Dissociative Experiences Measure Oxford (DEMO), basic demographics, and outcome measures (i.e., Patient Health Questionnaire-9, Generalized Anxiety Disorder-7 Scale, and WHO Disability Assessment Schedule 2.0-Short Form). To identify the profiles characterised by the heterogeneous spectra of psychotic and dissociative symptoms, subscores of CAPE-P (Persecutory Ideations, Bizarre Experiences, Perceptual Anomalies) and DEMO (Unreality, Numbness/Disconnect, Memory Blanks, Zone-Out, Vivid Internal World) were entered as indicator variables in Latent Profile Analysis (LPA). The identified profiles were compared on levels of symptoms and outcomes using Multivariate analysis of variance (MANOVA) and post-hoc analyses.

Results: The current sample consisted of 2,852 adults (mean age = 34.76; 72.3% female). Four distinct profiles were identified. Amongst the four profiles, Profile 1 (81.1%) reported the lowest mean levels across all CAPE-P and DEMO subscores (ps LESS THAN .001). Profiles 2 (9.8%) and 3 (6.6%) had moderate subscores on CAPE-P and DEMO. Profile 2 scored higher than Profile 3 on unreality and numbness/disconnect (ps LESS THAN .001), whereas Profile 3 scored higher than Profile 2 on persecutory ideations, bizarre experiences, and perceptual anomalies (ps LESS THAN .001). Profile 4 (2.5%) reported the highest levels of all CAPE-P subscores and most of the DEMO subscores (ps LESS THAN .001; except unreality and numbness/disconnect when compared to Profile 2). In terms of outcome measures, levels of depression, anxiety, and disturbance to functioning were the highest in Profile 4, followed by Profiles 2 and 3 (which did not differ from each other, ps GREATER THAN .050), and then Profile 1 (ps LESS THAN .001).

Discussion: This is the first study to use a large community sample and multidimensional measures to address the knowledge gap of identifying latent subgroups with distinct profiles of co-occurring psychotic and dissociative symptoms. While the vast majority of the sample (81.1%) reported low levels of psychotic and dissociative symptoms on average, 18.9% of individuals experienced psychotic and dissociative symptoms that co-occurred to various extents. The use of multidimensional measures delineated two moderate-severity profiles that showed contrasting observations, revealing one profile characterised by heightened overall psychotic symptoms, and another profile heightened dissociative symptoms (unreality and numbness/disconnect). The findings also revealed a subgroup, although smallest in proportion, within the general population who had high severity of psychotic and dissociative symptoms at the same time. Comparison between profiles demonstrated that individuals with the highest level of both psychotic and dissociative symptoms also suffered from the poorest emotional and functioning outcomes. Future investigations may look into putative factors or mechanisms that potentially predict the variation in class membership.

T306. CLINICAL STATUS AND FUNCTIONING OF ADULTS WITH SCHIZOPHRENIA-SPECTRUM DISORDERS IN THE UNITED STATES: FINDINGS FROM THE MENTAL AND SUBSTANCE USE DISORDERS PREVALENCE STUDY

Natalie Bareis*¹, Mark Edlund², Heidi Guyer², Lisa Dixon¹, Mark Olfson³, Thomas Smith¹, Lydia Chwastiak⁴, Maria Monroe-DeVita⁴, Marvin Swartz⁵, Jeffrey Swanson⁵, Elizabeth Sinclair Hancq⁶, T. Scott Stroup¹

¹*Columbia University Department of Psychiatry*, ²*RTI International*, ³*Columbia University Mailman School of Public Health*, ⁴*University of Washington*, ⁵*Duke University School of Medicine*, ⁶*Treatment Advocacy Center*

Background: Life circumstances and characteristics of individuals living with schizophrenia spectrum disorders (schizophrenia) in US households are inadequately understood. Prior epidemiologic studies identifying prevalence of schizophrenia have been limited by use of screening questionnaires that reduce the accuracy of diagnostic determinations due to the complexity of schizophrenia. Clinical studies have been limited to individuals receiving treatment.

Methods: The US Mental and Substance Use Disorders Prevalence Study, conducted from October 2020-October 2022, is the first US national epidemiologic study of schizophrenia and other behavioral disorders since 2003. Unique to this epidemiological study, clinically trained interviewers administered the Structured Clinical Interview for the DSM-5 to make diagnoses among adults aged 18-65 years and collected their sociodemographic information. Using sampling weights, we compared adults with and without schizophrenia with respect to their sociodemographic characteristics and functioning; among adults with schizophrenia, we examined clinical characteristics.

Results: Among the household sample, people who identified as Black were 3.3 times as likely to have schizophrenia as those who identified as White (28.6% vs. 13.4%; Adjusted Odds Ratio 3.3, 95% confidence interval 1.3-8.1). These individuals were more likely to have completed no more than a high school or a GED degree (63.9% vs 36.3%, AOR 3.5, 1.6-7.7), less likely to be employed (16.9% vs. 61.0%; AOR 0.12, 0.1-0.3) and more likely to have annual family income LESS THAN \$20,000 (36.9% vs. 17.0%; AOR 3.6, 1.3-10.5) than those without schizophrenia. They were also less likely to be married or in a relationship than those without schizophrenia (25.3% vs 49.8%, AOR 0.3, 0.2-0.7; 29.7% vs 69.7%, AOR 0.4, 0.2-0.9 respectively). Alcohol and cannabis were the most common substances used by individuals with schizophrenia, with cannabis use 3 times as likely among those with than without schizophrenia (AOR 3.2, 1.7-6.0). Cigarette use was 4 times as likely among individuals with than without schizophrenia (51.1% vs 21.2%, AOR 4.2, 2.1-8.3). Mean Global Assessment of Functioning scores were poor and lower among people with than without schizophrenia (44.8 [standard error 2.0] vs. 77.2 [0.5], p LESS THAN 0.01). Among people with schizophrenia, 51.7% (95% CI 34.0-69.4) had a major depressive episode and 17.3% (4.7-30.0) met criteria for post-traumatic stress disorder in the past year. In the past year 56.4% (37.7-75.0) received mental health outpatient treatment and 25.5% (12.7-38.3) received minimally adequate treatment (≥ 1 antipsychotic and ≥ 4 outpatient visits).

Discussion: This innovative national epidemiological study found that people with schizophrenia in US households experience pervasive social and economic disadvantages. While prior long-term longitudinal cohort studies have found that many people with schizophrenia have achieved life milestones and may recover, in this cross-sectional study most were unemployed, many lived in poverty, and a majority had serious functional impairment. Few received adequate treatment despite the development of multiple effective psychosocial and antipsychotic treatments. In addition, the increased prevalence of schizophrenia among individuals who identify as Black, even when diagnoses were obtained using a semi-structured diagnostic interview, should be considered in relation to systemic factors such as poverty, trauma exposure and discrimination that are risk factors for psychosis

and may contribute to these higher rates. Policies, interventions, and further research are needed to mitigate these problems.

T307. REDUCED PITCH RANGE IN SCHIZOPHRENIA: TOWARDS QUANTIFICATION OF FLAT AFFECT THROUGH PROSODY AND SEMANTIC ANALYSIS OF SPEECH SAMPLE

Yunlai Gui^{*1}, Mingyuan Li¹, Mikisha Lyn Doop¹, Manaan Kar Ray², Lena Palaniyappan³, Timothy J. Crow⁴, Sohee Park¹

¹*Vanderbilt University*, ²*The Metro South Addiction and Mental Health Services*, ³*McGill University*, ⁴*University of Oxford*

Background: Past research indicates that prosody processing is impaired in schizophrenia. Monotonous speech in individuals with schizophrenia (SZ) is associated with negative symptoms such as flat affect (Parola et al., 2020; de Boer et al., 2023). But due to the variability of speech production, it has been difficult to quantify prosody from acoustic features of speech samples in clinical contexts. The current study examined both acoustic and semantic features of speech produced by SZ and healthy controls (CO) in structured clinical interviews from the UK and USA. In addition, we also recruited a small group of individuals with affective disorders (AF) to explore acoustic variations between schizophrenia and other psychiatric disorders.

Methods: There were two studies (acoustic and semantic). Speech samples were recorded by asking 4 open-ended neutral (home, hobbies) and emotional (sex, god) interview questions. Demographic information and symptom ratings were collected. Study 1 focused on the acoustic properties of the speech from 35 SZ, 15 AF, and 37 CO in Oxford, UK. We extracted the minimum and maximum fundamental pitch using Praat (praat.org) for the 4 topics. Study 2 focused on the semantics using the same interviews, which were transcribed verbatim. Transcripts from a total of 22 SZ and 13 CO participants from the UK and USA were available for analysis. We used the Linguistic Inquiry and Word Count (LIWC-22) software to extract content summary variables including word count, emotional tone, words per sentence, and linguistic variables that summarize parts of speech including pronouns, prepositions, verbs, and adjectives.

Results: In study 1, SZ had the most compressed pitch range while CO had the largest pitch range ($F(2,79)=4.89$, $P < 0.01$). We found a significant interaction between the themes (neutral vs. emotional) and diagnosis, such that SZ had a decreased pitch range when talking about emotional themes; AF remained constant, while CO had an increased pitch range ($F(2,79)=3.49$, $P=0.035$). In addition, for the God topic, reduced pitch range was correlated with negative symptoms ($r(45)=-0.34$, $P=0.019$), and higher maximum pitch was correlated with lower depressive scores ($r(45)=-0.33$, $P=0.027$). Higher maximum pitch was also correlated with lower depressive scores for the home topic ($r(42)=-0.33$, $P=0.031$). Overall, SZ spent less time talking during the emotional questions than CO ($F(2,79)=3.37$, $P=0.039$). In study 2, SZ used fewer emotional words than CO only when discussing home ($F(1,32)=5.45$, $P=0.026$), with no other group differences in content emotionality. The severity of negative symptoms was related to reduced use of affective words when talking about home ($r(22)=0.49$, $P=0.022$) and sex ($r(22)=0.65$, $P < 0.01$). Overall, SZ used more personal pronouns than CO ($F(1,33)=5.62$, $P=0.024$), while CO used more

prepositions ($F(1,33)=6.09$, $P=0.019$), adjectives ($F(1,33)=4.62$, $P=0.039$) and have more words per sentence than SZ ($F(1,33)=8.75$, $P < 0.01$).

Discussion: While CO increased the pitch range in emotional speech, the pitch range was reduced in SZ. Semantic analysis showed that SZ overall was not different from CO in their use of affective words. Given the symptom correlation, reduced pitch range could be a possible measure to estimate negative symptoms, regardless of emotional valences in speech samples. In addition, the semantic analysis showed that SZ talked about topics in a more specific way by using more personal pronouns such as “I”, while the speech content for CO was richer and more abstract with more adjectives and words per sentence. A larger and more age-matched sample would provide a better picture as subject recruitment is still ongoing.

T308. CORRELATION ANALYSIS BETWEEN COMPUTATIONAL MEASURES OF VOICE AND SPEECH AND PANSS SCORES FROM PATIENTS WITH SCHIZOPHRENIA-SPECTRUM DISORDERS IN REMISSION

Hugo Corona Hernández^{*1}, Janna de Boer¹, Silvia Ciampelli¹, Mara Fennema¹, Alban Voppel¹, Sanne Koops¹, Iris Sommer¹

¹*University Medical Center Groningen, University of Groningen*

Background: Clinical research capitalizing on methods of spoken language processing (SLP) (i.e., voice-related and acoustic measures) to assess psychotic symptoms has sought to find evidence that this quantitative approach can qualify as reliable, valid, and objective. A criterion to examine this consist in testing whether SLP measures correlate to the gold standard used in research and clinical practice to assess the severity of psychotic symptoms in individuals with schizophrenia-spectrum disorders (SSD), i.e., the Positive and Negative Syndrome Scale (PANSS). A recent meta-analysis (Parola et al., 2020) pulled evidence that pitch variability, proportion of spoken time, and pause duration correlate to negative symptoms as measured by PANSS scores. Yet, it also emphasized that replicating these findings having a large sample size and using a standardized set of acoustic features is warranted, which we decided to set as the aim of this study.

Methods: Data from 111 patients with SSD in remission was collected. Severity of psychotic symptoms was assessed using the PANSS. Three scores were used for this study: the PANSS scale total, and the totals of the negative and positive subscales. Patients’ speech was elicited using a semi-structured interview comprising open-ended questions designed to prevent excessive emotional arousal. Individual audio recordings of each patient's speech were the basis to computationally derive the 88 acoustic features of the extended Geneva Minimalistic Acoustic Parameter Set (eGeMAPS). Correlational analyses between each of the three total PANSS scores and the acoustic features were done separately. A two-steps visual inspection of scatter plots first without and then with regression line was used to identify pairs of variables seemingly showing a linear correlation, allowing to select the variables for statistical tests. Normal distribution of residuals was assessed through Shapiro–Wilk tests to determine whether (non)-parametric correlations were appropriate. Adjusted p-values $< .05$ were considered significant, correcting for multiple comparisons using the Bonferroni method.

Results: Shapiro-wilk tests confirmed that non-parametric (spearman) correlations were needed. The PANSS scale total score seemed to linearly relate to 28 eGeMAPS features, 14 out of which correlated to PANSS scale total with absolute ρ between .30 and .36 (all adj-p $< .05$). Most of these were measures of loudness ($n = 5$). The PANSS

negative total score seemed to linearly relate to 39 eGeMAPS features, 17 out of which correlated to PANSS negative total score with absolute ρ between .30 and .48 (all adj-p LESS THAN .05). Most of these were measures of loudness ($n = 7$). The PANSS positive total score seemed to linearly relate to 30 eGeMAPS features, with measures related to fundamental frequency ($n = 9$), loudness ($n = 8$), timbral information ($n = 5$), sound intensity ($n = 5$), and pronunciation of vowels ($n = 3$). There were no significant correlations between the PANSS positive total score and these 30 features.

Discussion: Our results suggest that SLP measures can capture information related to both negative psychotic symptoms and total psychopathology, unlike that of positive symptoms. Future research should disentangle whether loudness differently accounts for negative psychotic symptoms and total psychopathology.

T309. CONDITIONED HALLUCINATIONS ARE ASSOCIATED WITH INCREASED TOP-DOWN CONNECTIVITY: AN INTRACRANIAL EEG STUDY

Yufei Cai¹, Julia Rodriguez-Sanchez*², Yanyan Li¹, Chao Zhang³, Rick Adams², Daniel J. Hauke², Kai Zhang³, Albert Powers⁴, Liang Wang¹

¹CAS Key Laboratory of Mental Health, Institute of Psychology, Beijing, ²University College London, ³Department of Neurosurgery, Beijing Tiantan Hospital, Capital Medical University, Beijing, ⁴Yale University School of Medicine, New Haven, CT

Background: Auditory hallucinations are a major feature of psychosis spectrum disorders. Growing evidence suggests that they are caused by an overreliance on prior beliefs, which dominate inference above incoming sensory evidence. Conditioned hallucinations (CH) can be induced in healthy individuals by pairing stimuli across two modalities (Powers et al., 2017, Science), allowing to investigate the role of perceptual priors and sensory evidence, as well as the underlying neural mechanisms.

Methods: Intracranial electroencephalography data was collected from 19 patients with medically-refractory epilepsy during the CH task. Briefly, participants were instructed to detect a 1000-Hz auditory target embedded in white noise which co-occurred with a visual stimulus. In a subset of 7 patients, we used dynamic causal modelling to analyse effective connectivity between the posterior superior temporal sulcus (STS) and the inferior frontal gyrus (IFG), previously shown to mediate CH.

Results: Replicating past results, participants reported perceiving a tone on trials when no target was present (CH trials), with higher CH rates in those with high hallucination proneness. During CH trials, there was increased alpha/beta (8-30 Hz) activity in the IFG and increased gamma (30-150 Hz) activity in the STS, compared with trials where participants correctly reported the absence of a target. The STS also showed delayed gamma activity in CH relative to correct hit trials. Both effects were best explained by a task-modulated increase in connectivity from the IFG to the STS (posterior probability GREATER THAN .95).

Discussion: We show that task-induced hallucinations are caused by an increase in top-down connectivity. Our results support the hypothesis that hallucinations arise from an overreliance on prior beliefs.

T310. SELF-ESTEEM IN CHILDREN WITH FAMILIAL HIGH RISK OF SCHIZOPHRENIA OR BIPOLAR DISORDER AND CONTROLS ASSESSED LONGITUDINALLY IN A POPULATION-BASED COHORT STUDY

Mette Krantz^{*1}, Ditte Ellersgaard², Nicoline Hemager³, Maja Gregersen⁴, Anne Søndergaard³, Aja Greve⁵, Julie Marie Brandt⁶, Lotte Vedum⁷, Melanie Ritter¹, Christina Bruun Knudsen⁷, Anna Krogh Andreasen⁸, Carsten Hjorthøj⁹, Ole Mors¹⁰, Anne Thorup¹¹, Merete Nordentoft¹²

¹Mental Health Services in the Capital Region of Denmark, Child and Adolescent Mental Health Centre - BFOR, ²Mental Health Services in Capital Region of Denmark, Mental Health Centre Copenhagen, ³CORE - Copenhagen Research Centre for Mental Health, Mental Health Services in the Capital Region of Denmark, Mental Health Centre Copenhagen, ⁴CORE - Copenhagen Research Centre for Mental Health, Mental Health Services in the Capital Region of Denmark, Child and Adolescent Mental Health Centre - BFOR, ⁵Psychosis Research Unit, Aarhus University Hospital Psychiatry, ⁶CORE-Copenhagen Research Centre for Mental Health, Mental Health Center Copenhagen, Capital Region of Denmark, Copenhagen University Hospital, ⁷The Psychosis Research Unit, Aarhus University Hospital Psychiatry, ⁸Psychosis Research Unit, Aarhus University Hospital - Psychiatry, ⁹Copenhagen Research Center for Mental Health-CORE; Mental Health Center Copenhagen, Copenhagen University Hospital, Denmark, ¹⁰Psychosis Research Unit, Aarhus University Hospital, ¹¹Mental Health Services in Capital Region of Denmark, Child and Adolescent Mental Health Centre, ¹²Copenhagen Research Centre for Mental Health (CORE), Mental Health Centre Copenhagen, Copenhagen University Hospital

Background: Self-perception is of immediate importance for well-being and quality of life and low self-esteem is a risk factor for mental illness. Children of parents with schizophrenia or bipolar disorder are at increased risk of experiencing a range of difficulties related to developmental, parental and social factors which might influence self-esteem negatively, and further, their risk of developing mental illness is increased, compared to the background population. Therefore, assessing self-perception and identifying predictors of low self-perception in this group can aid to obtain knowledge on how to support a positive development and possibly prevent mental illness.

Methods: In a nationwide cohort of children of parents with schizophrenia or bipolar disorder, we assessed self-esteem at ages 7, 9, 11 and 14 with the questionnaire "I Think I am", age-appropriate versions, consisting of the subscales "Physical appearance", "Skills and talents", "Psychological well-being", "Relationships with family" and "Relationships with others". Background information concerning family characteristics and interviews concerning psychopathology, level of parental functioning, levels of stimulation and support provided at home, and bullying was assessed for both children and caregivers.

Results: A total of 519 children participated with data from at least one time point (N=514 at age 7, N=466 at age 9, N=439 at age 11, and N=415 at age 14). Across all time points of assessment, children of parents with schizophrenia had lower total scores compared with controls ($p \leq 0.001$), and at age 11, this was also the case for children of parents with bipolar disorder ($p = 0.002$). Across all ages except for age 9, overall differences were found between groups in proportions with low, medium, and high self-esteem. For children of parents with schizophrenia, subscale differences both concerning skills, appearance, well-being and relationships were present at all assessments while no subscale differences were present between children of parents with bipolar disorder and controls at age 7. However, subscales resembling those with differences between the schizophrenia risk group and controls began

likewise to differ for the bipolar risk group from age 9. Experience of bullying, and low levels of stimulation and support provided at home at age 7 predicted low age 14 self-esteem, and low self-esteem at age 7 predicted presence of a mental disorder at age 11.

Discussion: This study demonstrates that particularly children of parents with schizophrenia, but also bipolar disorder, perceive themselves more negatively than children of parents with none of these disorders. It highlights the need for awareness of low self-esteem among children at familial high risk of severe mental disorder, and suggests that awareness of risk factors for self-esteem, including experience of bullying and living in an inadequate home environment, is needed. Further, our results suggests that self-esteem may be a relevant predictor of later psychopathology and thus relevant to assess for prevention and early intervention among children at familial risk of schizophrenia or bipolar disorder.

T311. PREVALENCE OF PSYCHOTIC DISORDERS IN PROBLEM GAMBLERS: A SYSTEMATIC REVIEW AND META-ANALYSIS

Olivier Corbeil*¹, Laurent Béchard², Elizabeth Anderson³, Charles Desmeules⁴, Maxime Huot-Lavoie⁴, Lauryann Bachand³, Sébastien Brodeur⁴, Pierre-Hugues Carmichael⁵, Christian Jacques³, Marco Solmi⁶, Isabelle Giroux³, Michel Dorval², Marc-André Roy⁴, Marie-France Demers²

¹Laval University, ²Faculty of Pharmacy, Laval University, ³School of Psychology, Laval University, ⁴Faculty of Medicine, Laval University, ⁵Center of Excellence on Aging in Quebec, ⁶Department of Psychiatry, University of Ottawa

Background: High rates of psychiatric comorbidities have been found in people with problem gambling (PBG), including substance use, anxiety, and mood disorders. Psychotic disorders have received less attention, although this comorbidity is expected to have a significant impact on the course, consequences, and treatment of PBG. This review aimed to estimate the prevalence of psychotic disorders in problem gamblers.

Methods: Medline (Ovid), EMBASE, PsycINFO (Ovid), CINAHL, CENTRAL, Web of science, and ProQuest were searched on November 1, 2023, without language restrictions. Studies involving people with PBG and reporting the prevalence of psychotic disorders were included. Risk of bias was assessed using the Joanna Briggs Institute critical appraisal for systematic reviews of prevalence data. The pooled prevalence of psychotic disorders was calculated using a random effects generalized linear mixed model.

Results: Of 1271 records screened, 22 studies (n = 19,131) were included. The overall prevalence of psychotic disorders was 4.9% (95% CI, 3.6 – 6.5%, I² = 88%). Among the different types of psychotic disorders, there were no significant differences between the prevalence of schizophrenia, non-affective psychotic disorders, and any psychotic disorders, including affective psychoses. No differences were found for factors such as type of population (treatment-seekers vs non-treatment-seekers) and treatment setting (inpatient vs outpatient). The majority of included studies had a moderate risk of bias.

Discussion: There is a need to better understand the comorbidity of psychotic disorders in problem gamblers, as this knowledge is key to promoting appropriate prevention and treatment strategies for the non-negligible proportion of individuals affected.

T312. HOMOCYSTEINE, RENAL FUNCTION AND NEUROLOGICAL SOFT SIGNS IN INDIVIDUALS WITH SCHIZOPHRENIA

Michael Treiber*¹, Sofia Athanasiou², Kostas Chovardas², Theocharis Kyziridis², Olympia Letsiou², Eva-Maria Tsapakis², Konstantinos Fountoulakis²

¹Medical University of Vienna, ²Aristotle University of Thessaloniki

Background: Schizophrenia is associated with several markers of inflammation and aberrant neurodevelopment. Homocysteine (Hcy) is suggested to have a pathogenic impact on neurodevelopment, the cardiovascular system and renal function, through induction of oxidative stress and excitotoxicity. Neurological soft signs (NSS) refer to a group of subtle sensory and motor deficits, linked to symptom severity in schizophrenia. In this study we aim to evaluate associations between psychopathology, NSS, Hcy, and blood-based parameters of renal function in individuals with schizophrenia.

Methods: Patients were recruited at the 3rd Department of Psychiatry of Aristotle University of Thessaloniki (Ethics Committee approval no. 74/2023, 17/12/2023). We recruited (a) in-patients with schizophrenia following acute symptom resolution and stabilization, and (b) stable out-patients with schizophrenia provided they were on maintenance treatment for a minimum of six months. Psychopathology was assessed with the Positive and Negative Syndrome Scale (PANSS). We evaluated NSS using the Greek version of the Neurological Evaluation Scale (NES). Blood samples were drawn after an overnight fasting and tobacco abstinence for over twelve hours. We used the Pearson correlation with Bonferroni post-hoc corrections for multiple comparison to test for correlations between PANSS scores, NSS, Hcy, Folate, and biochemical indices of renal function, namely urea and creatinine.

Results: A total of 26 patients (10 female and 14 in-patients) with schizophrenia were included in this preliminary analysis of an ongoing observational study. Mean age of participants was 41.3 (SD 11.2) years. We observed hyperhomocysteinaemia (Hcy levels GREATER THAN 10 $\mu\text{mol/L}$) in 87% of our sample. The correlation between Hcy and NSS was not significant. In an explorative analysis, however, NSS were significantly correlated with PANSS scores ($r=.390$, $p=.05$). The “sensory integration” subgroup of the NES correlated significantly with the PANSS positive scale scoring ($r=.522$, $p=.009$). After Bonferroni correction, Pearson’s correlations revealed a significant association between Hcy and folate ($r=-.594$, $p=.014$), urea ($r=.559$, $p=.030$), but the correlation between Hcy and creatinine did not survive Bonferroni correction.

Discussion: Our preliminary data showed that Hcy levels are positively associated with renal function parameters such as urea and creatinine, although the correlation with creatinine did not remain significant after correction for multiple comparisons. Imbalance in the Hcy metabolism, thus oxidative stress and excitotoxicity, have been associated with renal dysfunction [Yang et al. 2020]. High Hcy levels, associated with increased creatinine and blood urea levels, were reported in hypertension, a main cause of renal dysfunction and a comorbidity often found in individuals with schizophrenia. On the other hand, Hcy levels were negatively associated with folate levels. Moreover, the positive correlations between the “sensory integration” subgroup of the NES and the PANSS positive scale scoring seem to contribute to reported findings on the impairment of sensory integration in psychotic disorders. Hcy did not correlate with symptom severity or NSS. These are preliminary results, however, and recruitment is currently ongoing to increase the validity of our conclusions. Nevertheless, it should be kept in mind that antipsychotics per se may be associated with renal function decline, thus further research investigating strategies that are lowering Hcy levels, such as folic acid and cyanocobalamin (Vitamin B12) substitution might provide deeper insight.

T313. PSYCHOTIC EXPERIENCES AND ITS CLINICAL CORRELATES IN ADOLESCENTS WITH PTSD SECONDARY TO A RECENT SEXUAL ASSAULT

Department of Psychiatry, Hospital Clinic of Barcelona / Fundació Clinic per la la Recerca Biomèdica (FCRB). CIBERSAM.

Background: Adolescence is the developmental period with the highest risk of suffering a sexual assault (SA) as well as a critical period for developing psychotic symptoms. Sexual trauma is a significant risk factor for developing psychosis (Lowey, 2019; Varese, 2012). Posttraumatic Stress Disorder (PTSD) symptoms partly mediate the association between trauma and psychotic experiences (PEs) (Strelchuk et al., 2022). AIM: To examine PEs and its clinical correlates in a sample of adolescent women survivors of a recent SA.

Methods: Ongoing prospective longitudinal study including help-seeking adolescent women who meet criteria for PTSD attended in the two reference clinical programs for sexual violence in Barcelona (Hospital Clínic, Hospital Vall d'Hebrón). Sample: 24 SA-PTSD adolescents (17.2±1.6 years, 82% Caucasian, age at SA 16.5±1.8) and 22 community control adolescents (CC, 17.4±1.1 years, 91% Caucasian). Inclusion/exclusion criteria: 12-18 years, meeting criteria for PTSD secondary to SA suffered in the previous year, IQ GREATER THAN 70, not having neurological conditions. Additional exclusion criteria for CC sample were having a history of sexual violence or PTSD. Instruments: Clinician-Administered PTSD scale for DSM-5-Child/Adolescent version (CAPS-CA-5), Community Assessment of Psychic Experiences-42, Spanish version (CAPE-42), Adolescent Dissociative Experiences Scale (A-DES), Global Functioning: Role and Social scales.

Results: SA-PTSD and CC adolescents did not significantly differ in age ($t=0.49$, $p=0.626$), race ($\chi^2=2.91$, $p=0.234$) nor familial socioeconomic status (mostly medium, $t=0.51$, $p=0.612$). CA-CAPS-5 symptoms severity in SA-PTSD group was high (total symptoms: 40.14±9.42). SA-PTSD adolescents had higher PEs than CC (CAPE-42 total symptoms: 91.38±21.14 VS 67.18±11.93, $t=4.83$, p LESS THAN 0.001; positive dimension: 1.9±0.48 VS 1.5±0.31, $t=3.82$, p LESS THAN 0.001; negative: 2.3±0.60 VS 1.8±0.40, $t=3.86$, p LESS THAN 0.001; depressive: 2.6±0.69 VS 1.7±0.25, $t=5.85$, p LESS THAN 0.001) and higher distress levels (positive dimension: 2.3±0.51 VS 1.73±0.50, $t=4.01$, p LESS THAN 0.001; negative: 2.45±0.68 VS 2.03±0.46, $t=3.86$, p LESS THAN 0.001; depressive PEs: 2.76±0.60 VS 2.2±0.64, $t=3.11$, $p=0.003$).

Total CAPE-42 symptoms in SA-PTSD adolescents were correlated with PTSD intrusion symptoms (0.631, $p=0.002$), mood/cognitive alterations (0.513, $p=0.015$), hiperarousal (0.445, $p=0.038$) and total PTSD symptoms (0.654, $p=0.001$), and with dissociative symptoms (0.756, p LESS THAN 0.001). They were negatively correlated with social functioning (-0.545, $p=0.009$). Positive PEs were correlated with PTSD total severity symptoms (0.596, $p=0.003$), intrusion symptoms (0.504, $p=0.017$), hiperarousal (0.555,

p=0.007) and dissociative symptoms (0.731, p LESS THAN 0.000). Negative PEs were correlated with PTSD total severity symptoms (0.524, p=0.012), intrusive (0.496, p=0.019) and mood/cognitive PTSD alterations (0.478, p=0.025), and with dissociative symptoms (0.647, p=0.001). They were negatively correlated with lower social functioning (-0.580, p=0.005). Depressive PEs were correlated with PTSD total severity symptoms (0.666, p=0.001), intrusive (0.788, p LESS THAN 0.001), and mood/cognitive PTSD symptoms (0.536, p=0.010) and dissociative symptoms (0.638, p=0.001), and with lower social (-0.689, p LESS THAN 0.001) and role (-0.523, p=0.012) functioning.

Discussion: Adolescents with SA-PTSD showed higher PEs than CC and experienced them as more distressing. PEs were correlated with PTSD symptoms severity, dissociative symptoms and poorer functioning. Positive, negative and depressive PEs appeared to be specifically correlated with different dimensions of PTSD whereas dissociative symptoms appeared to be correlated with all them. ACKNOWLEDGMENTS: Fund Alicia Koplowitz.

T314. GENE EXPRESSION IMPUTATION PROVIDES CLINICAL AND BIOLOGICAL INSIGHTS INTO TREATMENT-RESISTANT SCHIZOPHRENIA POLYGENIC RISK

Lucía Prohens Coll*¹, Natalia Rodriguez², Alex Gonzalez-Segura², Albert Martínez-Pinteño³, David Olivares Berjaga⁴, Irene Martínez Serrano⁵, Aitor González⁶, Gisela Mezquida⁷, Mara Parellada⁸, Manuel J. Cuesta⁹, Miquel Bernardo¹⁰, Patricia Gassó¹¹, Sergi Mas¹²

CIBERSAM, ¹¹University of Barcelona-IDIBAPS-CIBERSAM, ¹²Department of Basic Clinical Practice, University of Barcelona, IDIBAPS, CIBERSAM

Background: Treatment-resistant schizophrenia (TRS) is defined as a less than 20% reduction of positive symptoms after at least two trials of non-clozapine antipsychotics, each at an adequate dose and duration of treatment, and potential comorbid factors such as addiction (Potkin et al., 2020) and poorly treated due to the underutilization of clozapine, the gold standard and only evidence-based antipsychotic prescribed for this condition (Rubio and Kane, 2020). As longer delays in clozapine initiation are associated with poorer treatment outcomes (Shah et al., 2018) the identification of predictors and biomarkers for the early detection and treatment of TRS is an essential step. In this study, we investigated

the biological and clinical aspects of TRS within a polygenic framework. With a gene expression imputation LESS THAN on from the largest genome-wide association LESS THAN on study GWAS of TRS (Pardiñas et al., 2022) we could translate it to regulatory mechanisms that can be associated with clinical features of TRS in a cohort with first episode psychosis (FEP).

Methods: We performed transcriptome imputation LESS THAN on using S-PrediXcan in the largest GWAS of TRS to find gene LESS THAN cally regulated gene expression (GReX). To test if the GReX was associated with TRS, we performed a TWAS using predic LESS THAN on models (MASHR-based models) trained on nine brain LESS THAN ssues based on GTEx v8 release data: putamen (PUT), substantia nigra, (SN) prefrontal cortex (FL), hypothalamus (HTH), hippocampus (HIP), cerebellum (CB), caudate (CAU), anterior cingulate cortex (CNG) and amygdala (AMY). Next, for each LESS THAN ssue, we constructed a GReX risk score (GReX-PS) of the iden LESS THAN fied genes in a sample of genotyped FEP pa LESS THAN ents to test the associa LESS THAN on of the GReX-PS with clinical phenotypes, including clinical symptomatology, global func LESS THAN oning and cogni LESS THAN ve performance.

Results: GReX-RSs constructed with the SN, HIP and AMY at a p-value = 0.5 were significantly (p LESS THAN 0.001 according to Holm-Bonferroni sequen LESS THAN al correc LESS THAN on method) associated (SN: $R^2=0.061$, $F(3197)=4.25$, p LESS THAN 0.001; HIP: $R^2=0.088$, $F(3197)=6.33$, p LESS THAN 0.001; AMY: $R^2=0.098$, $F(3197)=7.14$, p LESS THAN 0.001) and significantly predicted (SN: $\beta=0.15$, 95 % CI= p GREATER THAN 0.001) and was significantly associated with more cogni LESS THAN ve impairments in sustained agen LESS THAN on ($\beta=-0.13$, 95 % CI=[-0.20;- 0.05], p LESS THAN 0.001). The p-value of 0.5 was selected because it explained the largest propor LESS THAN on of variability in all cases. In comparison with random sets of proteins of similar size from the genome, the PPI networks built with the lists of genes included in the GReX-RS, (using pvalues= 0.5) which were significantly associated with clinical data (SN 814 genes, HIP 887 genes, AMY 1155 genes and FL 1112 genes), showed significantly more connec LESS THAN ons than expected ($p=1.9\times10^{-5}$; 1.9×10^{-3} ; 1.8×10^{-6} ; 1.0×10^{-16} ; respec LESS THAN vely). A cluster analysis iden LESS THAN fied two func LESS THAN onal clusters in the SN network, cluster 1 enriched with biological processes related to the immune system and the major histocompa LESS THAN bility complex II, and cluster 2 enriched with mitochondrial gene expression and transla LESS THAN on and RNA metabolic processes. The HIP network included three clusters: cluster 1 enriched with cellular metabolic processes (including nitrogen compounds, RNA, DNA and proteins) and response to stress, cluster 2 enriched with transport and immune system processes, and cluster 3 enriched with acid metabolic processes. Two clusters were iden LESS THAN fied in the network constructed with AMY genes: cluster 1 enriched in nucleic acid processes and cluster 2 enriched in cellular localiza LESS THAN on processes. Finally, three clusters were defined in the FL network: cluster 1 enriched in nucleic acid processes, cluster 2 enriched in acid and lipid metabolic processes and cluster 3 enriched in mitochondrial gene expression.

Discussion: Our analysis provides evidence that the polygenic basis of TRS includes gene LESS THAN c variants influencing gene expression in key brain areas like the substantia nigra, hippocampus, amygdala and prefrontal cortex, which are closely related to the suggested clinical predictors of TRS (persistence of nega LESS THAN ve symptomatology and cogni LESS THAN ve altera LESS THAN ons in sustained agen LESS THAN on) in FEP pa LESS THAN ents. This gives more insight into the biological mechanisms and clinical explana LESS THAN on

underlying TRS, support the idea of TRS as a distinct subtype of schizophrenia with neurobiological differences from treatment-responsive schizophrenia, offering insights into improving prevention and treatment from the earliest stages of the illness.

T315. EFFECTS OF DELUSIONAL AND DISTRESSING MEMORIES ON NEGATIVE PRIMING PERFORMANCE AMONG INDIVIDUALS WITH DELUSIONS

Suzanne So¹, Chen Zhu^{*2}, Chui-de Chiu¹, Gloria HY Wong³, Ryan Balzan⁴, Sandra Saurman Chan¹

¹The Chinese University of Hong Kong, ²Shenzhen University, ³The University of Hong Kong, ⁴Flinders University

Background: It has been suggested that patients with schizophrenia have impaired inhibitory control (IC), manifested as problems in ignoring irrelevant information during information processing. Research has shown that IC is correlated with the overall severity of psychotic symptoms and that improvement in IC is associated with symptom reduction. It is of interest to examine the relationship between IC and delusions in particular, because it has been argued that delusions may be maintained by the failure to inhibit irrelevant information from entering the appraisal. It has been suggested that cognitive control may be further disrupted by aberrant salience, a tendency to attribute significance to irrelevant stimuli, which is heightened when an individual is experiencing psychotic symptoms actively. Therefore, adopting a single-symptom approach and a more sensitive negative priming (NP) paradigm, this study aimed to (i) examine the association between NP performance and delusions, and (ii) compare NP performance between a delusional memory condition and two control conditions (distressing memory and neutral).

Methods: Adults with schizophrenia and delusions (PANSS P1 score GREATER THAN 3) were tested with the negative priming (NP) paradigm, as well as clinical ratings and demographic measures. During the baseline interview, autobiographic memories of a delusional experience and a distressing experience were elicited using the MADS interview (Wessely et al., 1993) and the autobiographical memory test (AMT, Williams and Broadbent, 1986) respectively. For the AMT, participants were individually presented with negative emotion words (e.g. sad, regretful, angry, fearful, worried, frustrated). For both types of memories, participants were encouraged to provide detailed information about the experience and confirmed their ability to vividly recall it.

In the 96-trial numerical NP task, participants were instructed to respond to the count of integers while ignoring the identity of the integer. Reaction times (RT) and accuracy of the button-press responses were recorded. In the 48 NP trials, the target of the probe is the same as the distractor of the prime (e.g. '111' □ '2'), whereas in the 48 non-NP trials, the probe trial is unrelated to the prime (e.g. '44' □ '3'). An NP score is calculated as the RT difference between correct NP and non-NP trials. All participants completed the neutral condition first, followed by the two memory conditions in a counterbalanced order.

Results: The sample consisted of 68 patients (41.54±12.63 years of age, 34 females) with a non-affective schizophrenia spectrum disorder and active delusions. Forty-one were on medication (CPZ 481.07±500.09). The average number of years in psychiatric service was 8.5±8.79. The average IQ was 92.25±10.86. GAD-7 was 7.13±5.95. PHQ-9 was 8.76±6.54.

PANSS scores were 17.24 ± 4.57 (Positive), 13.79 ± 4.39 (Negative), and 29.46 ± 7.8 (General psychopathology). PANSS delusions (P1) score was 4.68 ± 0.97 . PSYRATS scores were 9.63 ± 11.93 (Hallucinations) and 13.82 ± 4.45 (Delusions). Across experimental conditions, the NP effect was relatively small (2.55 ± 30.33). One-way repeated ANOVA test found no significant effect of conditions ($F(2,132) = 0.54$, $p = 0.584$). None of the NP effects in any conditions was significantly correlated with PANSS delusions (P1), PSYRATS total scores, or PSYRATS dimensions scores (all p s GREATER THAN .050). The NP effects were not significantly correlated with IQ, PHQ-9, GAD-7 or antipsychotics (p s GREATER THAN .050).

Discussion: The negative priming effect was reduced in patients with delusions. This was not correlated with delusionality. Activation of memories did not significantly influence inhibition control.

T316. USING ACOUSTIC SPEECH ANALYSIS TO DIFFERENTIATE BETWEEN SCHIZOPHRENIA SPECTRUM DISORDERS AND BIPOLAR DISORDER

Sanne Koops^{*1}, Hugo Corona-Hernández¹, Mara Fennema¹, Janna de Boer¹, Silvia Ciampelli¹, Alban Voppel¹, Iris Sommer¹

¹*Department of Biomedical Sciences of Cells and Systems, University Medical Center Groningen, the Netherlands.*

Background: Schizophrenia spectrum disorder (SSD) and bipolar disorder (BD) lay on a continuum and cannot always be distinguished. Yet, one or the other diagnosis has implications for treatment and prognosis. To complicate things further, diagnosis may change over time and in some patients diagnosis and treatment need to be re-assessed.

Given the importance of speech patterns during the diagnostic process in current clinical practice, there has been extensive research exploring the potential of automatic speech analysis to enhance the diagnostic process. To date, most of this research has focused on classifying diagnosed patients from healthy controls, or classifying between subtypes of similar diagnoses. However, it would be of large clinical value if a speech-based tool could aid in differentiating between psychiatric conditions. Here, we explored the value of using automatically extracted acoustic features of spontaneous speech in distinguishing patients diagnosed with SSD from patients diagnosed with BD.

Methods: Spontaneous speech was obtained during a short semi-structured interview of 64 participants diagnosed with SSD and 64 participants diagnosed with BD. Using OpenSMILE, the extended Geneva Acoustic Minimalistic Parameter Set (eGeMAPS) was used to extract 88 acoustic features. These features include 6 temporal parameters (e.g. speech rate), 24 frequency parameters, 43 spectral parameters (e.g. Mel-frequency cepstral coefficients) and 14 parameters related to energy or amplitude (e.g. intensity). These features were fed into a random forest algorithm with 10-fold crossvalidation to assess their ability in accurately classifying the two conditions. Gini-importance scores were calculated to estimate the importance of specific predictors in the model.

Results: The model reached an accuracy of 0.73 in classifying participants with SSD and BD on the basis of acoustic parameters of speech. The model showed an AUC of 0.79, precision of 0.69 and recall of 0.82. We found that voiced segments per seconds obtained the highest importance score in the final model, with on average more segments in people diagnosed as

BD ($M = 2.34$, $SD = 0.63$) than in those diagnosed with SSD ($M = 1.79$, $SD = 0.63$), indicating shorter speech segments in patients with BD.

Discussion: These initial results show that a machine learning classifier on the basis of automatically extracted acoustic speech parameters can distinguish between patients with SSD and BD. Voiced segments per seconds proved to be the most important predictor in this model. Shorter speech segments in BD may be attributed to symptoms related to (hypo)mania, such as more energetic or pressured speech, or jumping from topic to topic. Previous research demonstrated a higher rate of voiced segments in SSD compared to healthy controls. This may be more due to symptoms of disorganized speech in patients with SSD, resulting in more segmentation compared to healthy controls but with a less pronounced segmentation compared to BD.

Besides existing evidence of the potential of speech technology to differentiate a diagnosis from no diagnosis, these results now show that the technology also shows promise for differentiating between diagnostic categories in the field of psychiatry.

T317. EVALUATION OF DIFFERENT INTERVIEW PROTOCOLS WITH MACHINE LEARNING ALGORITHMS FOR AT-RISK MENTAL STATES (ARMS) CONVERSION SCREENING

João Medrado Gondim^{*1}, Alexandre Loch², Felipe Argolo³, Ana Caroline Lopes-Rocha⁴, Julio Cesar Andrade⁴, Martinus Theodorus van de Bilt⁴, Leonardo Peroni⁴, Natalia Mansur Haddad⁴, Guillermo Cecchi⁵, Natalia Mota⁶, Wagner Farid Gattaz⁴, Cheryl Corcoran⁷, Anderson Ara⁸

¹Campinas State University, ²University of Sao Paulo, ³Universidade de São Paulo (USP), ⁴Institute of Psychiatry, Laboratory of Neuroscience (LIM 27), University of Sao Paulo, Brazil, ⁵IBM TJ Watson Research Center, ⁶Institute of Psychiatry, Federal University of Rio de Janeiro, Rio de Janeiro, Brazil, ⁷Icahn School of Medicine At Mount Sinai, ⁸Department of Statistics, Federal University of Paraná, Curitiba-PR, Brazil

Background: At Risk Mental State (ARMS) is a preclinical stage indicating possible conversion of a patient into neurosis or psychosis. However, this preclinical stage is not deterministic for conversion alone, posing a problem when screening these patients. This work applies machine learning algorithms to investigate the use of two interview protocols with facial and head movement features, extracted from brief video-recordings, to assess whether ARMS participants will convert or not to psychosis.

Methods: 21 non-converters and 31 converters were interviewed with a memory reports protocol (MR) and the Structured Interview for Prodromal Syndromes subject overview (SO) while being recorded. We then extract facial landmarks frame-by-frame, employed to create facial and head movement features, either by simply summarizing each points' values (with median absolute deviation and interquartile range) or using them to create new features (head angles, distance or angle between points), also summarized later. 649 features were generated for both interviews from each participant, originating 1298 final features that were tested with Wilcoxon's Ranksum to select 87 that better separate the two groups, 4 from SO videos and 83 from RM videos.

These features were employed in the training of machine learning algorithms in different scenarios: first only the 4 SO features, secondly only the 83 RM features and then the 87 features from both videos used all together and separately with a Voting Classifier. Also, the

selected features were tested, comparing their correlation with 16 prodromal symptoms diagnosed values with Spearman's correlation test and their distribution with the absence (diagnosis ≤ 1) or presence (diagnosis ≥ 2) with Wilcoxon's Ranksum test.

Results: After 1000 rounds of leave-group-out training, each classifier achieved 72%, 79%, 79% and 81% F1 Score, using, respectively, SO, MR, both sets of features all together and separately. Considering the Sensibility (true positive rate), metrics were, respectively: 69%, 75%, 77% and 80%. Moreover, selected features from SO and MR videos showed significant p-values considering the absence or presence of differing prodromal symptoms, highlighting: the interquartile range of the angle between the tip of the nose and the midpoint between eyes, on the MR videos, and "Experience of Emotions and Self" (p-value: 0.0019) and the Spearman's correlation coefficient between the left corner of the mouth and the midpoint of the left eyebrow on the X axis, on the SO videos, and "Dysphoric Mood" (p-value: 0.0066). Also, 12 different MR features had a relevant (GREATER THAN 0.3) Spearman's correlation coefficient, emphasizing: the Spearman's correlation coefficient between two eyelids points in the Y axis and "Disorganized Communication" ($\rho=0.4251$).

Discussion: Our study shows how different protocols generate distinct information that, employed in combination, can provide diagnosticians with more precise information when assessing for conversion of ARMS participants. Selected features from SO and MR protocols showed significant correlations with different prodromal symptoms, leading to diverse usages of facial landmarks on the screening of ARMS patients.

T318. THE CLINICAL HIGH RISK STATE FOR SCHIZOPHRENIA SHARES NEURAL MECHANISMS OF SOCIAL COGNITIVE DEFICITS WITH CHRONIC SCHIZOPHRENIA

Jessica Lee^{*1}, Aida Murati¹, Nahian Chowdhury¹, Daniel Ruiz-Betancourt¹, Fabiola Plaza¹, Juan Sanchez-Peña¹, Gaurav Patel¹

¹*Columbia University and New York State Psychiatric Institute*

Background: Evidence suggests that social cognition disruptions are present in individuals at clinical high risk (CHR) of developing schizophrenia. However, whether the neural mechanisms underlying these disruptions are similar to participants with schizophrenia (SzP) remains unclear. Here we study whether CHRs share the same eye-tracking deficits and disruptions of the underlying temporoparietal junction and superior temporal sulcus (TPJ-STs) that we have previously found in SzP.

Methods: We collected eye-tracking data in 41 healthy controls (HC), 26 CHR and 43 SzP while they performed The Awareness of Social Inference Test (TASIT). We quantified eye-tracking deviation as the z-transformed distance from the mean of the HCs on each video frame. We further examined whether saccadic eye-movements towards moving facial expressions differed between groups as a function of both the face motion velocity and the amplitude of the saccade. To examine the functional integrity of the TPJ-STs, we used BOLD-fMRI data collected from a subset of 22 HC, 17 CHR and 23 SzP watching a 15-minute silent movie clip to quantify association of the inter-subject correlation (ISC) of each TPJ-STs area to TASIT performance. To examine the structural integrity of the TPJ-STs, we compared the functional connectivity from 22 minutes of resting state fMRI data collected from an overlapping sample of 41 HC, 30 CHRs and 42 SzPs.

Results: TASIT sarcasm performance in both HC and CHR was higher than SzP ($F(2,59)=13.67$, $p < 0.001$). However, CHR eye-tracking was divergent from HC

in the same intervals as SzP ($t(25)=3.75$, p LESS THAN .001). Additionally, CHRs made less large-amplitude saccades ($5-10^\circ$) to the same velocities of face-motion as SzP (37% reduction, p LESS THAN .01). In the movie-fMRI experiment, the ISC of the TPJm hub area in CHRs did not differ from HC as it did in SzP. However, only in CHRs, increased ISC of the TPJp high-level theory-of-mind area correlated with better TASIT sarcasm performance ($r(15)=-.66$, $p=.004$). In the resting-state fMRI experiment, we observed significantly decreased connectivity between the STS language and early visual areas ($F(2,111)=4.36$, p LESS THAN 0.05) in CHRs that was similar to SzPs. We also observed that the connectivity strength of the STS language to both late visual ($F(2,111)=4.11$, p LESS THAN 0.05) and auditory areas ($F(2,111)=5.02$, p LESS THAN 0.01) in CHRs was between HC and SzP.

Discussion: Together, the results suggest that CHR share some mechanisms of social cognition impairments with SzP. They also point to potential top-down mechanisms that mitigate the resulting impact of these impairments on social functioning. Identification of shared and distinct neural mechanisms of social perception in CHR and SzP will aid in better understanding of the pathophysiological mechanism underlying social deficits in schizophrenia.

T319. ASSESSING CONTROL OVER VISUAL AND VERBAL HALLUCINATIONS USING BISTABLE PERCEPTUAL TASKS

Gabriela Hernández-Busot*¹, Catalina Mourgues-Cordern², Adrianisse Vega-Reyes², Dayanna Seguí-Moró², Albert Powers III²

¹Yale, ²Yale University School of Medicine Department of Psychiatry

Background: Perceptual experiences, such as visual and auditory verbal hallucinations occur both in the general population and in those with psychosis. The degree to which individuals can voluntarily control such experiences significantly impacts their likelihood of seeking help. To determine whether control over perceptual events overall is higher in those with higher degrees of control over their hallucinations, we employed bi-stable auditory and visual tasks to a large sample of international voice-hearers.

Methods: The study analyzed data from 359 participants from the Yale Control Over Perceptual Experiences (COPE) study, who reported at least monthly auditory hallucinations over the last six months. We conducted our study using two bi-stable tasks: the auditory "Yanny or Laurel" task, where participants could hear either "Yanny" or "Laurel," and a visual task featuring dots perceived as moving either horizontally or vertically. The study was structured into six blocks, each designed to explore different facets of perceptual switching: The initial block established the 50% threshold for perceptual switches; the second block measured the natural rate of these switches, highlighting participants' inherent perceptual variability; the third and fourth blocks aimed to control perceptual changes, with the third block instructing participants to minimize perceptual switches and the fourth encouraging them to increase switches to evaluate perceptual flexibility; the fifth block measured the average time it took for participants to alter their percept along with low-level sensory biasing; and the final (sixth) block assessed how long participants could maintain a single perceptual viewpoint against low-level biasing in the opposite direction. This approach allowed for a nuanced understanding of how individuals perceive and modulate their sensory experiences in response to bi-stable stimuli. Subsequently, participants were subdivided based on their self-reported control over hallucinations into low (scores ≤ 2) and high (scores ≥ 3) control groups, utilizing the degree of control subscale from the COPE questionnaire.

Clinical measures such as the White Bear Suppression Inventory (WBSI), Launay-Slade Hallucination Scale (LSHS), Auditory Hallucinations Rating Scale (AHRs), COPE, and Peters et al. Delusions Inventory (PDI) were assessed.

Results: Preliminary findings show that individuals with lower control who exhibited higher tendencies towards thought suppression (as indicated by WBSI total, distraction, and intrusion scores of $r = -0.1055$, $r = -0.2009$, and $r = -0.1412$, respectively) were able to switch their visual perceptions more swiftly; this pattern was not observed in the high control group.

Discussion: These results suggest a potential mechanistic link between the propensity for thought suppression and the capacity to alter perceptions of ambiguous visual stimuli. In contrast, the lack of significant correlations within the high control group suggests that those with greater control over their hallucinations might employ different coping mechanisms or demonstrate a unique kind of perceptual adaptability. Future research will aim to refine these observations by employing a computational model to derive estimates of the precision of perceptual priors and examine how these estimates correlate with symptom severity. We also plan to evaluate performance metrics that are closely related to clinical outcomes.

T320. IMMUNOGLOBULIN LEVELS IN SCHIZOPHRENIA/OCD DURING RITUXIMAB TREATMENT: ASSOCIATIONS WITH CLINICAL RESPONSE

Mats Humble*¹, Sofia Sigra Stein¹, Daniel Eklund¹, Susanne Bejerot²

¹Örebro Universitet, School of Medical Sciences, ²University Health Care Research Center, Faculty of Medicine and Health, and School of Medical Sciences, Örebro University,

Background: It has been hypothesised both for schizophrenia (SCZ) and obsessive-compulsive disorder (OCD), that immunological/inflammatory factors are involved in the pathophysiology, at least in subgroups of patients. However, despite major research efforts within immunopsychiatry, we still lack a coherent view of detailed immune mechanisms and possible pathogens involved. Our aim was to scrutinise the clinical effects in SCZ and OCD of a potent immunomodulatory treatment that is proven useful in clearly autoimmune disorders (such as rheumatoid arthritis or multiple sclerosis) and relate these to immunochemical findings.

Methods: We conducted a small pilot study of treatment-resistant, severely ill psychiatric patients, 9 with SCZ and 10 with OCD. They were treated with rituximab, an anti-B-cell agent directed at CD20-carrying lymphocytes. One single infusion of 1000 mg rituximab (Mabthera®) was given at baseline and the patients were followed for one year. Symptoms were rated with Positive and negative syndrome scale (PANSS), Yale-Brown obsessive-compulsive scale (Y-BOCS) and Clinical global impression (CGI), and global functioning with Personal and social performance scale (PSP). Before the treatment and 5 months post-treatment, serum levels of the immunoglobulin classes IgA, IgG and IgM were measured. These were then related to therapeutic results and other clinical variables.

Results: A significant symptomatic and functional improvement was seen in 7/9 patients with SCZ and in 4/10 patients with OCD. Before treatment, IgA-values were bimodally distributed (.63 – 2.0 and 2.6 – 3.7 g/L, respectively, population reference .88 – 4.5). Two non-responder patients (one SCZ, one OCD) were IgA-deficient. The SCZ patients in the higher mode responded significantly better than those in the lower ($\chi^2 = 5.1$, df 1, $p = .023$). All five individuals with comorbid autism belonged to the low mode ($\chi^2 = 6.1$, df 1, $p = .013$). Baseline IgG ranged between 7.5 and 16.5 (reference 6.7 – 14.5 g/L) and IgM between .35 and 2.9 (.27 – 2.1 g/L). Two OCD patients had supranormal levels of IgM, one of them (a rituximab responder) also of IgG.

Discussion: We have shown an association between symptomatic improvement and immunoglobulin levels in SCZ, but not in OCD. Higher IgA at baseline was related to clinical response in SCZ but not in OCD. Since most serum IgA has its origin in the gut-associated lymphoid tissues (GALT), our findings suggest that interactions between the GALT and the enteric microbiome may be involved in SCZ. The study was explorative and due to the small sample size, all results should be viewed with utmost caution. Another limitation is that no subclass or isotype analyses were performed.

T321. NAVIGATING THE NEXUS: CHILDHOOD TRAUMA, CANNABIS USE, EMOTION REGULATION IN THE MULTI-HIT FRAMEWORK OF PSYCHOSIS

Kareem Hamada¹, Efim Oykhman¹, Lola Nedic¹, Nora Sun¹, Sahil Sood¹, Peter Levin¹, Nicole Rychagov¹, Matcheri Keshavan¹, Elisabetta C. del Re^{*2}

¹Harvard Medical School, ²Harvard Medical School, Veterans Affairs Boston Healthcare System, Beth Israel Deaconess Medical Center

Background: Over the past 20 years, the interplay between childhood trauma (CT), cannabis use (CA), emotion regulation (ER), and the development of psychosis spectrum disorders has garnered significant attention. The psychosis spectrum encompasses several disorders, such as Schizophrenia (SZ), Bipolar 1 with psychosis (BP), and Schizoaffective Disorder (SAD). The present review distills current knowledge on the relationship between CT, CA, and ER by examining literature published within the last five years. The objective is to present a concise yet comprehensive overview and propose a novel multi-hit framework for understanding the onset of psychosis.

Methods: To identify studies relating CT, CA and ER within psychosis, a search was conducted on December 10, 2023, in PubMed and Google Scholar. Studies were identified for fit using inclusion and exclusion criteria. Inclusion criteria were: 1) Relevance 2) Peer-reviewed papers 3) Within last 5 years, 4) English language 5) Quantitative or qualitative study design, 6) Populations: SZ, BP, SAD 7) Outcomes related to CT, CA, ER, and psychosis. Exclusion: 1) Irrelevant 2) Non-peer-reviewed 3) Pre-print 4) Not English, 5) Other diagnoses, 6) Animal studies, 7) Insufficient data or unclear methods 8) duplications.

Results: 54 studies were included in this review. As expected, psychosis patients have significantly higher prevalence of CT and CA. In the presence of both risk factors, CT and CA mediate each other's effect on psychosis risk, with contribution by risk genetic background. Poor emotion regulation was positively associated with both CT and CA and related to risk of developing psychosis. However, the influence of CT, CA, and emotion regulation varied across SZ, BP, and SAD.

Discussion: Our findings support a novel multi-hit framework for psychosis onset, wherein a combination of interacting environmental and genetic risk factors impact risk of psychosis. Emotion regulation impairment here is key, both as a risk and as an outcome of psychosis. Future studies should integrate emotion regulation assessments alongside CA, CT, and genetic risk factors to clarify interactions.

T322. OPEN BOARD

T323. SELF-ESTEEM AND SELF-STIGMA AMONG PERSONS WITH SCHIZOPHRENIA SPECTRUM DISORDERS: A CROSS-SECTIONAL STUDY

Ana Silva Pinto*¹, Marta Almada², Alexandra Sousa³, Isabel Fonseca⁴, Paula Freitas², Alice Lopes²

¹*Unidade de Psiquiatria Comunitária, Serviço de Psiquiatria e Saúde Mental, Centro Hospitalar Universitário de Santo António,* ²*ICBAS - Instituto de Ciências Biomédicas Abel Salazar, Universidade do Porto,* ³*Unidade Corino de Andrade, Centro Hospitalar Universitário do Porto,* ⁴*EPIUnit and Instituto de Saúde Pública da Universidade do Porto (ISPUP),*

Background: The relationship between self-stigma and self-esteem in patients with severe Mental illness (SMI) has garnered increased attention in recent years. Few studies have been carried out in Portugal on this subject, for that reason this study aimed to explore the relationship between self-stigma and self-esteem among adults with a diagnosis of schizophrenia spectrum disorders (SSD). For this goal, we assess the prevalence of self-stigma of psychiatric patients with diagnosis of mental illness; and investigate the correlates of elevated self-stigma with self-esteem.

Methods: A total of fifty-one outpatients with severe mental illness diagnosis, participated in this cross-sectional study. They were recruited from a community psychiatry unit from Porto, Portugal. The attending psychiatrist assessed each by face-to-face interview technique. After voluntary informed consent, evaluations included sociodemographic data, illness characteristics, and self-reported standardized scales.

Self-stigma (ISMI) and Rosenberg self-esteem scale (RSES) were assessed. Data analyses were performed using the SPSS version 28.0 (IBM Corp., Armonk, NY). p-values LESS THAN 0.05 were considered significant.

Results: From the study sample, 66.7% were male, with mean age of 44.8 ± 11.0 and 56.9% were single. 33.3% reported living with their parents while 31.4% were living with a partner/spouse. Most participants had a diagnosis of schizophrenia (60.8%). Concerning the level of education, 58.8% completed basic education, and 23.5% achieved upper secondary education. Nevertheless, most patients were retired due to illness (62.7%) and 19.6% were employed. In this study, moderate to high self-stigma levels was found in 31.4 % participants. No significant correlations were found with age, level of education, age at diagnosis, duration of illness, and number of hospitalizations. In the correlation analysis between the study variables, a negative correlation between self-stigma and self-esteem ($\rho = -0.745$; P LESS THAN 0.001) was reported.

Discussion: Conclusion: This study investigates, the prevalence and the correlates of self-stigma and Self-esteem among outpatients within a community psychiatric unit from Porto, Portugal. Our findings suggest a high prevalence of elevated levels of self-stigma among these persons in the SSD. Moreover, our results support previous evidence that internalized stigma is strongly associated with diminished self-esteem. Therefore, targeting internalized stigma and self-esteem among persons with SMI will likely improve their clinical and functional outcomes.

T324. SUBCLINICAL PSYCHOTIC EXPERIENCES NOT ASSOCIATED TO OXIDATIVE STRESS AS INDICATED BY SKIN ADVANCED GLYCATION END PRODUCTS

Julia Hagen^{*1}, Amber Cornelissen¹, Rada Veeneman¹, Sanne van der Heijden¹, Arjen Sutterland¹, Jentien Vermeulen¹, Lieuwe de Haan¹

¹*Amsterdam UMC (AMC), University of Amsterdam*

Background: The pathophysiological role of redox dysregulation and oxidative stress in the development of schizophrenia is becoming increasingly evident. Advanced glycation end products (AGEs) are produced in a state of oxidative stress. Skin autofluorescence measures indicating AGEs (SAF-AGEs) serve as marker for cumulative oxidative stress.

Increased SAF-AGEs have been demonstrated in recent onset psychosis and chronic schizophrenia. Investigation of the association between SAF-AGEs and subclinical psychotic experiences in the general population can help further elucidate the relation between redox dysregulation and psychotic symptoms.

Methods: Data was provided by the Lifelines cohort study. Subclinical psychotic experiences were measured with the Psychosis Screening Questionnaire (PSQ). SAF-AGEs measurements were performed. In a linear mixed model, adjusting for family ties and sex, the association between age-adjusted Z-scores of SAF-AGEs and PSQ was assessed. Additionally, polygenic risk score for schizophrenia, sociodemographic factors, cardiometabolic parameters and presence of chronic illnesses were hierarchically added to the model.

Results: Of 30,862 included participants, 4.3% reported (subclinical) psychotic experiences (PSQ GREATER THAN = 1). Age-adjusted Z-scores of SAF-AGEs was not associated with PSQ ($B = .003$ [95% CI -4.98e-05 - 5.81e-03], $p = 0.054$) in a linear mixed model adjusting for sex and family ties. Adjustment for additional confounders and a sensitivity analysis in participants aged 25-50 years showed similar results. Post-hoc, earlier findings of an association between SAF-AGEs and a (self-reported) diagnosis of schizophrenia were replicated ($B = 0.65$ [95% CI 0.40 - 0.89], p LESS THAN 0.001).

Discussion: No association was found between SAF-AGEs and subclinical psychotic experiences in the general population. Results imply that subclinical psychotic experiences are unrelated to systemic oxidative stress.

T325. INVESTIGATION INTO THE EFFECTS OF LB-102 AND ITS ENANTIOMERS, LB-103 AND LB-104, ON COGNITIVE AND NEGATIVE DEFICITS IN THE SUB-CHRONIC PHENCYCLIDINE RODENT MODEL FOR SCHIZOPHRENIA SYMPTOMATOLOGY

Ben Grayson^{*1}, A R Vaino², Z Prensky², A Eramo², V T Grattan², C Clarke¹, J Fletcher¹, I Mitsadali¹, M Harte¹

¹*b-neuro, University of Manchester*, ²*LB Pharmaceuticals Inc*

Background: Sub-chronic treatment with the N-methyl-D-aspartate receptor (NMDAR) antagonist phencyclidine (scPCP) in adult rats produces behavioural and neurobiological changes of relevance to the symptomatology and pathophysiology of schizophrenia. We have demonstrated that this approach produces robust deficits in several behavioural paradigms, including novel object recognition (NOR) for cognition and social interaction (SI) for negative symptomology (Cadinu et al., 2018 *Neuropharmacol* 142: 41-62). As such NMDAR antagonist animal models are widely used for evaluating novel therapeutic candidates for these unmet clinical needs.

LB-102 is a novel analogue of amisulpride currently in development as a treatment for schizophrenia. Receptor occupancy studies, both in humans and in rodents, have shown that LB-102 binds to dopamine receptors in the brain at substantially lower doses than amisulpride while maintaining an equally benign safety profile (Abbas et al., 2009 *Psychopharmacology* 205: 119-128). LB-102, a racemic mixture ($K_i(5HT7/D2) = 38$), displays polypharmacology. LB-103 (S enantiomer) strongly binds to dopamine D2/3 receptors ($K_i(5HT7/D2)$ GREATER THAN 2500), while LB-104 (R enantiomer) preferentially binds to 5HT7 receptors ($K_i(5HT7/D2) = 1$) (Grattan et al., 2019, *ACS Omega* 4: 14151-14154).

Aim: We investigated the effects of LB-102, LB-103 and LB-104 to reverse cognitive and social behaviour deficits in the clinically relevant and well-validated scPCP model to understand the contributions of D2/3 and 5HT7 activity on behavioural outcomes.

Methods: Female Lister Hooded rats received vehicle (saline) or PCP (2 mg/kg, i.p. bidaily for 7 days, followed by a minimum 7-day washout period). Prior to the behavioural experiments rats were administered LB-102, LB-103 or LB-104 at 5, 15, or 45mg/kg (p.o., 180 minutes before testing). Animals were then tested in the NOR and SI tests to assess effects on cognitive and negative symptoms associated with schizophrenia.

Results: NOR - We found deficits in the discrimination index (DI, measure of novelty preference in the NOR task) in scPCP-treated animals, when compared to vehicle treated animals. Further analysis of the DI was carried out to compare the efficacy of LB-102, LB-103 and LB-104 at equivalent doses. A one-way ANOVA followed by planned post-hoc analysis found that: LB-102, LB-103 and LB-104 at 5 mg/kg had a significant reduction in DI when compared to vehicle treated animals. LB-102 and LB-104 at both 15 and 45 mg/kg had a significant improvement in DI when compared to scPCP treated animals, an effect not seen with LB-103.

SI - We report a significant reduction in sniffing duration induced by scPCP compared to vehicle. These deficits were reversed following acute treatment with LB-102 and LB-104 but not LB-103.

Discussion: In conclusion, LB-102 and LB-104, but not LB-103, were effective in overcoming scPCP-induced deficits in cognitive and social behaviour testing, which reflect specific schizophrenia symptom domains. These results suggest that the increased affinity of LB-104 for 5-HT7 manifests in behavioural assays but that the magnitude is subtle enough that 2X greater K_i is not noticeable. The relative decrease in dopamine binding with LB-104 may improve tolerability, though interrogating safety in animal studies can be challenging.

Lunch and Poster Session II

F1. DIFFERENCES IN CORTICAL NEUROIMAGING IN OFFSPRING OF PATIENTS WITH BIPOLAR DISORDER: INSIGHTS FROM INTELLIGENCE QUOTIENT STRATIFIED ANALYSES

Patricia Camprodon-Boadas^{*1}, María Ortuño², Inmaculada Baeza³, Elena De la Serna⁴, Josefina Castro-Fornieles⁴, Gisela Sugranyes⁵

¹Fundació de Recerca Clínic Barcelona-Institut d'Investigacions Biomèdiques August Pi i Sunyer (IDIBAPS), ²Fundació Clínic Recerca Biomèdica - Institut d'Investigacions Biomèdiques August Pi i Sunyer, Clinical and Experimental Neuroscience, ³Hospital Clínic de Barcelona, ⁴Hospital Clínic of Barcelona, 2014SGR489, CIBERSAM., ⁵Institute of Neuroscience, Hospital Clínic of Barcelona, 2014SGR489, CIBERSAM, CERCA-IDIBAPS

Background: Previous studies have failed to identify global differences in cortical neuroimaging measures between offspring of patients diagnosed with bipolar disorder (BpO) and controls (Sugranyes et al., 2015; 2017). However, BpO exhibit overall increased rates of psychiatric disorders and impairment in certain cognitive domains during youth, and some BpO have been found to belong to a poorer functioning cognitive cluster, in association with smaller lobar structural measures (Valli et al., 2022). The current study aimed to analyze cortical gray matter volume and surface area measures in an extended sample of these BpO, subdivided into three groups based on their intelligence quotient (IQ; high, medium, or low), in order to help further understand potential heterogeneity within these individuals based on a standardised measure.

Methods: The study involved a total of 404 data acquisitions, which included longitudinal assessments from 10 BpO with a low IQ, defined as a score less than 90 (BpO-L), 75 BpO with a medium IQ (BpO-M) with scores ranging between 90 and 110, 55 BpO with a high IQ (BpO-H), with a score exceeding 110, and 85 CcO, assessed at different time points. Participants were matched for age and sex. All participants completed an IQ assessment using the Wechsler Intelligence Scale for Children or Adults depending on age and underwent a structural magnetic resonance imaging scan on a 3Tesla scanner. Cortical surface reconstruction was applied to measure gray matter volume and surface area for each cortical lobe. Multilevel mixed-effects linear regression models were conducted, with cortical structural measures as dependent variable, including group, age, sex, and total intracranial volume as fixed factors. Additionally, random effects were incorporated for family relatedness (considering subjects who were siblings) and the subject code (accounting for different number of assessments).

Results: No significant differences were observed in age or sex between groups. Values of IQ (means, standard deviation) were 83.3 ± 2.9 for the BpO-L group, 102.5 ± 1.0 for the BpO-M group, 120.1 ± 1.1 for the BpO-H group and 108.9 ± 0.7 for the CcO group ($F = 72.176$; $p < 0.001$). Significant differences between groups were found in cortical gray matter volume in the left frontal lobe ($F = 2.742$; $p = 0.043$), though pairwise comparisons did not reveal significant differences between specific groups. Differences were also identified for cortical gray matter volume in the left temporal lobe ($F = 3.781$; $p = 0.011$), where CcO exhibited higher levels than BpO-L ($p = 0.050$). There were also significant group effects in surface area of the left frontal lobe ($F = 3.779$; $p = 0.011$), with the BpO-M group showing lower levels than both BpO-H ($p = 0.031$) and CcO ($p = 0.041$), and in the right temporal lobe ($F = 3.543$; $p = 0.015$), with the BpO-M group exhibiting lower levels than CcO ($p = 0.046$).

Discussion: Our study uncovered regions of diverging cortical structural metrics when stratifying BpO according to IQ. Incorporating additional variables such as functioning, or the presence of psychopathology will help to fully understand heterogeneity within this population. Further investigations into these factors will contribute to a more nuanced understanding of brain-based heterogeneity within the BpO group.

F2. BEYOND PSYCHOSIS RISK: VALIDATING TRANSDIAGNOSTIC, HETEROTYPIC HIGH-RISK CRITERIA

Rochelle Ye^{*1}, Cassandra Wannan², Stephen Wood², Joseph Kambeitz³, Lana Kambeitz-Ilankovic³, Stefan Borgwardt⁴, Paolo Brambilla⁵, Rebekka Lencer⁴, Eva Meisenzahl⁶, Raimo Salokangas⁷, Christos Pantelis⁸, Alessandro Bertolino⁹, Rachel Upthegrove¹⁰, Nikolaos Koutsouleris¹¹, Barnaby Nelson², Dominic Dwyer²

¹University of Melbourne, ²Orygen, ³University of Cologne, ⁴University of Lübeck, ⁵University of Milan, ⁶Ludwig Maximilians University, ⁷University of Turku, ⁸The University of Melbourne, ⁹University of Bari, ¹⁰University of Birmingham, ¹¹Ludwig-Maximilian-University

Background: The ultra-high risk for psychosis (UHR) criteria facilitated the development of an early identification and prevention paradigm in psychiatry. However, recent evidence shows that 76% of UHR individuals do not transition to psychosis and 68% develop other severe mental illnesses. Additionally, further research has demonstrated the presence of earlier illness stages preceding UHR. This evidence indicates a need to expand UHR to capture the transdiagnostic presentations of risk, heterotypic outcomes, and earlier stages of illness. The Clinical High At-Risk Mental State (CHARMS) criteria were developed to achieve these goals by operationalising four stages of illness: asymptomatic (Stage 0), mild impairment (Stage 1a), high-risk (Stage 1b), and severe illness (Stage 2). CHARMS has been validated in pilot studies with inconclusive results. We aimed to validate the CHARMS criteria in a large international sample of help-seeking individuals and to determine if the stages are associated with genetic risk for mental illness. We hypothesised that CHARMS Stage 1b would identify increased risk for serious mental illness and later stages of illness would be associated with increased genetic risk.

Methods: 749 help-seeking individuals from a longitudinal, multisite cohort study investigating prediction tools for psychosis-related outcomes (PRONIA) were stratified into four stages using CHARMS. Participants were assessed on positive, negative, and depression symptoms, social occupational functioning, and quality of life. DNA was extracted from 619 participants; schizophrenia and depression polygenic risk scores (PRS) were calculated using the Psychiatric Genomic Consortium reference sample, generated over a range of 10 P-values. Group differences were determined using ANOVAs and significant differences were explored using post-hoc t-tests. 2-sided P values were assessed at a significance level of false discovery rate corrected P LESS THAN .05. Linear mixed effects models were used to investigate longitudinal trajectories.

Results: Participants were stratified into Stage 0, Stage 1a, Stage 1b, and Stage 2. Significant group level differences between stages were found for all clinical and functioning measures, with higher stage associated with higher symptomatology and lower functioning. There were significant stage differences between positive, ($F_{3,719} = 212.30$, P LESS THAN .001, $\eta^2 = 0.47$), negative, ($F_{3,716} = 252.27$, P LESS THAN .001, $\eta^2 = 0.51$), and depressive symptoms, ($F_{3,668} = 287.29$, P LESS THAN .001, $\eta^2 = 0.56$). Significant increase in functioning impairment in both social ($F_{3,722} = 578.48$, P LESS THAN .001, $\eta^2 = 0.71$) and disability

domains, ($F_{3,722} = 432.81$, $P < .001$, $\eta^2 = 0.64$), across stages. Significant stage differences on quality of life ($F_{3,630} = 149.31$, $P < .001$, $\eta^2 = 0.42$), except between Stage 1b and Stage 2. These differences were largely maintained over time. Significant stage differences were found for schizophrenia PRS across four thresholds ($\eta^2 = 0.03$) and for depression PRS across five thresholds ($\eta^2 = 0.03$). Post hoc exploration showed linear increases in schizophrenia PRS score across stages. 14.3% of participants in Stage 1b transitioned to Stage 2 within 18 months.

Discussion: The findings validate CHARMS for identifying people at high risk of developing serious mental illness, and show that higher stage is associated with increased symptomatology, greater genetic risk, poorer functioning, and lower quality of life. Additionally, we demonstrate the utility of CHARMS in capturing early stages of illness preceding high-risk. There was no significant difference between Stage 1b and Stage 2 in quality of life. Overall, this highlights the need for early intervention and prevention beyond psychosis.

F3. ASSOCIATIONS BETWEEN CHILDHOOD MALTREATMENT SUBTYPES AND SYMPTOMS OF PSYCHOSIS, DEPRESSION, ANXIETY, AND POSTTRAUMATIC STRESS IN A MEXICAN GENERAL POPULATION SAMPLE

Tamara Sheinbaum^{*1}, Tecelli Domínguez², Fernando Salvador-Cabañas³, Lourdes Nieto², Rebeca Robles², Neus Barrantes-Vidal⁴, César Celada², Mauricio Rosel², Ricardo Saracco²

¹*Instituto Nacional de Psiquiatría "Ramón de la Fuente Muñiz"*, ²*Instituto Nacional de Psiquiatría "Ramón de la Fuente Muñiz"*, ³*Benemérita Universidad Autónoma de Puebla*, ⁴*Universitat Autònoma de Barcelona*

Background: Ample research demonstrates that childhood maltreatment confers risk for multiple forms of psychopathology across clinical and subclinical levels of expression, including depression, anxiety, posttraumatic stress, and psychosis phenotypes. However, studies on this topic in Latin American countries, such as Mexico, remain relatively scarce, especially those using a dimensional approach to assessing maltreatment and psychopathology. The present study aimed to examine (i) the prevalence of childhood maltreatment subtypes (emotional, physical, and sexual abuse and emotional and physical neglect) and (ii) associations between maltreatment subtype scores and dimensional assessments of depression, anxiety, posttraumatic stress, and positive psychotic experiences and related distress in a Mexican general population sample.

Methods: The sample comprised 1,550 participants (79.2% female; mean age=29.5 years) from the Mexican general population who completed a battery of self-report questionnaires via an online survey. The study measures included the Childhood Trauma Questionnaire, the Prodromal Questionnaire-Brief, the Posttraumatic Stress Disorder Checklist for DSM-5, and screening measures for anxious and depressive symptoms based on the World Health Organization's most recent classification of mental disorders for primary care settings.

Results: Using the established CTQ cut-off scores for "low to moderate severity," the prevalence of maltreatment in the sample was 63.1% for emotional abuse, 61.5% for emotional neglect, 47% for sexual abuse, 41.2% for physical abuse, and 37.8% for physical neglect. All the maltreatment subtypes had significant bivariate associations with positive psychotic experiences and distress as well as with the symptoms of depression, anxiety, and posttraumatic stress. The regression analyses examining the maltreatment subtypes as simultaneous predictors indicated that emotional abuse had a unique association with all the outcome

measures. Additionally, emotional neglect had a unique association with symptoms of depression, and sexual abuse had a unique association with symptoms of posttraumatic stress.

Discussion: The high prevalence of maltreatment in the sample is consistent with epidemiological research indicating that adverse and traumatic experiences are common in the Mexican population. In addition, the finding that emotional abuse was uniquely associated with all the outcome measures aligns with emerging research highlighting the critical relevance of emotional abuse as a risk factor for different forms of psychopathology, over and above other maltreatment subtypes. Furthermore, the specific associations found between emotional neglect and depression and between sexual abuse and posttraumatic stress are notable and parallel findings from the international literature. Overall, the results support previous calls for increased research and policy attention to the more “silent” types of maltreatment and underscore the need for longitudinal investigations to inform prevention and intervention efforts in the Mexican population.

F4. IMPLICATIONS OF MHC-CLASS II PEPTIDES ON B CELL LINES IN THE PATHOGENESIS OF SCHIZOPHRENIA

Nicole Brace*¹, Antonia Pritchard¹

¹*University of the Highlands and Islands*

Background: One of the leading hypotheses to the cause of schizophrenia is the two-hit theory. This proposes that an initial hit, caused by a genetic vulnerability to developmental disturbances, is followed by a second hit of an environmental trigger during a critical period of brain maturation, such as prenatal infection, stress, or drug abuse. This second hit activates the consequences of the first, leading to neurodevelopmental changes, brain dysfunction and schizophrenia. This study focuses on an immune disturbance as the second hit. Altered profiles of immune cells and mediators in the circulation and brain, and the presence of brain-reactive antibodies emphasize the role of immunity. A family history of autoimmune conditions increases the risk of schizophrenia, along with infection and inflammation. The major histocompatibility complex (MHC) cluster locus on chromosome 6 is a schizophrenia genome wide association study (GWAS) peak and experimental evidence suggests that MHC-class II peptide presentation is altered in schizophrenia patients. Mechanisms suggested include changes to the development and function of immune cells and neurons, and synaptic pruning; all of which could alter brain function. Anormal MHC II could promote survival of auto-reactive B cells contributing to a failure in immune tolerance. Together, these data suggest an association between B cell function and schizophrenia. Although many associations have been identified, the mechanism of involvement is still poorly understood.

Methods: Four B cell lines (two derived from healthy controls and two from schizophrenia patients) were selected. These cell lines were genotyped to determine their MHC class II allele types and MHC II peptide complexes were enriched for using an anti-human HLA-DR antibody, L243. Peptides were subsequently eluted from MHC complexes and, following liquid chromatography separation, analysed via high resolution mass spectrometry. The profile of identified peptides was analysed using Proteome Discoverer and the profile of peptides bound to specific MHC II genotypes was assessed using the IEDB prediction tools. Similarities and differences between the cell lines were investigated, including features of the proteins from which the peptides originated and of the peptides themselves in binding to the MHC II molecule.

Results: We found that the cell lines each contained a distinct repertoire of MHC II peptides, whilst there were some overlaps there were also many which were unique to each cell line and

unique to each condition. Global differences to the peptide properties, including the number of peptides and characteristic such as length and source, also appeared to be unique to the cell lines. We also observed that some of the peptides were derived from proteins and genes that have been implicated in schizophrenia.

Discussion: The heterogeneity of the immune response in humans, as well as in the disease and pathogenesis of schizophrenia is reflected in the MHC II genotypes of the cells and the MHC II peptide repertoire identified. Increasing the number of samples may identify peptide targets which may act as a biomarker for the disease.

In summary, this study provides novel insights into the molecular mechanisms of MHC-class II peptide presentation and its relevance to schizophrenia. Our results in conjunction with findings previously reported in the literature, suggest that MHC-class II peptides may play a role in the pathogenesis of schizophrenia by triggering autoimmune or cross-reactive responses against brain antigens. Understanding the nature of the MHC II peptides displayed by B cells adds a new dimension to the exploration of schizophrenia's causes, offering potential insights for early identification and improved patient outcomes.

F5. COMBINING THE RISK: A POLY-ENVIRONMENTAL RISK SCORE AND PSYCHOTIC EXPERIENCES IN ADOLESCENTS

Diandra Bouter¹, Nina Grootendorst*¹

¹*Erasmus University Medical Center*

Background: Psychotic experiences are common in adolescents and predictive of both psychotic and non-psychotic disorders. Many risk factors have been shown to be associated with psychotic experiences, yet investigating single risk factors does not account for the combined or even additive effect of risk factors. The poly-environmental risk score (PERS) combines well-researched environmental risk factors in a clinical model to calculate the risk for psychotic experiences.

Methods: The current study is embedded in a cohort of adolescents (n=966) at risk of psychopathology based in the Rotterdam area, the Netherlands. We used 16 binarized risk factors for psychosis obtained from meta-analyses to calculate the PERS. Adolescent risk factors were: winter or spring birth, obstetric complications, ethnic minority status, urbanicity, cannabis use and experiences of bullying, adverse life events, physical abuse, sexual abuse, and neglect. Six parental factors were used: higher paternal age, low socioeconomic status, psychopathology, substance abuse, divorce, and death.

Results: A higher PERS was positively associated with more psychotic experiences. Furthermore, the PERS was a clear indicator of adolescents reporting psychotic experiences above the cut-off for clinically relevant psychotic experiences.

Discussion: A combined score of multiple risk factors in the association with psychotic experiences in adolescents has a relatively small effect size as compared to the effect of the individual risk factors. Future research should take the combined effect of risk factors into account when examining the determinants of psychopathology.

F6. MESENCEPHALIC ASTROCYTE-DERIVED NEUROTROPHIC FACTOR (MANF) PREDICTS EMOTION PROCESSING IMPROVEMENT BY COGNITIVE REMEDIATION THERAPY IN RECENT-ONSET PSYCHOSIS

Francesc Estrada*¹, Josep Maria Crosas², Maribel Ahuir², Raquel Aguayo², Juan David Barbero², Meritxell Tost², Itziar Montalvo², Diego Palao², Javier Labad³

¹*Parc Taulí Sabadell (Spain)*, ²*Department of Mental Health, Hospital Universitari Parc Taulí, Institut d'Investigació i Innovació Parc Taulí I3PT, Universitat Autònoma de Barcelona*,

³*Consorci Sanitari del Maresme, Mataró, Spain*

Background: Patients with schizophrenia show deficits in social cognition and particularly in the theory of mind (the ability to attribute mental states to oneself and others), which contribute to impairments in functional performance (1). Cognitive remediation therapy (CRT) might improve social cognitive deficits in people with schizophrenia (2), although there is an important variability in the response between patients. We aimed to explore whether proteomic biomarkers related to neurology processes could predict the response to CRT in emotion processing tasks in patients with recent-onset psychosis (ROP).

Methods: 28 stable outpatients (9 women) with ROP (psychotic disorders with LESS THAN 3 years of illness) aged between 18 and 35 years old were included in a randomized clinical trial (NCT04418570). Patients were randomized to receive a computerized CRT facilitated by a therapist for three months (2 sessions/week) (n=14) or treatment as usual (TAU) (n=14). The Emotion Recognition Task (ERT) from the CANTAB was used to assess emotion processing at baseline and after 3 months. Fasting blood samples were obtained at baseline and after 3 months. A Proximity Extension Assay (PEA) was conducted with Olink® Technology and the Olink Target 96 Neurology® panel was used to determine the protein expression of 92 neurology-related proteins in plasma. Statistical analyses were conducted in R. The glmnet package was used for performing a Lasso Regression (LR) in order to identify potential biomarkers associated with cognitive changes in ERT variables (reaction time and total hits), considering a coefficient GREATER THAN 0.1 in the LR. Significant biomarkers associated with longitudinal changes in ERT were included in a mixed linear regression testing the effects of time, group (CRT vs TAU), biomarker, and the interactions between time, group and biomarker.

Results: Of all 92 proteins explored in the Olink Neurology panel, one protein was associated in longitudinal changes in ERT reaction time: mesencephalic astrocyte derived neurotrophic factor (MANF), which had a coefficient of -0.146. When including MANF in the mixed linear regression analysis, a significant time x group x MANF interaction was found ($\eta^2=0.70$, $p=1.275e-06$). Patients with higher MANF expression at baseline visit reported improvements in ERT reaction time when compared to those with lower MANF.

Discussion: Our exploratory study suggests that MANF expression might predict the response in social cognition to CRT in people with early psychosis. Interestingly, MANF offers cellular protection in neurodegenerative disorders and promotes the survival of cultured midbrain dopamine neurons (3). If our results are replicated in further studies, MANF could be a biomarker that could help to identify early psychosis patients who would benefit from receiving CRT to improve emotion processing. Moreover, since MANF is also a potential therapeutic target in neurodegenerative diseases, it could be a potential target for future cognitive enhancement treatments in schizophrenia and related psychotic disorders.

F7. PREDICTORS OF BETTER ACADEMIC PERFORMANCE IN INDIVIDUALS WITH UHR FOR PSYCHOSIS

Alp Uçok*¹, Ezgi İnce Guliyev¹, Cem Horasan¹, Çağla Ceren Türkoğlu¹, Mesut Keskin¹, Melis Ceylan¹

Background: Lower levels of education have been associated with the development of psychosis. Investigating educational achievement in individuals with UHR for psychosis may shed light on the origins of the alterations and on the variability of outcomes in this group. The aim of this study is to search the predictors of better academic performance during the follow-up in individuals with UHR for psychosis.

Methods: Totally there are 150 individuals with UHR for psychosis in Early Psychosis Program in Istanbul Faculty of Medicine sample. All of them had completed a cognitive battery and we collected clinical data by using BPRS, CAARMS, SANS, SAPS, Calgary DSS, PAS, childhood trauma questionnaire and GAF at baseline. Twenty-nine of them were already university students or graduated from university. We obtained information by contacting them by telephone or e-mail if they dropped-out from follow-up. During the follow-up 30 of the individuals with UHR passed the university entrance examination and started university. We regarded these 30 individuals as with better academic performance, and compared their baseline clinical and cognitive parameters with the rest of the sample (n=72) by excluding those who have already attended university before first admission.

Results: Mean age of the sample is 20.4±4.4 and 71.3% of them are male. Mean duration of follow-up after first admission is 24.9±44.3 months. Baseline SANS score (34.9 vs 42.2, p=0.034) and alogia subscale score were lower in those with better academic performance. However, there was no difference both in SAPS and CAARMS scores at baseline. School performance between 12-15 years was related to academic performance later, but statistical significance was in trend level (p=0.07). Childhood physical trauma (5.3 vs 7.1, p= 0.004), emotional neglect score (11.2 vs 16.4, p=0.002) and CTQ total score (35.7 vs 44.9, p=0.01) were significantly lower in those with better academic performance. Composite scores of the attention, and executive function domains, and global cognitive performance were better (p LESS THAN 0.001 for all) in better academic performance group. Difference in composite score for learning-memory domain was in trend level (0.06). Although rate of middle-income families was relatively similar in both groups (63.5% vs 75.1%), frequency of low-income families was higher in worse academic performance group (28.8% vs 3.6%, p=0.009.) Family history of psychosis, alcohol/substance use, baseline level of depression, past suicide attempts and global functioning were not found related to later academic performance.

Discussion: Our findings suggest that baseline cognitive performance is strongly related to academic performance during the follow-up. However, some environmental variables like childhood trauma and economic level of their family have also an impact on academic performance. Besides these, lower level of negative but not positive symptoms was found related to better academic performance later.

F8. AN AUDIT OF THE CLINICAL MONITORING OF EXTRA-PYRAMIDAL SYMPTOMS (EPS) IN AN IRISH MENTAL HEALTH SERVICE (MHS)

Rebekah Aubry^{*1}, Thomas Hastings², Micheal Morgan³, Kevin Kilbride⁴

¹*Lucena Clinic, St John of God*, ²*Dr. Thomas Hastings M.P.C.*, ³*1HSE South Louth CAMHS, St. Mary's Hospital Campus*, ⁴*Program for the Homeless MHS, Usher's Island Day Hospital*

Background: Published studies demonstrate very low rates of EPS monitoring in patients prescribed antipsychotics. [1-2] EPS adversely quality of life, function and treatment adherence. [3-4] The 'HSE National Clinical Programme for Early Intervention in Psychosis' recommends that

medications should be reviewed regularly for side effects, and that the physical complications of medications should be monitored regularly and collaboratively [5] . ‘NICE Guidelines’ recommend assessment for movement disorders before starting antipsychotic medication, and to monitor and record side effects of treatment and their impact on functioning, and the emergence of movement disorders, regularly and systematically throughout treatment [6] . References:

5. HSE National Clinical Programme for Early Intervention in Psychosis; Model of Care Executive Summary. (Section 3.2 Pharmacotherapy). May 2019.
6. NICE Clinical Guideline; Psychosis and schizophrenia in adults, Treatment and management (Sections 1.3.6.1 and 1.3.6.4). 2014.

Methods: An Audit Tool and review of clinical notes in the prior 6 months evaluated: the rate of any EPS monitoring, subjective and objective EPS symptom monitoring rates, and any use of a structured assessment tool. The novel EPS Scale (EPSS) [7] was introduced following a 1h training session and video. EPS monitoring rates were re-audited 8 month post-intervention. In addition, NCHD’s completed anonymous pre/post intervention surveys rating their comfort

monitoring and documenting EPS, their current monitoring practices and the perceived quality and usefulness of the training. References:

7. Hastings T, Tibbo P, Williams R. Extrapyramidal Symptom Scale (EPSS). Canadian Consortium for Early Intervention in Psychosis. 2022.

Results: Pre-intervention Audit (t1, n=232) – Sep 2021, Only 14.8% of psychiatric inpatients’ records had any documentation of EPS monitoring (of those, 9.2% noted subjective symptoms and 14.8% noted objective symptoms). For community patients in the other two settings, there was no record at all. Post-intervention Audit (t2, n=214) – June 2022 The EPSS had been completed within the previous 6 months for 75% for the inpatients, 79.6% for the community rehabilitation patients, and 18% for the community/assertive outreach (specialist homeless) patients. Pre-intervention Survey (n = 12): The majority of respondents reported poor confidence levels in their ability to assess and document EPS and indicated that they never or only rarely used a structured tool. Post-intervention Survey (n=12): All respondents found the training session very helpful or helpful (4-5/5 on Likert-like scale), indicated that they believed the EPSS training session would result in an improvement in their ability to screen for and document EPS as part of their ongoing clinical practice.

Discussion: - We confirmed that EPS are not as frequently monitored as recommended, across multiple practice sites within a Dublin North City MHS. Monitoring rates improved across all participating practice following adoption of the EPSS. Successful adoption was possible at no cost. We intend to continue to use the EPSS and to audit performance in our MHS, to ensure ongoing high rates of adherence to practice standards for monitoring EPS.

F9. UNDERSTANDING AND PREVENTING VIOLENT CRIME IN INDIVIDUALS WITH SEVERE MENTAL DISORDERS – A MIXED-METHODS APPROACH (PREVIO): A STUDY PROTOCOL

Laoura Ziaka*¹, Martin Tesli², Unn Haukvik³, Jaroslav Rokicki¹, Christine Friestad¹

¹*Oslo University Hospital*, ²*Norwegian Institute of Public Health*, ³*University of Oslo*

Background: Epidemiological studies have estimated that individuals with severe mental illness commit approximately 5% of registered violent crime. For this patient group, management and prevention of violence risk is a shared responsibility between the criminal justice system and health services. As such, public and professional warnings are raised about system coordination and cooperation shortcomings which may hinder optimal treatment and increase suffering for this group. We present a three level cross disciplinary mixed-method study approach (PreVio) which in close collaboration with the practice field (police, correctional, and mental health services) seeks to enhance our understanding of violent crime in severe mental disorders. Our aim is fourfold: 1) examine changes in violent crime over time and the possible impact of legal reforms, 2) identify subgroups and developmental trajectories of crime and mental illness across the life course, 3) investigate sociodemographic and psychological risk and protective factors, 4) employ visual Methods: to study single cases and identify the link between events at the individual level.

Methods: The PreVio project (funded by Research Council Norway) combines large registry based epidemiological analyses (level 1) with clinical characterization/ studies on a quantitative small scale (level 2), and case based qualitative analyses (level 3). The quantitative data stem from two datasets: a population-wide registry linkage (ForenPsych, N $\approx$ 8 mill) with information on severe mental illness, violent crime, and sociodemographic factors, and a clinical dataset (sTOP, N $\approx$ 200 participants) including data on psychological characteristics and individual risk and protective factors for four groups (i.e., psychosis patients with and without a history of severe violence, non-psychotic violent offenders, healthy controls). Different statistical Methods: (e.g., logistic and Cox regression, difference-in-differences estimation, etc.) will be used. Qualitative explorations from visual criminology utilizing Life History Plots (LHP) of single cases will identify crucial time points for future interventions.

Results: The project is in its initial stages. The ForenPsych dataset has obtained approval from relevant ethical and legal authorities. Data from the National Population Register, The Norwegian Patient Registry, Penal Sanctions and sociodemographic variables from Statistics Norway are underway and include a wealth of variables not previously investigated. For the sTOP dataset, data collection has been completed and involves groups matched on age, sex, diagnosis, and clinical variables. Qualitative data will be derived from the sTOP study's available case material. LHP will be developed for a selected subsample. The selection of items for visualization will be informed based on the knowledge stemming from the project's quantitative part (i.e., ForenPsych and sTOP Results:). This dynamic approach ensures that qualitative analysis aligns with emerging quantitative findings.

Discussion: The PreVio project introduces an innovative, cross-disciplinary three level mixed-Methods: approach to the investigation of the relationship between severe mental disorders and

violent crime. Combining quantitative data for societal and clinical insights into violence prevalence and characteristics, the study also incorporates a qualitative component using the LHP visual method. Through multidisciplinary research involving experts in epidemiology, forensic and clinical psychiatry, criminology, sociology, and law, in close cooperation with experienced practitioners, the final aim is to increase our understanding of the developmental trajectories of crime and mental illness.

F10. THE INFLUENCE OF EXPOSOMIC AND POLYGENIC LIABILITY FOR SCHIZOPHRENIA ON THE PERSISTENCE OF DISTRESSING PSYCHOTIC EXPERIENCES IN EARLY ADOLESCENCE

Thanavadee Prachason*¹, Matteo Di Vincenzo², Gaia Sampogna², Angelo Arias-Magnasco³, Bochao D Li⁴, Lotta-Katrin Pries³, Jim van Os⁵, YOUTH-GEMs Investigators⁶, Bart P. F. Rutten³, Sinan Guloksuz⁷

¹ Ramathibodi Hospital, Mahidol University, ²University of Campania "Luigi Vanvitelli", ³School for Mental Health and Neuroscience, Maastricht University Medical Centre, Maastricht, the Netherlands, ⁴UMC Utrecht Brain Center, University Medical Center Utrecht, Utrecht University, Utrecht, The Netherlands, ⁵Brain Centre Rudolf Magnus, University Medical Centre Utrecht, Utrecht, the Netherlands; King's College London, King's Health Partners, Institute of Psychiatry, ⁶YOUTH-GEMs Investigators, ⁷School for Mental Health and Neuroscience, Maastricht University Medical Centre, Yale University School of Medicine

Background: Psychotic experiences (PEs) are a significant risk factor for both psychotic and non-psychotic disorders with a peak incidence in adolescence. When persisting, PEs, especially those associated with distress, are linked with poor outcomes. However, research on risk factors for the persistence of distressing PEs is still limited. In this study, we aimed to examine the influence of genomic and exposomic liability for schizophrenia on persistent distressing PEs in early adolescence.

Methods: The data were derived from the Adolescent Brain and Cognitive Development (ABCD) Study release 5.0. This study included 5,122 European participants who had genetic data and underwent annual assessments starting from baseline (ages 9 – 10) until the 3-year follow-up (ages 12 – 13). The Prodromal Questionnaire-Brief Child Version was used to assess past-month PEs and associated distress. Binary variables indicating lifetime distressing PEs were generated at different cutoff thresholds of persistence, varying from one to four waves. Polygenic risk score for schizophrenia (PRS-SCZ) was calculated. Conforming to our previous study exposome score for schizophrenia (ES-SCZ) was calculated using lifetime exposure to childhood adversity domains, cannabis use, winter birth, hearing impairment, and bullying reported up to the 2-year follow-up (ages 11 – 12). PRS-SCZ and ES-SCZ were dichotomized at the 75th percentile (hereafter PRS-SCZ75 and ES-SCZ75, respectively). Finally, the associations of PRS-SCZ75 and ES-SCZ75 with distressing PEs at varying degrees of persistence were tested using multilevel logistic regression analysis. All models were adjusted for age and sex, with additional adjustment for family income and parental education as sensitivity analyses.

Results: PRS-SCZ75 was significantly associated with distressing PEs at a threshold of one (OR 1.28 [95% CI 1.08, 1.53], $p = .004$), and two (OR 1.34 [95% CI 1.08, 1.65], $p = .007$) out of four waves. On the contrary, ES-SCZ75 was significantly associated with distressing PEs at all thresholds of persistence (all p LESS THAN .001). Notably, the influences of ES-SCZ75 tended to increase at higher thresholds of persistence (one wave: OR 2.94 [95% CI 2.38, 3.62];

two waves: OR 3.56 [95% CI 2.79, 4.56]; three waves: OR 4.86 [95% CI 3.44, 6.94]; four waves: OR 4.61 [95% CI 2.94, 7.23]). Sensitivity analyses, incorporating family income and parental education, confirmed all significant findings including the gradient influences of ES-SCZ75 on persistent distressing PEs.

Discussion: Exposomic liability for schizophrenia was more strongly associated with distressing PEs than genomic liability for schizophrenia in early adolescence. There was evidence of increasing influences of ES-SCZ on the persistence of distressing PE, highlighting an important role of accumulating exposure to environmental risks for schizophrenia on the persistence of subclinical psychosis expression in the young population.

F11. APPLYING VISUAL METHODS TO STUDY VIOLENCE AND PSYCHOSIS IN FEMALE PRISONERS AND FORENSIC PATIENTS: A PILOT STUDY

Christine Friestad*¹, Danielle Arlanda Harris², Anja Vaskinn¹, Unn Haukvik³

¹*Oslo University Hospital*, ²*Griffith University*, ³*University of Oslo*

Background: There has been a disproportionate growth in the number of women in correctional and forensic systems during the last decade. This is a cause for concern given the lack of knowledge about the background of women convicted of violent crime. Risk factors for violence seem to be similar for both men and women, also in forensic samples characterised by severe mental illness. What remains to be seen, however, is whether the timing, ordering, and duration of events can be differentiated by gender. For example, the onset and duration of psychosis and its treatment might be distinct for men and women. The emerging field of visual criminology provides an approach that is particularly suited to investigate this question, but it has yet to be applied to the study of violence and mental illness. In this study, and for the first time, we create and present individual Life History Plots for a pilot sample of women with an intersecting history of criminality and mental illness. This project represents a novel cross-disciplinary approach to the study of this vulnerable group.

Methods: The current study employs a data visualisation tool called the Life History Plot to explore and examine the criminal and psychological histories of a small sample of women. The aim of the visualization is to plot the temporal ordering of a selection of officially recorded information such as arrests, convictions, diagnoses, and periods of custody or hospitalisation. This approach allows for the identification of connections and relationships between events and situations at the individual level, providing a dynamic view of a single person's life course. We include illustrations for three separate women that were constructed using criminal conviction data, sentencing remarks, and archival files/records.

Results: Cases 1 and 2 were women in their twenties who were sentenced for attempted homicide. Case 3 was 41 years of age and charged with a series of criminal offences ranging from drug crimes and vandalism to violence against public officials. The backgrounds of all three women were characterised by childhood adversity and drug abuse, but there were important differences in their criminal histories. For the women with severe mental illness, their engagement in criminal activity was highly concentrated. In contrast, the woman sentenced to preventive detention revealed a longer and much more diverse criminal history.

Discussion: Plotting the timing and ordering of criminal events against other noteworthy periods of a person's life history allows for the observation of potentially important patterns of criminal development with relation to the progression of their mental ill-health. Our results suggest that the Life History Plot is a useful visualisation technique that holds promise for the further study of female clients in the forensic and correctional system.

F12. INVESTIGATING THE COGNITIVE AND ENVIRONMENTAL CORRELATES OF PRODROMAL SYMPTOMS IN CHILDREN WHO WERE BORN VERY PRETERM: A PILOT STUDY

Zeyuan Sun^{*1}, Laila Hadaya¹, Lucy Vanes¹, Andrew Lawrence¹, David Edwards¹, Paola Dazzan¹, Chiara Nosarti¹

¹*Institute of Psychiatry, Psychology, and Neuroscience, King's College London,*

Background: Very preterm birth (LESS THAN 33 weeks' gestation) has been associated with an elevated risk of neurodevelopmental impairments in cognition and behaviour, and with a greater likelihood of receiving a psychiatric diagnosis, including psychosis, compared to term birth. This study aimed to investigate the association between very preterm children's self-reported psychotic-like experiences, their cognitive outcomes and individual-level and area-level environmental factors, namely parenting style and neighbourhood disadvantage.

Methods: Participants were very preterm children (n=101; median gestational age 30.00 weeks; range=24.00–33.27) drawn from the ongoing Brain, Immunity and Psychopathology following very Preterm birth study. All children completed a comprehensive neurodevelopmental assessment at a median age of 10.17 years (range=7.42–13.17). The association between self-reported prodromal symptoms (Prodromal Questionnaire–Brief Child Version; PQ-BC), IQ (Wechsler Intelligence Scale for Children-fourth edition), temperament (Temperament In Middle Childhood Questionnaire), general mental health (Strengths and Difficulties Questionnaire), parenting style (Arnold's Parenting Scale), emotion regulation (Emotion Regulation Checklist), emotion recognition (Emotion Recognition Task, developed in-house) and autism traits (Social Responsiveness Scale-Second Edition) was investigated using stepwise linear regression. Our dependent variable was PQ-BC distress weighted symptom score, while all cognitive and behavioural measures listed above, sex, socioeconomic status (Index of Multiple Deprivation 2019) and age at assessment, were included in the model as independent variables.

Results: Reduced distress-weighted symptom scores was associated with better emotion regulation (b=-0.74 [95%CI: -1.25 to -0.22], se=0.26, t=-2.83, p=0.006), higher effortful control (b=-5.53 [95%CI: -11.50 to -0.43], se=3.01, t=-1.84, p=0.069) and more neighbourhood disadvantage (b=-0.61 [95%CI: -1.36 to -0.15], se=0.38, t=-1.60, p=0.113).

Discussion: Our results suggest that better emotion regulation and effortful control (encompassing attentional focusing, attentional shifting, inhibitory and activational control of behaviours) were associated with less distressing psychotic-like experiences among preterm children. These self-regulatory strategies may protect very preterm children from experiencing distressing psychotic-like symptoms.

F13. DEVELOPMENT AND PRELIMINARY VALIDATION OF THE POSTPARTUM PSYCHOTIC EXPERIENCES SCALE (PPES)

Feten Fekih-Romdhane^{*1}, Diane El Hadathy², Covadonga González-Nuevo³, Diana Malaeb⁴, Habib Barakat², Majda Cheour¹, Souheil Hallit²

¹*Tunis El Manar University, Faculty of Medicine of Tunis,* ²*Holy Spirit University of Kaslik, Jounieh, Lebanon,* ³*University of Oviedo, Oviedo, Spain,* ⁴*Gulf Medical University, Ajman, United Arab Emirates*

Background: If not promptly detected and treated, postpartum psychosis carries the potential for detrimental consequences, including the risk of infanticide or suicide. Making available a valid and reliable self-report measurement instrument for postpartum psychotic experiences (PEs) opens future research to measure psychosis proneness and the clinically relevant subclinical psychosis phenotype during this critical period, and may offer novel perspectives for prevention and early intervention strategies in postnatal care. In addition, large-scale, multi-country longitudinal research is warranted to elucidate the processes underlying the postpartum PEs construct, as well as its various correlates and outcomes. Such research is expensive to perform and, consequently, a cost-effective strategy for identifying postpartum women at-risk for PP is required. The contribution of this work is to design and validate a novel self-report measure, the Postpartum Psychotic Experiences Scale (PPES), to screen for attenuated psychotic symptoms during postpartum.

Methods: This cross-sectional study was conducted from September 2022 until June 2023, enrolling 438 women 4-6 weeks after delivery (mean age: 31.23 ± 5.24 years).

Results: Starting from an initial pool of 22 items, both Exploratory Factor Analysis and Confirmatory Factor Analysis suggested that all remaining 15 items loaded into a single factor with an excellent internal consistency (Cronbach α of .95 and a McDonald ω of .95). The PPES showed good convergent validity against another validated measure of PEs, i.e. the Prodromal Questionnaire-Brief (correlations of GREATER THAN 0.8). In addition, PPES scores correlated with measures of postpartum depression and perinatal anxiety, thus attesting for its good concurrent validity. A PPSE score of 8.5 (sensitivity=85.2%, specificity=78.6%) was defined as the optimal cutoff point. According to this cutoff value, 47% of women in our sample were considered at possible risk for postpartum psychosis.

Discussion: This study provides, for the first time, a specific self-report measure to assess postpartum PEs reliably and validly. The PPES appears to be a convenient-to-use and economic screening tool to detect signs and symptoms of attenuated psychosis in the postpartum women populations at risk for psychosis. While postnatal and postpartum care tends to be typically more focused on the mother and baby's physical health, routine screening for signs of psychosis during postpartum should also be highly recommended, as this may enhance the ability to timely manage the condition and prevent its potential harmful outcomes for both mother and baby. We believe that using the PPSE in maternity healthcare services could potentially result in a significant increase in detection of postpartum, relative to standard referral methods and will hopefully raise exciting prospects for future research in the field.

F14. THE RELATIONSHIP BETWEEN CLIMATE CHANGE ANXIETY AND PSYCHOTIC EXPERIENCES IS MEDIATED BY DEATH ANXIETY

Feten Fekih-Romdhane^{*1}, Diana Malaeb², Alvaro Postigo³, Fouad Sakr⁴, Mariam Dabbous⁴, Sami El Khatib⁵, Sahar Obeid⁶, Majda Cheour¹, Souheil Hallit⁷

¹Tunis El Manar University, ²Gulf Medical University, Ajman, United Arab Emirates,

³University of Oviedo, ⁴Lebanese International University, ⁵Lebanese International University,

⁶Lebanese American University, ⁷Holy Spirit University of Kaslik

Background: As climate change persists, accelerates, and intensifies, and since mitigating factors are absent, mental health impacts are expected to follow the same patterns. Therefore, it appears of utmost importance to deepen and broaden the knowledge and understanding of how and through which mechanisms climate change anxiety (CCA) may interplay with mental health outcomes. Based on the stress-vulnerability model of psychosis, the present study

proposed to examine the relationship between CCA and psychotic experiences (PEs), and to test the theoretically-driven hypothesis that death anxiety acts as a mediator in this relationship. **Methods:** This study adopted a cross-sectional approach involving a sample of young adults aged 18 to 35 years (mean age = 24.56 ± 22.49 years; 63.9% females) originating from and residing in Lebanon.

Results: The results of the mediation analysis showed that death anxiety partially mediated the association between CCA and PEs. Higher CCA was significantly associated with higher death anxiety; higher death anxiety was significantly associated with more PEs. Finally, higher CCA was directly and significantly associated with more PEs.

Discussion: Analyses revealed that the relationship between CCA and PEs is both direct and indirect. The indirect relationship is verified through the intermediary role of death anxiety. To be specific, young people could experience greater degree of death anxiety with the increase of their CCA level, resulting in more severe psychotic symptoms. These findings make important contributions to the existing literature in a relatively new and evolving field of research. The threat of climate change has been described as “existential”, shedding light on its potential danger to social system and humans’ life itself. Being confronted with the reality and inescapability of death as a result of climate change is the essence of death anxiety. Death anxiety is suggested, in turn, to play a certain role in triggering or exacerbating PEs, which replicates findings from earlier studies that death anxiety is likely to exist as a risk factor for psychotic symptoms in young adults from the general population. The key tentative recommendation is that addressing death anxiety might alleviate the association between CCA and PEs. In addition, government decision-makers need to recognize the necessity of considering climate change implications on mental health in policy and decision-making. To some extent, our study can also offer some enlightenment and possible future research directions for researchers in both climate change and early intervention in psychosis fields.

F15. COGNITIVE IMPAIRMENTS AND CLINICAL SYMPTOMS AMONG ADOLESCENTS WITH A HISTORY OF CHILD MALTREATMENT: CLINICAL CONCERNS

Caroline East-Richard^{*1}, Catherine St-Pierre¹, Gabriel Demers¹, Élisabeth Anderson¹, Marie-Michèle Champagne¹, Élisabeth Thibaut², Amélie M Achim³, Danielle Nadeau⁴, Caroline Cellard⁵

¹Université Laval, ²McGill University, Douglas Mental Health University Institute, ³Université Laval, CERVO Brain research center, ⁴Centre de recherche universitaire sur les jeunes et les familles (CRUJeF), ⁵Université Laval, Centre de recherche universitaire sur les jeunes et les familles (CRUJeF), CERVO Brain research center

Background: Child maltreatment history is highly prevalent among people with psychotic disorder and is a major risk factor for the development of such disorders. Child maltreatment is also associated with cognitive impairments, both in children and adults who have experienced child maltreatment. However, recent meta-analyses have highlighted the lack of research in the adolescent population. More specifically, few studies have investigated broad cognitive and clinical profiles in the adolescent population with a history of child maltreatment, while cognitive and clinical difficulties may represent relevant intervention targets in this at-risk population. This study aimed to assess the cognitive and clinical profiles of adolescents with a history of child maltreatment.

Methods: Forty adolescents with a history of child maltreatment were recruited from two child welfare service centers in Quebec, Canada. Inclusion criteria for this group were the following: (1) aged between 12 and 17, (2) having been exposed to child maltreatment. These adolescents were compared to 40 adolescents recruited from the general community without a history of child maltreatment. Clinical and cognitive assessments were carried out over three sessions. Several cognitive measures were used to assess the cognitive profile. Regarding the clinical measures, they assessed self-esteem (Culture Free Self-Esteem Inventories - 3rd Edition) and clinical symptoms or problems (Achenbach's Youth Self-Report). For the group with a history of child maltreatment, data on child maltreatment were collected from their records at the welfare service centers.

Results: Differences between groups were significant on cognitive outcomes ($p < .001$), with lower performance in the group with a history of child maltreatment in processing speed, verbal and visuospatial working memory, verbal and visual episodic memory, visuospatial abilities, and executive functioning. Increased internalized symptoms ($p = .009$), such as anxious/depressed symptoms and somatic complaints, were observed in the group with a history of child maltreatment, as well as externalized symptoms ($p < .001$), such as rule-breaking and aggressive behaviors. Attention and social problems were also more severe in the group with a history of child maltreatment ($p < .05$), as well as thought problems such as obsessive thoughts and auditory or visual hallucinations. Additionally, this group showed lower self-esteem ($p < .001$).

Discussion: Overall, adolescents with a history of child maltreatment showed several cognitive impairments and clinical symptoms. Such impairments may have negative impacts on many areas of their lives and deserve clinical attention. Since child maltreatment represents a risk factor for the development of psychotic disorders, the presence of child maltreatment should be an indication for preventative clinical measures such as addressing cognitive and psychological difficulties in trauma informed care. Clinical assessment aimed at the detection of psychotic symptoms may also be relevant. Finally, the use of neuroeducational tools may also be of relevance to promote better detection of cognitive difficulties and the implementation of strategies aimed towards the reduction of associated repercussions in daily life.

F16. CANNABIS-INDUCED PSYCHOSIS: INCIDENCE AND TRANSITION TO SCHIZOPHRENIA

Eline Rognli^{*1}, Heidi Taipale², Carsten Hjorthøj³, Ellenor Mittendorfer-Rutz⁴, Jørgen Bramness⁵, Ina Heiberg⁶, Solja Niemelä⁷, Bjarne Jacobsen⁸, Anne Høy⁶

¹Oslo University Hospital, ²Karolinska Institute, ³Copenhagen University Hospital, Mental Health Center Copenhagen, ⁴Karolinska Institutet, Sweden, ⁵Norwegian Institute of Public Health, ⁶UiT - Arctic University of Norway, ⁷University of Turku, Finland, ⁸Center for clinical documentation and evaluation

Background: Cannabis use is increasingly viewed as a risk factor for schizophrenia. The incidence of cannabis-induced psychosis, and the transition rate from cannabis-induced psychosis to schizophrenia, is less investigated.

Methods: National patient registries from Denmark and Sweden for the years 2000 to 2016, and from Norway from 2010 to 2015, were used to estimate annual incidence of different types of substance-induced psychosis including cannabis-induced psychosis. In a separate Norwegian study we estimated the cumulative hazard and the adjusted hazard ratios for transition from cannabis-induced psychosis to schizophrenia.

Results: The annual incidence rate of cannabis-induced psychosis increased from 2000 to 2016 with 113% in Denmark and with 265% in Sweden, and from 2010 to 2015 with 69% in Norway.

The six-year cumulative hazard for transition from cannabis-induced psychosis to schizophrenia in Norway was 36% (95% CI 31.4-41.0). The risk of transition from substance-induced psychosis to schizophrenia increased with lower age in men and with more episodes of substance-induced psychosis in both genders.

Discussion: The incidence of cannabis-induced psychosis has increased, and cannabis-induced psychosis is a considerable risk factor for later schizophrenia.

F17. LIFE HISTORY OF AGGRESSION IN A SOUTH AFRICAN STUDY OF XHOSA PEOPLE LIVING WITH SCHIZOPHRENIA

Olivia Wootton^{*1}, Christine Friestad², Christina Bell³, Jaroslav Rokicki⁴, Natalia Tesli⁵, Anja Vaskinn⁶, Gabriela Hjell⁷, Thomas Fisher-Vieler⁸, Ruben Gur⁹, Ezra Susser¹⁰, Unn K. Haukvik¹¹, Dan Stein¹

¹University of Cape Town, ²Institute of Clinical Medicine, University of Oslo, Centre for Research and Education in Forensic Psychiatry, Oslo University Hospital, ³University of Oslo, Oslo University Hospital, ⁴Centre of Research and Education in Forensic Psychiatry, Oslo University Hospital, ⁵University of Oslo and Oslo University Hospital, ⁶Centre for Research and Education in Forensic Psychiatry, Oslo University Hospital, ⁷University of Oslo and Østfold Hospital, ⁸University of Oslo, Oslo University Hospital, ⁹University of Pennsylvania, ¹⁰Columbia University, ¹¹NORMENT, Norwegian Centre for Mental Disorders Research, Institute for Clinical Medicine, University of Oslo, Institute of Clinical Medicine, University of Oslo, Centre for Research and Education in Forensic Psychiatry, Oslo University Hospital

Background: People living with schizophrenia (PLS) are at increased risk of committing acts of violence as well as experiencing violence themselves. The causes of violence in psychosis are multifactorial and many risk factors for violent behaviour have been identified, including adverse childhood experiences and social cognitive impairments. However, few studies have investigated the risk factors for violence in psychosis in low- and middle-income settings where differences in the socioeconomic context may affect the interaction between known risk factors and violent behaviour.

Methods: A subsample of participants (PLS = 179; controls = 357) from The Genomics of Schizophrenia in The South African Xhosa People Study completed The Childhood Trauma Questionnaire (CTQ), Life History of Aggression (LHA), Penn Emotion Identification Test, and Structured Diagnostic Interview for DSM-IV Axis I Disorders. Between group differences for childhood trauma, LHA, social cognition, and selected demographic and clinical factors were assessed using t-tests and chi-square tests. We tested if total scores for the LHA or CTQ were able to predict current social cognitive performance using multivariable linear regression.

Results: Scores for the CTQ and LHA were significantly higher for PLS and social cognitive performance was significantly worse for PLS compared to the control group. Current social cognitive performance was significantly associated with childhood trauma but not with aggressive behaviour over the lifetime.

Discussion: The null relationship between current social cognition and lifetime aggression may be due to the relatively low rates of aggression reported in our sample. The significant relationship between social cognition and childhood trauma in this sample provides evidence that the effect of childhood trauma on social cognition in adulthood persists even in environments where adverse childhood experiences are relatively prevalent.

F18. INSUFFICIENT PSYCHIATRIC TREATMENT IN 74% OF SEVERELY MENTALLY ILL OFFENDERS

Gitte Ahle*¹, Trine Arnglim², Tina Gram-Larsen², Mette Brandt-Christensen², Dorte Sestoft⁵

¹*Mental Health Center Amager*, ²*Forensic Psychiatric Department* ³*Ministry of Justice*, *Clinic of Forensic Psychiatry*

Background: The number of forensic psychiatric patients in Denmark has been increasing dramatically from 300 in 1980 to 4300 in 2014. A similar tendency has been seen in comparable countries, however, not to nearly the same extent. The aim of the study was to investigate if the patients had been offered sufficient psychiatric treatment prior to the committed crime.

Methods: The study is a retrospective, descriptive study based on the extraction of data from forensic mental assessment reports where sentence to psychiatric treatment was recommended. The sample includes all forensic mental assessment reports from all of Denmark conducted in the second half of year 2016. Data were extracted from the reports by a specialist in forensic psychiatry. The evaluation of the psychiatric treatment before the crime was made according to a consensus agreement of what constitutes sufficient treatment by the whole research group. Every tenth of the reports and all the reports where the crime was murder or attempted murder was evaluated by 4-6 specialists in forensic psychiatry and tested with Cohens kappa.

Results: There were 218 forensic mental assessment reports, The examined persons had a mean age of 38 years and 78% were men. 18% were homeless and 54% have previously been convicted. 70% had previously committed violence. Half of the persons were in psychiatric in- or out-treatment at the time of the intended crime. 7% had never been in contact with psychiatric services. Before the forensic mental assessment 118 were diagnosed with a non-affective psychosis. 18% more patients (139 versus 118) were diagnosed with a non-affective psychosis at the forensic mental examination than at the last contact with general psychiatry before the crime. We assessed 74% to have received insufficient treatment during the time leading up till them committing the crime. Insufficient treatment included not being admitted to the hospital when needed, a wrong diagnosis was allocated to the patient, or the patient was unstable at the time of the discharge from the hospital. 13 of the cases were charged of murder or attempted murder. We estimated that in 11 of these cases the patient had received insufficient psychiatric treatment during the time leading up to the intended crime.

Discussion: The finding of insufficient treatment in the majority of cases at the time of the crimes might indicate a link between the criminal behavior and inadequate treatment. Almost all the patients were known by the psychiatric services, many had previously been convicted and many had demonstrated violent behavior. These are all well-known risk factor for committing a crime. Moreover, psychosis were significantly under-diagnosed in the sample. It is critical that 18% more is diagnosed with a non-affective psychosis at the forensic mental assessment as untreated psychosis is also a risk factor for committing a violent crime. Our finding points to the importance of correct assessment of psychosis and of offering treatment to individuals with psychosis, especially when they have additional risk-factors for criminal behavior.

F19. INVESTIGATING THE CORRELATES OF PSYCHOTIC-LIKE EXPERIENCES DURING COVID-19 PANDEMIC IN SIX DIFFERENT COUNTRIES AMONG YOUNG ADULTS: A DATA MINING STUDY

Helin Yılmaz Kafalı*¹, İnanç Kabasakal², Sheikh Shoib³, Dmytro Martsenkovskyi⁴, Irfan Ullah⁵, Joan Soler Vidal⁶, Oluseun Peter Ogunnub⁷, Paola Fuentes Claramonte⁶, Gamze Erzin⁸, Özge Kılıç⁹, Mireia Solerdelcoll¹⁰, Chonnakarn Jatchavala¹¹, Victor Pereira Sanchez¹², Timothea Touloupoulou¹³

¹Işık University, ²Ege University, ³Director Health Services Kashmir, ⁴Bogomolets National Medical University, ⁵Kabir Medical College, University, Peshawar, ⁶FIDMAG Hermanas Hospitalarias Research Foundation, ⁷University of Lagos, Nigeria, ⁸Dışkapı Yıldırım Beyazıt Training and Research Hospital, ⁹Koç University, Department of Psychiatry, ¹⁰King's College London, ¹¹Prince of Songkla University, ¹²Stavros Niarchos Foundation Global Center for Child and Adolescent Mental Health, ¹³Bilkent University,

Background: By using association rule mining method, this study aimed to investigate the correlates of psychotic-like experiences (PLEs) during the SARS-CoV-2 pandemic in six different countries among the young adults.

Methods: 1466 participants aged between 18-24 from six different countries consisting of Indian (n=356), Ukraine (n=320), Pakistan (n=292), Turkey (n=264), Spain (n=135), and Nigeria (n=99) were recruited between July 2020 and July 2021. Community Assessment of Psychic Experiences-42 (CAPE-42-Pos), Patient Health Questionnaire (PHQ), Generalized Anxiety Disorder-7 (GAD-7), and Pittsburg Sleep Quality Index (PSQI) were filled out by using an online questionnaire to evaluate PLEs, depressive symptoms, anxiety symptoms, and sleep problems, respectively. Data regarding the presence of a diagnosed psychiatric disorder, chronic disease, cigarette and alcohol usage within the last 30 days, lifetime drug use, history of SARS-CoV-2 infection (yes/no), and psychiatric disorders in the first degree relatives were also collected. RuleGenerator Software was used to execute the association rule mining algorithm and obtain association rules. Rule mining was repeated for each country separately. The rules were evaluated through measures for interestingness, such as confidence and lift.

Results: In Turkey, 7.6% of the participants had both suicidal thought and had previous suicidal attempt. The ratio of having both a psychiatric disorder and a high CAPE score (≥ 38) in such patients was 6.19 times higher than the entire group of participants from Turkey. 75% of the participants using cigarette everyday and having suicidal thoughts in had high-CAPE score (OR=5.19). 7.6% of the participants from Turkey had both a psychiatric disorder and suicidal attempt. 40% of these individuals had high CAPE score (≥ 38) (OR=5). 40% of the participants using alcohol 3-5 times in a month and having suicidal thought had high CAPE score (≥ 38) (OR=4.8). In Pakistan, the 64.2% of the participants with severe anxiety (GAD ≥ 10) and having a psychiatric disorder in family had high CAPE score (≥ 38) and a psychiatric disorder (OR=18.7). 57.1% of these participants had both high CAPE-score and have medium-level sleep problems (PSQI from 6 to 10) (OR=16.6). 3.44% of the participants from Pakistan had both psychiatric disorder in family, had severe depression (PHQ ≥ 10) and severe anxiety level (GAD ≥ 10). 90% of these participants had high CAPE score (≥ 38) (OR=16.1). All of the participants with a psychiatric disorder, had a psychiatric disorder in family, and severe anxiety (GAD ≥ 10) had high CAPE score (≥ 38) (OR=16.1). Moreover, all of the participants with psychiatric disorder in family, medium PSQI score (6-10) and high GAD (≥ 10) had high CAPE score (OR=16.1). In Nigeria, 50% of the participants with severe sleep problems (PSQI GREATER THAN 11) had both high CAPE score (≥ 38) and severe depression (PHQ ≥ 10) (OR=6). 60% of the male participants with severe depression (PHQ ≥ 10) had high CAPE-score (OR=5.8). 9.2% of the participants from Nigeria had a psychiatric disorder, severe depression (PHQ ≥ 10), and severe anxiety (GAD ≥ 10). 44.4% of these participants had high CAPE score (OR=4.3). In Ukrain, 35.7% of the participants with chronic disease and severe anxiety (GAD ≥ 10) had high CAPE score (≥ 38) (OR=6.3). 25% of the participants with suicidal thought and severe anxiety (GAD ≥ 10) had both psychiatric disorder and high CAPE-score (OR=6.6).

23.8% of the participants with a psychiatric disorder and having suicidal thoughts had both high CAPE score (≥ 38) and severe anxiety level ($GAD \geq 10$) ($OR=5.4$). In India, 13% of the participants had severe sleep problems ($PSQI \geq 11$). 47.3% of these participants had high CAPE score (≥ 38) ($OR=3$). 81% of the participants with psychiatric disorder, suicidal thought, and severe sleep problems ($PSQI \geq 11$) had high CAPE score ($OR=5.1$). In Spain, 6% of the participants were using psychopharmacological treatment. 37.5% of the participants using psychopharmacological treatment had high CAPE score (≥ 38) ($OR=9.9$). 7.5% of the participants had severe sleep problems ($PSQI \geq 11$). 30% of the ones with the severe sleep problems had high CAPE score ($OR=7.9$). 17.6% of the participants who had Covid-19 infection in family and had severe anxiety ($GAD \geq 10$) had both high CAPE score (≥ 38) and severe depression ($PHQ \geq 10$) ($OR=7.8$).

Discussion: Our results showed us that in Turkey having suicidal thoughts/attempts and using cigarette (everyday), and alcohol (3-5 times in a month); in Pakistan having a psychiatric disorder, psychiatric disorder in family, severe depression, and severe anxiety; in Nigeria severe sleep problems, being a male, severe depression, having a psychiatric disorder, and severe anxiety; in India having a chronic disease, severe anxiety, having a psychiatric disorder, suicidal thoughts; in Spain using psychopharmacological treatment, severe sleep problems, Covid-19 infection in family, and severe anxiety were associated with PLEs. Association rule mining model allowed us to find country-specific risk factors regarding PLEs.

F20. AN EXAMINATION OF THE RELATIVE ROLE OF STATIC AND DYNAMIC FACTORS IN PREDICTING RISK FOR REHOSPITALIZATION IN INDIVIDUALS WITH SCHIZOPHRENIA-SPECTRUM DISORDERS: HIGHLIGHTING THE ROLE OF AGGRESSION AS A PRIMARY RISK FACTOR

Shreya Jagtap^{*1}, Cory Gerritsen², Jessica D'Arcey³, Hanna Hamzai⁴, Sylvia Romanowska⁵, Michael Best⁵

¹Centre for Addiction and Mental Health, University of Toronto, ²Centre for Addiction and Mental Health, The University of Toronto, ³University of Toronto Scarborough, Centre for Addiction and Mental Health, ⁴University of Toronto, ⁵University of Toronto Scarborough

Background: Individuals with schizophrenia spectrum disorders (SSDs) typically require a high level of intensive treatment service, such as inpatient hospitalization, with rates of rehospitalization ranging from 52% to 64% between one to five years after discharge. Existing literature has focused on largely static demographic variables such as sex, age, employment status, and education as key factors associated with rehospitalization rates in individuals with SSDs. Dynamic clinical risk factors such as comorbid substance use, aggression, self-harm, impairments in activities of daily living, and length of initial hospitalization have received less attention but are also associated with subsequent rehospitalization. The primary aim of this study was to determine which of these factors are related to subsequent hospital admissions. The secondary aim was to elucidate the incremental changes in the strength of that relationship with dynamic less-established clinical factors related to aggression, functioning, and self-harm beyond the traditionally-established demographic contributors.

Methods: This retrospective chart review study assessed demographic and clinical variables in a sample of 883 individuals with an SSD admitted to an inpatient psychiatric unit from 2015-2020. Demographic data and admission-related incidents (e.g., aggression; need for restraint/seclusion) were obtained from electronic medical records. Clinical variables were obtained from Resident Assessment Inventory, as well as calculated using electronic medical record data (e.g., length of stay). To investigate the factors associated with the event of

rehospitalization, a Cox proportional hazards regression analysis was performed. To examine their incremental predictive capacity, a negative binomial regression analysis was performed.

Results: In our Cox regression model, only scores on the RAI: Harm to Others scale were associated with the event of rehospitalization ([OR] = 1.18, 95% [CI], 1.01 to 1.37). We conducted two negative binomial models with Model 1 consisting of static demographic variables and Model 2 consisting of static demographic and dynamic clinical variables. A chi-square likelihood ratio test comparing deviance scores between both indicated that Model 2 provided a significantly stronger model fit ($p = \text{LESS THAN } .001$). Model 1 was significant, χ^2 likelihood ratio = 119.19, $p = \text{LESS THAN } .001$. Sex (male) was found to significantly predict the number of rehospitalizations ($B = -.25$, $p = .041$). Model 2 was also significant. In this model, identifying as male ($B = -.26$, $p = .045$), the number of aggressive incidents ($B = .03$, $p = .004$), a shorter length of initial rehospitalization ($B = \text{LESS THAN } .001$, $p = .036$), lower RAI: Self Harm scale scores ($B = -.18$, $p = .023$), and not being referred for concurrent disorders treatment services ($B = .57$, $p = .041$) was shown to significantly predict a greater number of subsequent hospitalizations.

Discussion: Our findings highlight that dynamic clinical factors are better predictors of rehospitalization outcomes than static factors. Notably, factors related to aggression and harm are particularly associated with rehospitalization outcomes, while there was no relationship found between positive symptoms and hospitalizations. It may be that a propensity towards aggressive behaviour is more greatly associated with instability in the community upon discharge compared to symptom severity, leading to an increased likelihood of rehospitalization. Thus, the implementation of treatment interventions that target and mitigate aggressive behaviour may be important adjuncts alongside treatment for the stabilization of symptoms, to reduce rehospitalization rates for individuals with SSDs.

F21. DYNAMIC ASSOCIATIONS AMONG NEGATIVE SCHIZOTYPY, ANTICIPATORY PLEASURE, AND SUICIDAL IDEATION

Rebecca Salzano*¹, Richard Linscott¹

¹*University of Otago*

Background: Negative schizotypy is a major risk factor for suicidal ideation. According to previous literature, deficiencies in pleasure are evident in negative schizotypy and suicidal ideation, suggesting a possible link. In particular, low levels of anticipatory pleasure predict negative symptoms and suicidal ideation more strongly than consummatory pleasure. We investigated whether anticipatory pleasure mediated the associations of negative, positive, and disorganised schizotypy to suicidal ideation.

Methods: Psychology undergraduates ($n = 532$) underwent baseline assessments for schizotypy, pleasure capacity, and suicidal ideation, followed by nine follow-up assessment waves at three-day intervals over 30 days. Baseline assessments included self-report measures of schizotypy (Brief Revised Updated version of the Schizotypal Personality Questionnaire, SPQ-BRU), suicidal ideation (Columbia-Suicide Severity Rating Scale, C-SSRS), and anticipatory and consummatory pleasure (Temporal Experiences of Pleasure Scale, TEPS; and Dimensions of Interpersonal Pleasure Scale, DIPS). Follow-up assessments included measures of anticipatory and consummatory pleasure (State Experience of Pleasure Scale, SEPS) and suicidal ideation (C-SSRI). Baseline data were analysed using a structural equation model, and longitudinal data using a general linear mixed-effects model. Bias-corrected bootstrapped confidence intervals were used to assess statistical significance.

Results: Interpersonal (standardised beta $c1 = .11$; bootstrapped 95% confidence interval = [.01, .21]), disorganised ($c3 = .17$ [.08, .27]), and cognitive-perceptual schizotypy ($c4 = .12$ [.17, .28]) had significant total relationships with ideation at baseline. In cross-sectional analyses, anticipatory pleasure fully mediated the relationship between interpersonal schizotypy and suicidal ideation ($c1' = -.03$ [-.13, .08]) and partially mediated the relationship between disorganised schizotypy and suicidal ideation ($c3' = .13$ [.04, .22]). Interpersonal ($c1 = .06$ [.02, .13]), social anxiety ($c2 = .10$ [.02, .17]), disorganised ($c3 = .10$ [.02, .17], and cognitive-perceptual schizotypy ($c4 = .08$ [.01, .17]) had significant total effects on changes in ideation over time. In longitudinal analyses, changes in anticipatory pleasure fully mediated the association of interpersonal schizotypy ($c1' = .01$ [-.02, .13]) and social anxiety ($c2' = .05$ [-.02, .12]) with changes in ideation and partially mediated the relationship of disorganised schizotypy with changes in ideation ($c3' = .08$ [.00, .15]). Cognitive-perceptual schizotypy was neither cross-sectionally ($c4' = .17$ [.07, .28]) nor longitudinally ($c4' = .08$ [.002, .16]) related to ideation through anticipatory pleasure. Consummatory pleasure did not have any mediatory effects on any cross-sectional or longitudinal relationships.

Discussion: Across 10 time points, all subtypes of schizotypy were significantly associated with the emergence of suicidal ideation. Cross-sectional and longitudinal findings indicated that anticipatory but not consummatory pleasure mediated the relationship between interpersonal schizotypy and suicidal ideation and partially mediated the relationship from disorganised schizotypy to suicidal ideation. Our findings echo prior research indicating elevated suicidal ideation in individuals with lower pleasure levels and reduced anticipatory pleasure in negative schizotypy. Addressing deficits in anticipatory pleasure may help to develop targeted prevention and intervention strategies among individuals displaying negative schizotypy.

F22. LONGITUDINAL TRAJECTORIES OF BRAIN DEVELOPMENT IN CHILDREN AND ADOLESCENTS AT FAMILY RISK FOR SCHIZOPHRENIA AND BIPOLAR DISORDER

Isabel Valli^{*1}, Mireia Masias², Angels Calvert³, Jose Pariente⁴, Elena De la Serna⁵, Eduard Vieta⁶, Gisela Sugranyes⁷, Josefina Castro-Fornieles⁸

¹*Instituto de Investigaciones Biomedicas de Barcelona, CSIC-IDIBAPS-CIBERSAM*, ²*BCN-Medtech, Universitat Pompeu Fabra*, ³*IDIBAPS*, ⁴*Magnetic Resonance Image Core Facility, Institut d'Investigacions Biomèdiques Agustí Pi i Sunyer (IDIBAPS), Barcelona, Spain*, ⁵*Centro De Investigación Biomédica En Red De Salud Mental, CIBERSAM*, ⁶*Bipolar Disorder Program, Department of Psychiatry and Psychology, Institute of Neuroscience, Hospital Clinic, University of Barcelona, IDIBAPS, CIBERSAM, Barcelona, Catalonia, Spain.*, ⁷*IDIBAPS (August Pi i Sunyer Biomedical Research Institute) / Hospital Clínic Barcelona*, ⁸*Hospital Clinic de Barcelona. Centro de Investigación Biomédica en Red de Salud Mental, CIBERSAM Barcelona*

Background: Subcortical brain abnormalities are among the most robust findings in schizophrenia and bipolar disorder. Similar yet subtler abnormalities have been observed in youth at clinical or family risk for both disorders. These abnormalities are considered neurodevelopmental in origin and their investigation can contribute to the understanding of neurobiological changes that precede illness onset. However, evidence in high-risk populations has mainly been cross-sectional, whereas the brain is undergoing important maturational

changes over the years before symptoms emerge. A limited number of longitudinal studies therefore examined whether those observed are stable trait structural abnormalities or rather differences that emerge during brain maturation. However, the available evidence largely focused on late adolescence and early adulthood. It remains thus unclear when these abnormalities emerge and how they progress. We therefore sought to investigate an earlier segment of the neurodevelopmental pathway, longitudinally examining children and adolescents at family risk. We tested whether and when their trajectories of subcortical brain development might diverge from those of healthy control participants. In the hippocampus we also examined the longitudinal development of anatomically distinct subfields, to assess whether potential volumetric abnormalities are widespread or rather initially localised and subsequently generalise.

Methods: We examined a total of 385 scans from 194 participants: 52 children of parents with schizophrenia (SZO), 75 children of parents with bipolar disorder (BDO) and 67 children of healthy control parents (HCO) aged 6 to 20 years. Each participant underwent 3T structural MRI imaging at 1 to 3 time points, each two years apart. Mixed models were used to compare groups in terms of volumetric longitudinal trajectories of lateral ventricles, thalamus, caudate, putamen, pallidum, nucleus accumbens, amygdala, the hippocampus and its subfields.

Results: We observed that high risk participants, taken together, showed diverging trajectories of hippocampal development compared to HCO, with significantly accelerated volumetric decline in the left hippocampus and at trend level in the right. When examining the two offspring groups separately, we observed overlapping trajectories of hippocampal development for SZO and BPO compared to HCO in the left hippocampus, whereas in the right hippocampus the divergence from HCO trajectories was more pronounced in SZO compared to BPO. When examining hippocampal subfields, we observed trend level volume differences in the subiculum and CA1 but no interaction with age, with no differences in terms of slope between high-risk individuals and HCO. No significant between-group differences were observed in the other subcortical structures examined.

Discussion: Our results suggest that dynamic changes occur across childhood and adolescence in individuals at family risk for psychosis. These are most pronounced in the hippocampus and especially in its anterior portions, similarly to what has been observed soon after symptoms emergence in first episode psychosis. Future studies, conducted once participants reach the mean age of onset for the examined disorders, will clarify whether diverging trajectories are most pronounced in those who will develop a psychotic disorder, and thus elucidate whether the observed differences are correlates of family proneness or could rather be used as predictors of future illness.

F23. ADOLESCENT MEDIA USE AND ITS ASSOCIATIONS WITH PSYCHOTIC EXPERIENCES

Vincent Paquin^{*1}, Manuela Ferrari¹, Soham Rej¹, Michel Boivin², Isabelle Ouellet-Morin³, Marie-Claude Geoffroy¹, Jai L. Shah¹

¹McGill University, ²Laval University, ³University of Montreal

Background: Adolescent media use has been associated with mental health problems and is thought to influence brain development. However, whether it is associated with psychotic experiences (PEs) remains unclear. The association between media use and PEs may vary according to the types of media involved and time-sensitive changes in the amounts of use over adolescence. We thus aimed to examine longitudinal trajectories of adolescent media use

between 12 and 17 years of age and their associations with PEs at 23 years. We considered four types of media use: TV viewing, video gaming, computer use, and reading.

Methods: The sample included 1226 participants (n=713 [58.2%] female) from the Québec Longitudinal Study of Child Development, a population-based cohort of children born in 1997 and 1998 and followed up annually or biannually from 5 months through 23 years of age. Participants reported their weekly amount of TV viewing, video gaming, computer use, and reading at 12, 13, 15 and 17 years of age. Lifetime occurrence of psychotic experiences was measured at 23 years of age with the 15-item Community Assessment of Psychic Experiences. Covariables included sociodemographic, genetic, and psychosocial characteristics between 5 months and 12 years of age. We used latent class mixed modeling to identify trajectories of media use. Associations between media use trajectories and PEs were examined with Gamma models.

Results: Between 12 and 17 years of age, participants followed lower, medium, or higher trajectories of TV viewing, video gaming, and reading. For computer use, they followed a lower, curved, or higher trajectory. In all types of media, a minority of participants followed trajectories of higher use: TV viewing, n=128 (10.4%); video gaming, n=145 (11.8%); computer use, n=353 (28.8%); and reading, n=140 (11.4%). Relative to lower video gaming (n=891 [72.7%]), a trajectory of higher video gaming was preceded by higher levels of mental health and interpersonal problems at 12 years, and adjusting for these factors explained the association of higher video gaming with PEs at 23 years. A curved trajectory of computer use (n=189 [15.4%] participants), characterized by increasing levels of use until 15 years of age followed by a decrease, was associated with higher PEs (estimated difference, +5.3%; 95% CI, +1.5%-+9.3%) relative to lower use (n=684 [55.8%] participants). This association was robust to covariable adjustment. Trajectories of TV viewing and reading were not associated with PEs, and there were no significant sex differences in the associations of media use trajectories with PEs.

Discussion: A sharp decline in computer use during late adolescence, as found in the curved trajectory, may be a marker of risk for future PEs. This association may reflect the onset of PEs during adolescence that lead to, or are concurrent with, a time-sensitive decrease in the amount of computer use. The higher video gaming trajectory was associated with more PEs at 23 years of age, however this association was explained by higher childhood mental health and interpersonal problems among higher video gamers. It is possible that some adolescents at risk for PEs turn to video games in response to psychosocial adversity, for example as a way of coping or because of the greater accessibility of video games relative to other activities. Overall, trajectories of adolescent media use and their psychosocial antecedents may be informative for the early identification of PEs. Better understanding the motivations for and mental health determinants of adolescent media use may contribute to the development of digital approaches to detect and prevent PEs.

F24. COMPENSATORY UPREGULATION OF C4 MEDIATES THE DEVELOPMENT OF ADULT BRAIN PATHOLOGY AFTER TRANSIENT PREFRONTAL MICROGLIA DEFICIENCY IN ADOLESCENCE

Sina-Maria Schalbetter*¹, Anja Krütli¹, Ron Rabin¹, Anina Sara von Arx¹, Olga Krzyzaniak¹, Han-Yu Lin¹, Johanna Furrer¹, Tina Notter¹, Urs Meyer¹

¹University of Zurich

Background: We have recently shown that microglia, the brain's resident immune cells, contribute to functional and structural maturation of the prefrontal cortex (PFC). Using a mouse

model of cell-specific, transient and local depletion of microglia, we found that deficiency of prefrontal microglia during adolescence is sufficient to induce an adult emergence of PFC-associated impairments in cognitive functions, dendritic complexity, and synaptic structures and functions. However, the precise molecular mechanisms mediating the long-term effects of adolescent microglia deficiency remain elusive. Based on the emerging role of the complement component 4 (C4) in physiological and pathological pruning of synapses, we explored the role of C4 in this novel mouse model of transient prefrontal microglia depletion during adolescence.

Methods: Brain region-specific and transient depletion of prefrontal microglia during adolescence was induced by a single, bilateral stereotaxic injection of clodronate disodium salt (CDS) into the medial portion of the PFC in 6-week-old C57BL/6 mice. Control mice received a bilateral stereotaxic injection of phosphate-buffered saline (PBS). The magnitude and specificity of microglia depletion were ascertained by post-mortem immunohistochemistry at 1, 5, 10, and 40 days post-injection (dpi), whereas mRNA levels of C4b were quantified at these dpi intervals using quantitative real-time PCR (qRT-PCR). RNAscope in situ hybridization was used to co-localize C4b gene expression with different cell populations, including microglia, astrocytes and neurons. PFC-specific downregulation of C4 during adolescence was used to explore whether compensatory upregulation of C4 mediates the development of adult brain pathology after temporary microglia deficiency in adolescence. This was achieved by bilateral injections of an AAV expressing a small hairpin RNA (shRNA) against murine C4, coupled with GFP (AAV-shRNA), in 3-week-old C57BL/6 mice. The control group received an AAV expressing GFP with a scramble shRNA sequence (AAV-Co). A battery of mPFC-dependent cognitive tests, including social recognition memory and temporal order memory, was conducted to probe C4's involvement in disputing adult cognitive functions.

Results: A single intra-PFC injection of CDS led to a robust (~ 80% depletion) but temporary (~ 1 week) microglia deficiency in the adolescent PFC without depleting other cell types, such as astrocytes and neurons. The expression of C4b was markedly (2-3 fold) upregulated in mice that were subjected to transient microglia depletion, starting from 5 dpi and persisting into the 40 dpi interval. This upregulation emerged mostly in astrocytes and, to a lesser extent, in neurons, but not in microglia. Pre-administration of shRNA targeting C4 expression effectively attenuated the upregulation of prefrontal C4b after microglia depletion. Importantly, blocking the compensatory upregulation of C4b by anti-C4 shRNA prevented the subsequent emergence of social recognition memory and temporal order memory deficits in adulthood.

Discussion: Using a selective and transient loss-of-function approach, our study identified compensatory upregulation of C4 in response to transient prefrontal microglia deficiency in adolescence. Furthermore, our data suggest that this upregulation of prefrontal C4 mediates the subsequent emergence of cognitive dysfunctions pertaining to schizophrenia and other PFC-related disorders.

F25. COGNITIVE FUNCTIONING IN PEOPLE WITH SUBCLINICAL PSYCHOTIC SYMPTOMS: A SYSTEMATIC REVIEW AND META-ANALYSIS STUDY

Sai Ting Chu^{*1}, Ivan Wai Lok Chu², Esther Wing-Chi Yip², Joe Kwun Nam Chan², Corine Sau Man Wong³, Wing Chung Chang⁴

¹*The University of Hong Kong*, ²*Department of Psychiatry, the University of Hong Kong*, ³*School of Public Health, LKS Faculty of Medicine, The University of Hong Kong*, ⁴*Department of Psychiatry, School of Clinical medicine, LKS Faculty of Medicine, The University of Hong Kong*

Background: Cognitive deficit is widely observed in schizophrenia patients and is associated with negative functional outcomes. However, comprehensive review and sources of heterogeneity in cognitive functioning in individuals with subclinical psychotic symptoms (PS) are lacking in previous meta-analysis. We conducted a systematic review and meta-analysis with an aim to evaluate the presence, degree, and patterns of cognitive impairment among individuals experiencing subclinical PS relative to those without subclinical PS. Meta-regression analyses were performed to examine sources of heterogeneity.

Methods: We systematically searched four electronic-databases until 6-July-2023 and conducted meta-analysis to synthesize estimates of cognitive functioning for individuals with subclinical PS relative to non-PS counterparts. Subgroup analyses and meta-regression models stratified by sex, age, study design (cross-sectional vs longitudinal), individual cognitive tasks used (i.e., MMSE vs IQ vs others), PS instrument (i.e., PSQ vs others) were conducted when applicable.

Results: Twenty-seven and 6 studies were included for meta-analysis of cognitive functioning with (n=82,561; 10,251 individuals with subclinical PS) and without (n=8,062; 813 individuals with subclinical PS) dichotomous PS cutoff. People with subclinical PS exhibited larger cognitive deficit in general cognition (Hedges' $g=-0.10$ [95% CI: -0.18 to -0.02]), verbal fluency (Hedges' $g=-0.05$ [95% CI: -0.10 to -0.00]), visual learning and memory (Hedges' $g=-0.21$ [95% CI: -0.38 to -0.03]) and working memory (Hedges' $g=-0.16$ [95% CI: -0.28 to -0.04]) relative to non-PS controls. Subgroup analysis in general cognition suggested more severe deficit was observed in both study designs with longitudinal design showing significantly larger deficit ($z=-2.83$, $p=0.005$), and cognitive instruments other than MMSE and IQ (-0.11 [-0.20 to -0.01]). Meta-regression in general cognition revealed subclinical PS was associated with age ($Q_m=11.34$, $p < 0.001$), sex ($Q_m=6.71$, $p=0.010$) and study design ($Q_m=8.01$, $p=0.005$). When concerning cognitive sub-domain, poorer performance in working memory was observed in subclinical PS compared to the counterparts without PS using Digit Span task (-0.18 [-0.32 to -0.05]) and with cross-sectional design (-0.26 [-0.41 to -0.12]). Exploratory analysis examining subclinical PS using scales without dichotomous PS cutoff revealed absence of significant difference in cognitive performance.

Discussion: Taken together, subclinical PS is associated with subtle cognitive deficit. Future studies should examine the underlying biological mechanism for cognitive functioning in subclinical PS.

F26. VISUAL PROCESSING OF SOCIAL AND NON-SOCIAL STIMULI IN SCHIZOPHRENIA: EXPLORING THE LINK TO PSYCHOPATHOLOGY

Hana Kutlikova^{*1}, Natália Čavojská², Vladimír Ivančík², Alexandra Straková³, Vanda Valkučáková², Ján Pečeňák⁴, Anton Heretik³, Michal Hajdúk²

¹Comenius University, ²Comenius University in Bratislava, ³Department of Psychology, Faculty of Arts, Comenius University, Bratislava, Slovak Republic, ⁴Department of Psychiatry, Faculty of Medicine, Comenius University, Bratislava, Slovak Republic

Background: Attentional deficits in the processing of socially salient cues are well established in schizophrenia. However, less is known about how they are related to the specific symptoms of schizophrenia. This study therefore aims to investigate the link between visual processing of social versus non-social scene components, in individuals with schizophrenic spectrum disorder (SZ) and in the healthy controls (HC) with specific focus on the role of positive and negative symptoms.

Methods: Using a free-viewing eye-tracking paradigm, we tested 30 individuals with SZ (52 % female, Mage = 40.60, 95% CI [37.01, 44.19]) and 31 HC (61 % female, Mage = 33.25, 95% CI [29.27, 37.23]). The task consisted of 12 complex scenes drawn from the IAPS database. Each scene contained both social and non-social components and the images were selected to balance arousal and valence, ensuring equal representation of high and low intensities in both dimensions. Participants were instructed to look at any part of the screen, and there was no secondary task involved. We measured eye-tracking parameters capturing both attentional engagement (time to first fixation, peak velocity of the first saccade) and attentional maintenance (number and duration of fixations and saccades). Psychopathology was assessed using Brief Psychiatric Rating Scale (BPRS) and Community Assessment of Psychic Experiences (CAPE-42).

Results: GLMMs of the eye-tracking parameters did not reveal any main effect of the group (SZ/HC), nor its interaction with the type of scene component (social/non-social). When taking into account the arousal and valence of the presented stimuli, SZ (M = 2709 ms, 95% CI [2333.7, 3085]) compared to HC participants (M = 2125 ms, 95% CI [1785.6, 2465]) showed significantly slower ($t(176) = -2.276, p = .024$) attentional engagement toward non-social aspects of the highly arousing negative scenes (Group x Valence x Arousal x Type interaction: $F(1, 917.89) = 5.50, p = .019$). Furthermore, in SZ, slower attentional engagement (i.e., longer time to the first whole fixation) toward non-social scene components was significantly associated with more severe negative symptoms measured by BPRS ($\rho = .467, p = .009$). On the other hand, the positive symptoms were related to slower attentional engagements in the social components of the presented scenes ($\rho = .538, p = .002$).

Discussion: Our study highlights the link between negative symptoms and attentional deficits in processing of the non-social information. More specifically, we show that individuals with SZ need longer time to engage with non-social aspects of highly arousing negative scenes, and that this delay is related to the severity of negative symptoms. Such results point to impaired cognitive processing of contextual information among SZ individuals, particularly in scenarios that are highly distressing. On the contrary, the positive symptoms in SZ seem to be related to the delayed attentional engagement toward central social aspects of the environment. While acknowledging the need for cautious interpretation due to multiple comparisons, our study provides preliminary evidence of a distinct role of negative and positive symptoms in the visual processing of non-social and social stimuli.

F27. PSYCHOEDUCATIONAL PROGRAMS FOR YOUNG WITH ULTRA HIGH RISK: TOOLS SUPPORTING DEPLOYMENT EARLY INTERVENTION IN FRANCE

Marion Feron¹, Trang Nu Thuy TON^{*2}

¹Service CRISALID CHI Clermont de l'Oise, ²none

Background: Early intervention occurs during cerebral adolescence, a period of opportunity for preventive support and a change of paradigm with a transdiagnostic, prospective view, development and implantation. It authorizes the ambition to be able to change the clinical trajectory of young users with clinical situations (high risk mental states) through targeted tools. Psychoeducation is considered as an efficient care tool for established and persistent psychiatric disorders. In the context of early intervention, users show low engagement in care.

Methods: A modular and adaptable program, based on cooperative pedagogy, free choice and concerted objectives is an integral part of the care pathway and a key element of recovery. These elements appear in description of this care pathways and this specific program, led by a

trained multidisciplinary team (including peer health mediator) and evaluated by mixed qualitative and quantitative indicators.

Results: "Cultivate your strengths and live fully"; consists of 2 basic sessions and then 6 optional sessions developed with the young people according to their needs (emotional regulation, psychosocial skills, rights, sexuality, health life, etc.). The objective is to preserve their self-determination, to choose their pathway, in a dynamic of partnership with health professionals.

Discussion: In a preliminary study, this program helps to increase Mental Well-Being (WEMWBS, Trousselard et al., 2016), Emotional regulation (DERS, Dan-Glauser et al., 2013), and use of coping strategies (problem-solving - WCC-R, Cousson et al., 1996), commitment to care, to support a change of vocabulary (verbatim analysis), and to reduce school and care dropout rates.

Psychoeducational programs based on adaptability according to needs are efficient to support recovery and free diffusion helps to develop early intervention in France.

F28. THE IMPACT OF EARLY LIFE STRESS ON SCHIZOPHRENIA-LIKE COGNITIVE DEFICITS IN MICE HETEROZYGOUS FOR A MUTATION IN GLUTAMATE DEHYDROGENASE: A GENE X ENVIRONMENT MODEL

Brigitte Baransi^{*1}, Kfir Asraf², Inna Gaisler-Salomon³

¹*School of Psychological Sciences, University of Haifa, The Integrated Brain and Behavior Research Center (IBBRC), University of Haifa,* ²*University of Haifa,* ³*University of Haifa*

Background: Schizophrenia (SZ) pathology has been associated with glutamate dysfunction, and its developmental trajectory is affected by stress exposure. One of the most coherent findings in psychiatric epidemiology is that early life stress (ELS) is a powerful determinant of mental health issues over a lifetime. In SZ, ELS is hypothesized to affect hypothalamic-pituitary-adrenal (HPA) axis function, which in turn impacts glutamate and dopamine transmission. Glutamate dehydrogenase1 (GDH in humans, Glud1 in rodents), is a mitochondrial enzyme involved in glutamate metabolism, and alterations in GDH mRNA expression have been found in the prefrontal cortex (PFC) of patients with SZ. Our previous studies showed that mice with a homozygous deletion of Glud1 in CNS (CNS-Glud1^{+/+} mice) or mice with a heterozygous deletion (CNS-Glud1^{+/-} mice) exposed to acute mild stress in early adulthood show significant behavioural abnormalities that mimic different aspects of SZ-like symptomatology. In the present study, we tested the impact of ELS on SZ-like behavioural deficits in heterozygous CNS-Glud1^{+/-} mice and their CNS-Cre⁺ controls. We assessed behavior in the open field, novel object recognition (NOR) and Water T-maze tasks. We also assessed performance in a novel overshadowing task, which measures salience attribution that is impaired in SZ and is associated with dopamine dysfunction. Following behavioral tasks, we quantified mRNA expression of glutamate and dopamine markers in the hippocampus and nucleus accumbens.

Methods: We used the limited bedding and nesting material (LBN) paradigm to induce ELS between postnatal days (PND) 3-9. Adult CNS-Glud1^{+/-} and CNS-Cre⁺ mice exposed to ELS or adequate bedding and nesting material (no-stress controls) were tested for behavioral alterations between PND70-90. Twenty days after the overshadowing test, we assessed mRNA expression changes of glutamate and dopamine markers using RT-PCR. We hypothesized that CNS-Glud1^{+/-} mice that undergo the ELS condition will show deficits in all behavioural tests

and abnormalities in glutamate and dopamine markers that mimic findings in patients with schizophrenia.

Results: We find that while ELS does not induce long-term changes in weight or general health conditions, ELS-exposed CNS-Glud1+/- mice display hyper-locomotion in the open field as well as impaired spatial acquisition and reversal in the Water T-Maze Task. Furthermore, we found that LBN disrupted overshadowing regardless of genotype. Our ongoing studies will reveal whether these behavioral alterations are accompanied by gene expression changes.

Discussion: Our findings indicate that ELS affects CNS-Cre+ and CNS-Glud1+/- mice differently, leading to cognitive abnormalities in adult mutant mice that resemble SZ symptomatology. ELS also has a long-term impact on salience attribution. The neural mechanisms of these findings remain to be determined.

F29. COGNITIVE REMEDIATION COMBINED WITH AEROBIC EXERCISE TO FURTHER IMPROVE COGNITION IN SCHIZOPHRENIA

Jacopo Sapienza*¹, Giulia Agostoni², Federica Repaci¹, Margherita Bechi¹, Irene Calzavara Pinton³, Mariachiara Buonocore¹, Marco Spangaro¹, Francesca Martini¹, Federica Cocchi¹, Carmelo Guglielmino¹, Antonio Vita⁴, Roberto Cavallaro⁵, Giacomo D'Este³, Marta Bosia⁵

¹San Raffaele Hospital, ²San Raffaele hospital, ³Spedali Civili of Brescia, ⁴University of Brescia, ⁵Vita-Salute San Raffaele University

Background: Cognitive impairment is a core feature of schizophrenia, on which pharmacological interventions have a limited impact. Cognitive remediation (CR) is the gold standard for addressing cognitive deficits, yet its effect sizes vary and often remain in the low-to-medium range, thus enhanced treatment approaches are needed. Emerging evidence supports the cognitive benefits of Aerobic Exercise (AE), suggesting that a combined intervention involving both AE and CR could result in greater cognitive enhancements, while granting additional advantages to physical health.

Methods: The sample included sixty clinically stabilized patients with schizophrenia recruited at:

Schizophrenia Research and Clinical Unit of IRCCS San Raffaele Hospital (Milan, Italy)

- Department of Mental Health and Addiction Services, ASST Spedali Civili of Brescia (Brescia, Italy).

Patients were randomly assigned 1:1:1 ratio to 3 groups:

- AE: 2 weekly 45 min-cycle ergometer sessions + 15 min stretching for 3 months.
- CR: 2 weekly sessions with Cogpack software.
- CR+AE.

MATRICES Consensus Cognitive Battery (MCCB) was used to evaluate cognition:

- T0 = baseline.
- T1 = after training.
- T2 = 3-month follow-up.

Results: CR+AE group compared to CR group (ANCOVA) showed significant improvements in:

- Attention ($F=6.85$; $p=.02$)
- Working Memory ($F=4.41$; $p=.04$)
- Verbal Learning ($F=4.80$; $p=.03$).

In addition, the comparison between CR+AE group and AE group (ANCOVA) highlighted significant improvements in:

- Processing Speed ($F=10.59$; $p=.002$)
- Working Memory ($F=4.14$; $p=.05$)
- Verbal Learning ($F=4.69$; $p=.03$).

Considering results at T2 (three-month follow-up) CR+AE group compared to CR group showed significant differences in:

- Processing Speed ($F=5$; $p=.03$)
- Social Cognition ($F=8.47$; $p=.01$).

CR + AE: the cognitive improvements achieved at T1 remained stable in the other domains, as shown by the lack of significant differences from T1 to T2.

Concerning the comparison between CR+AE vs AE groups at 3-month follow-up, results showed no significant improvement at T2 compared to T1, showing the stability of the improvements achieved after the intervention by the CR+AE group.

Discussion: The CR+AE group showed substantial cognitive improvements in various domains, including attention, verbal learning, working memory, and processing speed compared to the other groups, thus offering greater benefits with respect to CR or AE alone. While preliminary, these results are promising and underscore the potential value of implementing aerobic exercise in rehabilitative approaches aimed at addressing cognitive dysfunction in schizophrenia.

F30. STRATIFICATION OF THERAPY RESPONSE TO SHORT COMPUTERIZED COGNITIVE INTERVENTION: INVESTIGATING DIFFERENCES IN IMPAIRED AND SPARED COGNITIVE SUBTYPES IN RECENT ONSET PSYCHOSIS

Öznur Bastürk^{*1}, Julian Wenzel², Shalaila Haas³, Joseph Kambeitz⁴, Nikolaos Koutsouleris⁵, Dominic Dwyer⁶, Lana Kambeitz-Illankovic²

¹University Hospital of Cologne, ²University Hospital of Cologne, Department of Psychiatry and Psychotherapy, ³Icahn School of Medicine at Mount Sinai, New York, USA, ⁴University of Cologne, Department of Psychiatry and Psychotherapy, ⁵Ludwig-Maximilian-University, ⁶Ludwig Maximilian University

Background: Previous studies have identified two distinct cognitive subtypes in individuals with psychosis, one characterized by impaired cognitive performance across multiple cognitive domains and the other by spared cognitive performance similar as one seen in healthy individuals. Cognitive training (CT) has been shown to enhance the cognitive and functional abilities of patients with psychosis. Despite a large proportion of patients that benefits from the

training, considerable heterogeneity in response is present possibly due to distinct cognitive and neurobiological subtypes exhibiting characteristic features. This study aims to assess the effectiveness of cognitive training in individuals with recent-onset psychosis (ROP) and compare its efficacy across different cognitive subtypes. The primary outcome was cognitive performance, and the secondary outcome was functional outcome.

Methods: The sample in this study included in total of 90 patients with ROP (54 male, 36 females; Mean age = 27.4, SD = 6.6) 40 from the Department of Psychiatry and Psychotherapy at the University Hospital of Cologne in Cologne, Germany, and 50 from the Department of Psychiatry and Psychotherapy of the Ludwig-Maximilians-University (LMU) in Munich. The participants were randomly assigned to either the CT group (26 male, 18 females; Mean age 28.2, SD = 6.5) who were trained with the Social Cognitive Training from Posit Science for 10 hours over 6 weeks of admission to the hospital or the treatment as usual (TAU) group (28 male 18 female; Mean age 26.7, SD = 6.7). To assess cognitive performance and functioning, both groups underwent clinical assessments and completed a comprehensive neurocognitive battery before and after the intervention. Moreover, we utilized previously established cluster models based on their performance in eight cognitive domains to derive distinct cognitive subtypes.

Results: Our findings revealed a significant improvement in the cognitive domain of Processing Speed and Global Functioning (GF) role scores within the CT group, in comparison to the TAU group in which such improvements were absent ($F(1, 88) = 4.7, p = .03$; $F(1, 85) = 4.6, p = .03$). However, these results did not remain statistical significance after applying the false discovery rate (FDR) correction. Additionally, the cognitive subtypes of Wenzel et al. (2021) were validated in differences in distinct cognitive subtypes across attention ($t(81) = 5.19, p \text{ LESS THAN } .001$), executive functioning ($t(65) = 3.83, p \text{ LESS THAN } .001$), processing speed ($t(85) = 4.1, p \text{ LESS THAN } .001$), working memory ($t(88) = 2.72, p \text{ LESS THAN } .001$), and Positive and Negative Symptoms of Schizophrenia Scale (PANSS) scores (PANSS Positive: $t(79) = -2.41, p \text{ LESS THAN } .01$; PANSS Negative: $t(82) = -3.09, p \text{ LESS THAN } .001$; PANSS General: $t(84) = -2.6, p \text{ LESS THAN } .01$). Furthermore, the training group showed increase in the working memory scores for subtypes with impaired cognitive abilities, while those with spared cognition experienced a slight decline ($F(1, 75) = 6.2, p = .015, \eta^2 = .06$). Nevertheless, when accounting for baseline differences in the working memory domain between clusters the effect of the intervention did not maintain statistical significance.

Discussion: We were able to show differences in several primary and secondary outcomes in CT group as compared to TAU. The validation of two distinct cognitive subtypes was taken one step further by showing differences in cognitive training gains in the domain of working memory. However, these differences did not show to be robust after covering for baseline performance levels. These findings provide insights into the relationship between cognitive subtypes and cognitive training outcomes, however, still questioning the potential advantages of stratification based on cognitive data and leaving space to further research.

F31. DIFFERENTIAL EFFECTS OF AGE ON WORKING MEMORY PERFORMANCE IN SCHIZOPHRENIA AND BIPOLAR DISORDER

Catherine Barnes-Scheufler^{*1}, Melek Öyküm Yalçın², Carmen Schiweck¹, Benjamin Peters³, Jutta Mayer⁴, Lara Rösler⁵, Michael Wibral⁶, Robert Bittner¹, Andreas Reif¹

¹University Hospital Frankfurt, ²Institute of Medical Psychology, Goethe University,

³Zuckerman Mind Brain Behavior Institute, Columbia University, ⁴Goethe University Hospital

Background: Working memory (WM) is a core cognitive function which is involved in other crucial constructs of human cognition. Cognitive impairment including WM is a central syndrome in persons with schizophrenia (PSZ) and bipolar disorder (PBD) and is associated with functional outcome. Impairments in visuospatial WM have been observed in PSZ and PBD across illness phases and even before illness onset. A gradient of reduced working memory capacity (WMC) in bipolar disorder and schizophrenia has been observed, with PSZ showing the strongest degree of impairment. WM declines with increasing age in individuals without mental illness, but it is unclear if the same decline is present in PSZ and PBD.

Methods: 189 participants, ranging from 20 to 61 years old participated in this study. Participant groups were matched in age, years of education, and parental years of education. Two cognitive tasks were employed: a visuospatial change detection task to measure attentional control (AC) during WM encoding with four conditions: flickering-bias/predictive cue (F/P), flickering-bias/non-predictive cue (F/NP), non-flickering-bias/predictive cue (NF/P), non-flickering-bias/non-predictive cue (NF/NP) and a canonical color change detection task to assess WMC. All patients were diagnosed according to DSM-5 based on a clinical interview while healthy controls (HCS) were screened using Structural Clinical Interview SCID-I from the Diagnostic and Statistical Manual (Version IV, in German).

A multivariate General Linear Model (GLM) was used with post-hoc analyses to investigate the effect of age on AC and WMC. Two-tailed Spearman correlation analyses were conducted to investigate possible associations between age and information stored in each condition of AC or WM in each group.

Results: The GLM revealed a significant group by age interaction effect on both WMC (p LESS THAN 0.01) and AC (p LESS THAN 0.01). The least amount of information was stored by PSZ in WMC (mean = 2.96 items), and overall AC (0.90 items), followed by PBD (WMC = 3.13 items, AC = 0.97 items), and the most information was stored by HCS (WMC = 3.39 items, AC = 1.23 items). Post-hoc analyses showed significant differences in WMC between PSZ and HCS (p LESS THAN 0.01), as well as PBD and HCS (p = 0.040), and in AC between PSZ and HCS (p LESS THAN 0.001), as well as PBD and HCS (p LESS THAN 0.001). WMC scores correlated significantly negatively with age in HCS (r_s = -.311, p = 0.009), PBD (r_s = -.282, p = 0.033), but not in PSZ (r_s = -.114, p = 0.377). Significant negative correlations between age and three conditions of the AC task in PBD: F/P (r_s = -.301, p = 0.023), F/NP (r_s = -.282, p = 0.034), NF/NP (r_s = -.345, p = 0.009). Significant correlations between age and the same three conditions were observed in HCS: F/P (r_s = -.469, p LESS THAN 0.001), F/NP (r_s = -.315, p = 0.008), NF/NP (r_s = -.426, p LESS THAN 0.001). However, age did not correlate with information stored any conditions of the AC task in PSZ.

Discussion: We observed a differential effect of age on WMC and AC in PBD and PSZ. WMC and AC both declined with increasing age in WMC and most conditions in AC in PBD and HCS, but not in PSZ. These findings indicate that changes in WMC and AC performance across age vary between PSZ and PBD and HCS. This suggests different patterns of cognitive functioning across these groups, with performance in PBD closest to HCS which is compatible with the neurodevelopmental continuum theory. Furthermore, the results match previous studies suggesting earlier cognitive effects on aging in PSZ. Overall, our findings further our understanding of cognitive functioning across age and across mental disorders.

F32. THE DIE IS CAST: DECISION-MAKING UNDER RISK AND UNDER AMBIGUITY IN PATIENTS WITH PSYCHOTIC DISORDERS AND ALCOHOL USE DISORDER

Sarah Stumpp*¹, Alexander Wolber¹, Natascha Büchele¹, Leonie Lipinski¹, Stephanie N.L. Schmidt¹, Michael Odenwald¹, Brigitte Rockstroh¹, Daniela Mier¹

¹*University of Konstanz*

Background: Patients with alcohol use disorder tend to make disadvantageous decisions in tasks involving risk (Game of Dice Task, GDT) and ambiguity (Iowa Gambling Task, IGT). The literature on patients with psychotic disorders however is more heterogeneous, and only a few studies simultaneously investigated both decision-making tasks. This study aimed to explore whether patients with psychotic disorders and alcohol use disorder differ in decision-making under risk and ambiguity conditions.

Methods: In a preregistered study (<https://osf.io/n7z6y>), 40 patients with psychotic disorders, 50 patients with alcohol use disorder, and 36 healthy individuals completed the GDT and IGT. Net scores were calculated for both decision-making tasks (advantageous decisions minus disadvantageous decisions).

Results: The GDT net score was highest in healthy controls, followed by patients with alcohol use disorder and patients with psychotic disorders. The GDT net score significantly differed between groups ($p = .011$, $\eta^2 = .055$), with pairwise comparisons showing significant differences between patient groups and the control group, but not between patient groups. Regarding the IGT net score, the healthy controls achieved the highest score, followed by patients with psychotic disorders and those with alcohol use disorder. The IGT net score also differed significantly between groups ($p = .027$, $\eta^2 = .057$). Pairwise comparisons revealed a significant difference between patients with alcohol use disorder and the control group but not between patients with psychotic disorders and the control group.

Discussion: Both patient groups make disadvantageous decisions under risk conditions, but only patients with alcohol use disorder also make disadvantageous decisions under ambiguity conditions. This suggests more comprehensive impairments in decision-making behavior in alcohol use disorder. Since various studies have shown a link between disadvantageous decisions under risk and in the later blocks of the IGT with executive functions, further investigation should explore whether impairments in executive functions could explain the differences between individuals with psychotic disorders and those with alcohol use disorder.

F33. STIGMA MEDIATES THE RELATIONSHIP BETWEEN SOCIAL COGNITION AND SOCIAL FUNCTIONING IN A CLINICAL HIGH-RISK FOR PSYCHOSIS COHORT

Francesca Crump*¹, Tom Dinzeo², Kristen Woodberry³, Bruce Link⁴, Cheryl Corcoran⁵, Caitlin Bryant⁶, Donna Downing³, Ragy Girgis⁷, Gary Brucato⁷, Debbie Huang⁷, Grivel Margaux⁸, Drew Blasco⁸, Larry Seidman⁹, William McFarlane¹⁰, Lawrence Yang⁸

¹*Cambridge Health Alliance*, ²*Rowan University*, ³*Maine Medical Center*, ⁴*University of California at Riverside*, ⁵*Icahn School of Medicine At Mount Sinai*, ⁶*Beth Israel Deaconess/Harvard Medical Center*, ⁷*Columbia University*, ⁸*New York University*, ⁹*BIDMC*, ¹⁰*Center for Psychiatric Research, Maine Medical Center Research Institute*

Background: The clinical high-risk state for psychosis (CHR-p) was established as part of a movement to reduce duration of untreated illness and improve outcomes in schizophrenia-spectrum disorders. Although entering into early intervention programs has proven beneficial in curtailing threshold psychosis, many CHR-p individuals may face increased rates of stigmatization and discrimination due to accessing early treatment programs without ever developing a full psychotic disorder. Although research suggests that being labeled as CHR-p may elicit positive experiences, such as relief, individuals may employ negative coping strategies in response to early identification, such as secrecy and withdrawal, to conceal their mental health condition. Due to this increased awareness and motivation for concealment, CHR-p individuals may exhibit elevated social preoccupation that may hinder social cognitive performance and negatively impact social functioning.

Methods: This study examined stigma, social functioning, and social cognition in 173 CHR-p individuals recruited as part of a multi-site study conducted at Columbia, Harvard, and Maine Medical Centers. Pearson correlations and mediation analyses were performed to delineate potential causal mechanisms.

Results: Pearson correlations revealed several significant findings. Increased secrecy ($p=0.029$) and experiences of discrimination related to CHR-p status ($p=0.028$) was associated with impaired Theory of Mind (ToM) while increased stereotype agreement ($p=0.009$) was associated with more accurate social relationship perception. Additionally, increased positive emotions related to CHR-p symptoms was associated with impaired ToM ($p=0.023$) and social relationship perception ($p=0.021$). Mediation analyses demonstrated a positive direct effect between ToM and social functioning. Stigma mediated this relationship and was negatively associated with ToM and social functioning. Specifically, secrecy related to the CHR-p label and experiences of discrimination related to CHR-p symptoms fully mediated the direct effect ($p=0.032$) between ToM and social functioning.

Discussion: This study is the first to hypothesize a causal mechanism by which social cognition, stigma, and social functioning are related. A potential explanation for the relationship between stigma, ToM, and social functioning can be viewed through the interpersonal rejection sensitivity model whereby past experiences of rejection and exclusion impact future social perceptions. CHR-p individuals often face stigma and bullying due to their experiences, which may heighten their threshold of rejection sensitivity and lead to altered threat perception in social interactions. Therefore, CHR-p individuals who exhibit heightened rejection sensitivity due to higher instances of stigma may tend to be more secretive and have increased experiences of discrimination, which could negatively impact ToM and social functioning. These findings can help inform early intervention strategies aimed to reduce stigma, which could ultimately lead to improvements in ToM and social functioning if individuals are provided care that increases accurate threat perception.

F34. FACIAL EXPRESSIONS DURING SOCIAL INTERACTIONS IN INDIVIDUALS WITH SCHIZOPHRENIA

Vladimír Ivančík^{*1}, Natália Čavojská¹, Alexandra Straková¹, Vanda Valkučáková¹, Hana Kutlíková¹, Jakub Szabó¹, Ján Pečeňák¹, Anton Heretik¹, Michal Hajdúk¹

¹*Comenius University in Bratislava*

Background: Flat facial affect is a common negative symptom in individuals with schizophrenia. It is often rated based on the clinical judgments from structured interviews. Modern software provides opportunities to measure more objective, automated, and precise assessment of facial expressions. The goal of the study is to understand the role of facial affect

expression during social interactions. More specifically, to explore potential links to objective social skills and symptoms of schizophrenia.

Methods: The sample consisted of 40 patients with schizophrenia spectrum disorders (55 % female, mean age $M = 41.63$, $SD = 9.15$) and 32 healthy controls (66 % female, mean age $M = 32.42$, $SD = 10.16$). Social skills were measured by Conversation Probe, a performance-based measure. Participants were instructed to have a 3-minute unstructured conversation (meeting a classmate at a language course) with a research assistant. Interactions were videotaped and later rated by an independent rater on several domains (e.g. fluency, clarity, affect, overall social skills). In addition, dynamic and objective expressions of facial affect (e.g., happiness, anger, sadness) along with valence and arousal during interaction were examined by FaceReader, a software for analysis of facial affect recognition. Symptoms were measured by Brief Psychiatric Rating Scale and Community Assessment of Psychiatric Functioning. Mann-Whitney U-tests were used to compare patients and controls in social skills domains, as well as intensity of facial expressions. Pearson correlation coefficients were used to determine relationship strength between social skills domains, symptoms, and facial expressions during the interaction. Stepwise linear regression was used to test if valence and arousal of facial expressions predict overall social skills for each group.

Results: Overall, patients had lower global social skills than controls ($U = 1018.50$, $p < 0.001$). In terms of observer-rated affect, controls expressed significantly more emotions during interaction ($U = 983.00$, $p < 0.001$) and their affect was more appropriate ($U = 914.00$, $p < 0.001$). Using FaceReader, patients showed more neutral facial expressions than controls ($U = 346.00$, $p = 0.017$). Overall valence of facial expressions was lower in patients ($U = 841.00$, $p < 0.001$). This difference was driven mainly by less frequently expressed happiness ($U = 866.00$, $p < 0.001$) and surprise ($U = 769.00$, $p = 0.001$). In addition, patients' facial expressions contained less arousal ($U = 711.00$, $p = 0.016$). In the schizophrenia group, patients with dominant positive symptoms expressed more disgust during interaction ($r = 0.346$, $p < 0.05$). Severity of depression-anxiety related to increased expression of fear ($r = 0.499$, $p < 0.01$) and anger ($r = 0.374$, $p < 0.05$). For self-report symptoms, patients with more severe positive symptoms increasingly expressed fear ($r = 0.453$, $p < 0.01$). Specifically in schizophrenia group, arousal measured by facial expressions predicted overall social skills ($\beta = 0.361$, $p = 0.039$).

Discussion: We found evidence of aberrant facial expressions of emotions in individuals with schizophrenia, manifested by decreased expressions of positive emotions. Overall, as expected, patients showed more blunted affect, as evidenced both by ratings made by researcher observations, as well as by facial expression reading software. Emotions with negative valence, such as fear and disgust, were specifically linked to positive symptoms suggesting that different symptom domains might modulate the valence of facial expressions that might consequently impact quality of social interaction. Overall results warrant exploration of potential links between positive symptoms and facial expressions.

Funded by: APVV: 20-0185; UK/114/2023

F35. AEROBIC EXERCISE IMPROVES DORSAL HIPPOCAMPAL CA1 SYNAPTIC PLASTICITY AND NOVEL OBJECT MEMORY IN THE SUB-CHRONIC PHENCYCLIDINE RAT MODEL FOR SCHIZOPHRENIA

Ningyuan Sun^{*1}, Michael Harte¹, John Gigg¹

Background: Evidence suggests that aerobic exercise improves neurocognition and hippocampal function in patients with schizophrenia. Here, we introduced chronic exercise to the sub-chronic phencyclidine (scPCP) rat model for schizophrenia to investigate its effect on the cognitive impairment associated with schizophrenia.

Methods: 50 Female Lister Hooded rats were dosed with either saline or PCP (2 mg/kg, i.p.) twice daily for seven days. Running wheels were provided for aerobic exercise, 1 hour daily for 30 days. Novel object recognition memory was measured after 6 weeks of exercise. Synaptic plasticity in the dorsal hippocampus was then assessed via acute in vivo electrophysiology under urethane anaesthesia (30% w.v.; 1.4g/kg i.p.). The hippocampal CA1 Schaffer- evoked field excitatory postsynaptic potential (fEPSP) was analysed to measure short and long-term synaptic plasticity. Data were analysed with Student t-test and mixed-effect three-way ANOVA.

Results: Behavioural testing after exercise showed improved novel object recognition memory in the exercised scPCP group. Moreover, Exercise increased long-term potentiation after high-frequency stimulation, prevented depression after low-frequency stimulation in the scPCP group, and improved baseline short-term plasticity in both groups. In conclusion, chronic exercise appears to affect cognitive and hippocampal synaptic deficits in the scPCP rat model.

Discussion: Object recognition memory

- The sedentary scPCP group showed the expected deficit in the NOR task.
- The exercised scPCP group NOR performance increased and was not significantly different to the exercised vehicle group.

-This partial recovery of NOR performance after wheel running may be due to some exercised scPCP animals showing apparent neophobia while exploring, so they showed preference to the familiar object; this is still an improvement of object memory. Repeated NOR tasks with different objects might negate this confound.

CA1 hippocampus synaptic plasticity

- Exercise augmented short-term synaptic plasticity in both vehicle and scPCP groups
- This suggests a general effect of exercise on presynaptic release processes. Further analyses will investigate presynaptic differences between the vehicle and scPCP group (e.g. SV2A).
- Exercise increased post-HFS long-term synaptic responses only for the scPCP group.
- This effect was stronger for amplitude rather than slope, which implies that it might reflect altered feed-forward network inhibitory rather than monosynaptic excitatory response components.
- LFS produced a smaller reduction in fEPSP amplitude in the exercised scPCP group.
- The larger depotentiation effect of LFS in sedentary scPCP rats in reducing responses to near baseline (pre-HFS) values was rescued by exercise. As depotentiation is considered a synaptic model for forgetting, this result suggests that exercise may improve memory retention in scPCP animals by stabilizing synaptic weights in CA1.

F36. PEOPLE WHO PRESENT WITH DIMINISHED VOCAL EXPRESSIVITY ARE PERCEIVED AS LESS INTERESTING: CONVERGENT EVIDENCE FROM TWO STUDIES IN PEOPLE WITH SCHIZOPHRENIA SPECTRUM DISORDERS AND COMMUNITY CONTROLS

Amélie Achim*¹, Marion Fossard², Audrey Cayouette¹, Caroline Cellard³, Marc-André Roy⁴, Marie-France Demers⁵, Dominique Knutsen⁶

¹Université Laval, ²Université de Neuchâtel, ³École de Psychologie, Université Laval, ⁴Université Laval Faculty of Medicine, ⁵Pharmacy Faculty, Laval University, ⁶Université de Lille

Background: Most of the scientific literature on schizophrenia spectrum disorders (SSD) has thus far focused on the patients themselves; their symptoms, their cognitive deficits, their everyday functioning, etc. But one question that has received much less attention is that of the impact of these symptoms and deficits from the perspective of the people with whom people with SSD interact in the context of social interactions. Our objective was to examine the link between the level of expressivity perceived in the voice of people with SSD and how much interest they generated when they told stories in the context of a joint task.

Methods: In two independent studies, people with SSD and healthy participants performed a joint task with an interaction partner (a research assistant). During the task, the participant held a set of 6 images forming a story, and their task was to tell the story to the interaction partner. The interaction partner held the same images in a random order and had to place them in the correct order as the participant told the story. They could not see each other as they were separated by an opaque panel, but interaction partner could provide feedback (e.g. “ok” or “hum-hum”) or ask for clarifications if needed. The images differed between the two studies, such that in study 1 participants were telling movie scenes whereas in study 2 they were telling cartoon stories. The verbal interactions were tape recorded, and 4 independent judges subsequently listened to all the stories, blind to the participant’s group, and had to provide their subjective appreciation (scale of 1-10) regarding how easy it was to place the images in order (Facility ratings), how interesting the story was (Interest ratings) and how expressive the voice was (Expressivity ratings).

Results: 25 participants with a SSD and 22 community controls (CO) participated in study 1 while 51 participants with SSD and 68 CO participated in study 2. In both studies, very strong correlations were observed between how expressive the participants were perceived (Expressivity ratings) and how interesting their stories were rated (Interest ratings). In study 1, the correlation was of $r = .79$ ($p < .001$) in the SSD group and of $r = .79$ ($p < .001$) in the CO group. In study 2, the correlation was of $r = .89$ ($p < .001$) in the SSD group and of $r = .77$ ($p < .001$) in the CO group. Participants with SSD were rated as significantly less expressive (study 1: $F(1,45) = 12.2$, $p = .001$; study 2: $F(1,115) = 53.4$, $p < .001$) and less interesting (study 1: $F(1,45) = 5.1$, $p = .029$; study 2: $F(1,115) = 46.57$, $p < .001$) than the CO in both studies.

Discussion: These results suggest that the reduced expressivity observed in people with SSD could have an important impact on their social interactions. If the people with whom they interact in their everyday life find them less interesting, these people could be less motivated to interact with them again in the future, hindering social interactions both from the patient’s side (e.g. social avoidance) and from the side of the people with whom they could interact (decreased interest). While the correlational nature of this study prevents from drawing firm conclusions about the causal effect of voice’s expressivity on the interest generated by people with SSD, the strength of the associations and the fact that the results were replicated in two studies should already lead us to be even more proactive when it comes to trying to minimize the reduced expressivity symptoms of people with SSD, for instance through fine adjustment of medication dosages to avoid such side effects.

F37. THE MORE YOU EXPECT, THE MORE YOU'LL HEAR - COGNITIVE EXPECTANCIES AND AUDITORY HALLUCINATIONS IN PATIENTS WITH SCHIZOPHRENIA

Joachim Kowalski*¹, Małgorzata Dąbkowska², Adrianna Aleksandrowicz¹, Michał Jarkiewicz³, Frank Laroi⁴, Łukasz Gawęda⁵

¹*Institute of Psychology, Polish Academy of Sciences*, ²*Institute of Psychology, Polish Academy of Sciences and SWPS University of Social Sciences and Humanities, Warsaw, Poland*, ³*Institute of Psychiatry and Neurology, Warsaw, Poland*, ⁴*University of Oslo*, ⁵*Polish Academy of Sciences, Institute of Psychology*

Background: Various neurocognitive models explore the causes and mechanisms of perceptual distortions and hallucinations in both patients diagnosed with schizophrenia and the general population. One of the variants of the predictive coding account suggests that strong priors, like cognitive expectancy, may influence perception. The current study aimed to examine if stronger cognitive expectancies result in more auditory false percepts in groups of patients diagnosed with schizophrenia – with and without current auditory hallucinations – and healthy controls. We investigated group differences and explored the associations between false percepts, clinical hallucinations and hallucinatory-like experiences.

Methods: Study design: Patients diagnosed with schizophrenia or schizoaffective disorder with current auditory hallucinations (n=51) and without hallucinations (n=66) and healthy controls (n=51) underwent the False Perception Task under various expectancy conditions. All groups were examined for the presence and severity of hallucinations (PANSS, The Psychotic Symptom Rating Scale, Revised Hallucination Scale) and hallucinatory-like experiences (Multi-Modality Unusual Sensory Experiences Questionnaire). We examined the relationships between the susceptibility to false percepts in experimental task and measures of hallucinations and hallucinatory-like experiences.

Results: Study results We observed a main effect of condition across all groups, i.e., the stronger the cognitive expectancy, the greater the number of auditory false percepts. However, there were no group differences in the number of auditory false percepts. The number of auditory false percepts was positively correlated with measures of hallucinations and hallucinatory-like experiences in the currently hallucinating group and with self-report perceptual distortions in the healthy controls. However, no correlations were observed within the non-hallucinating group.

Discussion: Conclusions: The current study demonstrates that strong priors in the form of cognitive expectancies affect perception and play a role in perceptual disturbances. There is also a tentative effect suggesting that overreliance on strong priors is associated with clinical hallucinations. Future studies could explore whether the impact of cognitive expectancies is associated with other postulated mechanisms of hallucinations.

F38. THE PARANOIA PARADOX: THE ROLE OF TRUST, CONFIDENCE, AND PARANOIA IN E-HEALTH USAGE

Emma Palmer-Cooper*¹, Frances Greenway¹, Elena Nichele², Tayyaba Azim¹, Emma Gentry³, Mohamad Armouch³, Mohammad Naishe⁴, Mark Weal¹, Ann-Marie Hughes¹, Liz Dowthwaite³

Background: e-Health is the delivery of healthcare using digital information and communication technologies. Effective deployment of e-Health can support and improve attendance and engagement with psychosis and other mental health services. As such, developing appropriate e-Health interventions is a key research and clinical priority for mental health service provision. An essential consideration when developing e-Health systems for people with serious mental health problems is the potential role of internet- and technology-related delusions, which are increasingly common. Research has also recently highlighted specific constructs of cyber-paranoia and cyber-fear that are distinct from general trait paranoia in the general population. Delusional beliefs about digital systems must be considered alongside trust and confidence in e-Health systems when developing such interventions for mental health purposes. Our research aimed to better understand attitudes towards e-Health services among people with experience of psychosis and depression, as well as the general population, to inform responsible and ethical intervention development. We hypothesised that 1) people with experience of psychosis or depression (serious mental illness; SMI) would have higher levels of trait paranoia, cyber-paranoia, and cyber-fear, and less trust in digital and e-Health systems, 2) positive current and future attitudes towards digital systems and e-Health would be associated with more trust and confidence in digital systems, and less trait and cyber-paranoia. We also sought to explore attitudes towards e-Health using free-text written responses and interviews.

Methods: We recruited 476 participants (Controls=267; SMI= 209; mean age= 39.35, SD = 14.16; 62.18% female). In our 2-part mixed methods study, we first investigated attitudes, alongside current and future use of digital and e-Health systems, including the Digital Confidence Scale, Trust Index, Paranoia Scale, Prodromal Questionnaire-16, and the Cyber-Paranoia and Fear Scale. Participants were also able to provide written responses about their views on using e-Health. We then interviewed 30 individuals across participant groups to better understand their attitudes, beliefs, and motivations towards using e-Health systems. Quantitative data was analysed using group comparisons and correlations between variables of interest. Qualitative results were investigated using linguistic analysis for written responses, and thematic analysis of interview transcripts.

Results: We found no group differences in digital confidence, although the SMI group had slightly lower frequency of online activity and digital technology use. As expected, the SMI group scored significantly higher on trait paranoia and symptoms of mental ill-health. However, whilst there was a small significant difference in cyber-paranoia, there was no difference in cyber-fear. Those willing to use e-Health systems across groups to support mental health were significantly more confident using digital applications generally, and used e-Health services more often. They had slightly more trust in these services, and slightly less cyber-paranoia and fear. Digital confidence was positively associated with frequency of digital technology use, and a small negative association with cyber-paranoia across groups. Analysis of written responses about willingness to use e-Health systems highlighted that comfort in using these systems was attributed to accessibility, ease of use, reduced waiting times and anonymity. Discomfort was related to trust, fear of judgement, security and privacy concerns, usability, and cost.

Interviews highlighted the complicated relationship between trust and attitudes towards digital technology, and actual use. We identified a ‘paranoia paradox’, whereby people continued to use online and e-Health systems, and accept data usage agreements (e.g. cookies) for

convenience and ease of use, regardless of their overall attitudes of (mis)trust towards them and/or their developers. This was present in both clinical and control populations.

Discussion: Results demonstrate that use and attitudes towards e-Health systems do not differ greatly between people with serious mental health problems like psychosis and depression and the general public. Findings highlight the relatively small role that reported attitudes and paranoia play towards actual use of e-Health systems, and openness to use in the future. There are clear ethical implications for developers and prescribers of e-Health interventions, as individuals may use them despite lacking trust. To improve this situation, it is important that new technology and online systems are developed ethically, and responsibly, to be more trustworthy. This involves us all collectively imagining and considering the impact and consequences of new systems, and addressing them. Further, prescribers should themselves understand data usage and privacy, and be confident in and trust in systems they are recommending to patients.

F39. SOCIAL RELATIONS AND QUALITY OF LIFE 20-YEARS AFTER A FIRST EPISODE PSYCHOSIS

Marie Starzer*¹, Helene Gjervig Hansen², Carsten Hjorthøj³, Nikolai Albert⁴, Louise Birkedal Glenthøj⁵, Merete Nordentoft⁶

¹Gentofte University Hospital, University of Copenhagen, ²Copenhagen Research Centre for Mental Health, University of Copenhagen, ³Mental Health Center Copenhagen, University of Copenhagen, Denmark, ⁴Copenhagen Research Center for Mental Health – CORE, ⁵Mental Health Centre Copenhagen University of Copenhagen, ⁶Mental Health Services - Capital Region of Denmark, Mental Health Centre Copenhagen, The Lundbeck Foundation Initiative for Integrative Psychiatric Research, University of Copenhagen

Background: Life satisfaction transcends both symptoms and functioning, and for disorders with limited curative potential this outcome is highly important. Self-rated quality of life is lower in patients with schizophrenia compared to the background population, and poor quality of life has been associated with the severity of psychotic and negative symptoms and global functioning. Despite quality of life being a very important outcome for patients with psychosis, very few studies have examined it in long-term follow-up studies. Another important outcome are social relations. This is a less well-defined subdomain of social functioning which refers to the ability to adapt in social situations, engage in relationships and interact in a meaningful way with other people. Social relations is strongly associated with relapse, global functioning, mortality and quality of life and early intervention programs have specific treatment modalities such as family interventions or social skills training designed to improve this outcome. Despite this there is no consistently used measure to assess social relations, and often a dichotomous milestone outcome such as marital status is the only reported outcome. In general there are only a few long-term follow-up studies of first episode psychosis patients with follow-up of 20-years or longer, the Danish OPUS study is one of them. So far no other of these studies have reported long-term quality of life or social relation outcomes. The aim of the study was to determine self-reported quality of life and social relations 20-years after first episode psychosis and furthermore, to investigate if these outcomes were associated with each other. We also sought to examine differences in outcome depending on underlying psychosis diagnosis and identify possible predictors of poor outcome.

Methods: This study is a 20-year follow-up of the OPUS trial, a clinical trial that included 578 patients first diagnosed with a schizophrenia spectrum disorder between 1998 to 2000 578.

Patients were randomized to early specialized intervention treatment or treatment as usual. All participants were invited to participate in follow-up assessments 2, 5, 10 and 20 years after inclusion. In semi-structured interviews using validated rating scales symptom level, cognitive function, global level of functioning along with sociodemographic factors such as employment and family life, suicidal ideation and substance use were assessed. We used questionnaires to assess self-rated social relations and quality of life. We used ANOVA with post hoc Tukey test to determine associations between main outcomes and baseline diagnosis. Paired students t-tests were used to assess differences in social functioning and quality of life scores at the 10- and the 20-year follow-up assessments.

Results: Physical quality of life and environmental quality of life along with social dysfunction worsened over time. Higher physical quality of life was significantly associated with better subjective sense of social support, better cognitive functioning, lower social dysfunction, and fewer negative and psychotic symptoms. Higher psychological, social, and environmental quality of life were also associated with fewer negative psychotic symptoms, with better global functioning, with less social dysfunction and more social support.

Discussion: Examining the associations between quality of life and social relations with other poor outcomes highlights the importance of assessing these outcomes individually and with accurate measures. They are important treatment outcomes that merit targeted interventions.

F40. DELIVERING COGNITIVE REMEDIATION REMOTELY: FEASIBILITY, ACCEPTABILITY, AND COST EVALUATION

Matteo Cella¹, Lois Parri^{*1}, Kang Wang¹, Roisin Quinn¹, Nike Oyeleye¹, Huajie Jin¹, Til Wykes¹

¹*Institute of Psychiatry, Psychology, and Neuroscience King's College London,*

Background: Individuals with psychosis commonly experience cognitive difficulties impacting memory, attention, and planning abilities, hindering functional recovery in employment, education, and daily living. Cognitive Remediation (CR) is shown to address these issues effectively and is recommended internationally for schizophrenia. Despite proven efficacy, implementing CR in clinical settings poses challenges. The COVID-19 pandemic accelerated remote therapy adoption, and remote CR offers benefits like reduced time and cost, yet there is limited evidence on feasibility and acceptability. In this study, we aim to evaluate the acceptability and feasibility of remote therapist-supported CR in people with psychosis and estimate its cost and potential benefits.

Methods: A case series of participants aged 18-65 with non-affective psychosis who were provided therapist-supported remote CR using CIRCuITS™. Participants were assessed before and after therapy with measures of personal goal attainment (primary outcome), cognition, functioning and symptoms (secondary outcomes). Acceptability was assessed with post-therapy feedback interviews with data collected and analysed by service users. Feasibility was assessed using proportions and confidence intervals on pre-specified parameters. Indication of benefits was assessed with exploratory analyses comparing baseline and post-therapy scores on the pre-specified outcomes. The cost of providing remote CR was assessed from both healthcare and societal perspectives.

Results: Twenty-nine participants started therapy, with two dropping out; on average, participants attended 25.5 sessions. Interviews suggested that remote CR had good acceptability and led to perceived benefits. Significant and large improvements were observed in the primary outcome ($d=2.97$; 95%CI, 2.1 - 3.86). Cost analyses suggested that remote CR

has the same health care cost as face-to-face therapy but a lower societal cost (saving £263 per person).

Discussion: This study revealed remote CR's high engagement (~10% dropout), high acceptability, low societal costs, and significant treatment effects indicating meaningful benefits, notably in personal goal attainment. These results support the use of remote CR in psychosis services as an alternative delivery modality that may improve adherence, attendance, and user convenience. Barriers, such as poor digital literacy or device ownership, should be addressed before starting therapy. Further research, including the direct comparison between remote and in-person CR, will facilitate wider implementation.

F41. ASSOCIATIONS BETWEEN MOMENTARY SYMPTOMS AND DAILY-LIFE SOCIAL FUNCTIONING AFTER REMISSION OF FIRST EPISODE PSYCHOSIS: A HAMLETT ECOLOGICAL MOMENTARY ASSESSMENT STUDY

Matej Djordjevic^{*1}, Hannah Jongsma², Claudia Simons³, Priscilla Oomen⁴, Lieuwe De Haan⁵, Nynke Boonstra⁶, Martijn Kikkert⁷, Sanne Koops¹, Chris Geraets¹, Marieke Begemann¹, Machteld Marcelis⁸, Wim Veling¹

¹University Medical Center Groningen, ²Center for Transcultural Psychiatry 'Veldzicht', ³GGzE, ⁴University of Groningen, University Medical Center Groningen, ⁵Department of Psychiatry, Academic Medical Center, University of Amsterdam, Amsterdam, the Netherlands, ⁶NHL Stenden University of Applied Science/ GGZ Friesland, ⁷Arkin Mental Health Care Amsterdam, ⁸Maastricht University Medical Center

Background: Symptom severity and social functioning are important outcomes after first-episode psychosis (FEP), yet current evidence about associations between them is inconsistent and lacks momentary insights.

Methods: The current Ecological Momentary Assessment (EMA) study was conducted in 58 people in remission of FEP, as part of the HAMLETT (Handling Antipsychotic Medication: Long-term Evaluation of Targeted Treatment) trial. At baseline, participants were prompted to report symptoms and social context 10x/day for eight consecutive days. We employed multilevel mixed-effects regressions to investigate associations between self-reported momentary symptoms and concurrent social activity or company and subjective appraisal thereof. We also conducted retrospective clinical assessments of symptoms (PANSS) and social functioning (WHODAS 2.0) and investigated their cross-sectional associations using multivariable linear regression.

Results: Analyses of 3,101 EMA-questionnaires showed that momentary negative symptoms were associated with less proactive social activity and company (OR=0.96 [95%CI: 0.96; 0.97], OR=0.95 [95%CI: 0.93; 0.96], N.B. ORs per 1-point symptom-score change). Momentary positive and general symptoms were associated with more proactive social activity (OR=1.02 [95%CI: 1.00; 1.03], OR=1.02 [95%CI: 1.01; 1.03]). Each symptom domain was associated with lower activity appraisal overall, though activity-specific associations differed. Positive and general momentary symptoms were associated with lower company appraisal (B=- 0.25 [95%CI: -0.36; -0.14], B=-0.15 [95%CI: -0.23; -0.06]). When assessed retrospectively, only general symptoms were associated with poorer functioning (B=2.52 [95%CI: 1.69; 3.34]).

Discussion: Self-reported momentary symptoms are associated with daily-life functioning after remission of FEP. Retrospective observer-rated and momentary self-report assessment Methods: do not measure the exact same aspects or intensity of psychopathology.

F42. REGIONAL MEDIAL TEMPORAL VS. GLOBAL INTRA- AND INTER-NETWORK FUNCTIONAL CONNECTIVITY ACROSS THE PSYCHOSIS SPECTRUM: A TRANSDIAGNOSTIC COMPARISON

Igor Nenadic^{*1}, Jonas Hoffmann², Christian Gaser³

¹Philipps-Universität Marburg / UKGM, ²Philipps-Universität Marburg, ³Jena University Hospital

Background: Schizophrenia is characterised by changes in structural and functional connectivity. Most transdiagnostic comparisons involving schizophrenia and affective disorders or “affective psychoses” consider DSM categories, for example comparing schizophrenia with unipolar or bipolar disorders. However, this approach might fall short as it does not account for the vast phenotypic heterogeneity within these categories. In this study, we analysed both regional (medial temporal lobe) functional connectivity as well as global (brain-wide) connectivity and intra- vs inter-network connectivity of particular resting-state networks relevant to schizophrenia (esp. default mode network DMN, salience network SN, and frontoparietal network FPN) in a carefully selected cohort of patients with psychosis: we narrowed down the clinical phenotype to contrast patients with stable schizophrenia (GREATER THAN 2 years duration) and currently euthymic bipolar I disorder patients with previous psychotic features. This allowed us to test regional, intermediate and global network level connectivity between two diagnostically (and phenotypically) distinct but closely related phenotypes.

Methods: We used 3T MRI to obtain resting-state fMRI time series for a total of 155 subjects: 41 DSM-IV/5 schizophrenia patients (in remission after psychotic episodes), 19 currently euthymic (HAMD LESS THAN =2, YMRS LESS THAN =2) patients with bipolar I disorder and previous psychotic features (as assessed by SCID-I interview with a board-certified psychiatrist), and 95 psychiatrically healthy control subjects. Groups were matched for age and gender. RS fMRI data were pre-processed and analysed using the CONN toolbox. Analyses were implemented in general linear models in CONN, applying cluster-level FDR correction for multiple-comparisons across the brain / ROIs. First, we used simple seed-based functional connectivity analysis defining the anterior, middle, and posterior hippocampi as regions of interest (ROI), effectively correlating across the rest of the brain. Second, we tested a medial temporal lobe model, using anatomical ROIs from the Glasser atlas (entorhinal cortices, parahippocampal areas, presubiculum) and graph-theory based measures to characterise functional connectome changes between groups at the level. Third, we used independent component analysis (ICA) to extract resting-state network based on a data-driven approach, thus deriving DMN, SN, and FPN regions for subsequent analysis of intra-network and inter-network functional connectivity differences. Fourth, we used a global functional connectome analysis to contrast groups for differences across all 360 Glasser neocortex ROIs.

Results: First, seed-based functional connectivity of hippocampal subregions showed significant F-test effects for left and right anterior hippocampal regions, for which follow-up tests showed a significant effect for the schizophrenia vs. healthy control (HC) group-wise comparison; these group differences in connectivity included connections to the thalamus, precuneus, as well as right supramarginal gyrus / temporoparietal junction. Second, the medial temporal lobe model showed significant network parameter changes for global efficiency as well as cost and degree for the right parahippocampal cortices. Third, ICA analysis of intra- and inter-network level group differences showed no significant effects for intra-network connectivity for DMN, SN or FPN, but a group-difference for SN-to-FPN inter-network

connectivity, with post-hoc testing showing that this was driven by the schizophrenia group. Fourth, global-level analysis of between-ROI functional connectivity showed a complex pattern of mostly prefrontal, superior temporal, and cingulate areas.

Discussion: Addressing group heterogeneity remains a major focus, both problem and opportunity, in identifying brain-level changes associated with schizophrenia. Our approach of contrasting schizophrenia with bipolar I disorder with (previous) psychotic features (both in remission, and in euthymic state) demonstrates that schizophrenia seems to have a more profound impact on disturbed network, both at the regional level of the hippocampus as well as intermediary resting-state networks and global connectome changes. Of particular interest, the anterior hippocampus shows aberrant connectivity only in schizophrenia, but not bipolar disorder with psychosis. This area has recently been suggested as an “epicenter” for the development of (early) schizophrenia. Our findings characterise the functional connectome difference in schizophrenia and demonstrate changes that are unrelated to mere expression of psychotic symptoms (in the past) and distinguish schizophrenia patients from phenotypically similar affective disorder patients within the psychosis spectrum.

F43. THERAPEUTIC IMPORTANCE OF COMPLEMENT PATHWAY PROTEINS IN EARLY INTERVENTION IN PSYCHOSIS: A PROTEOMIC BASED VALIDATION STUDY IN CLINICAL HIGH RISK AND FIRST EPISODE PSYCHOSIS PATIENTS

Subash Raj Susai*¹, David Mongan², Melanie Föcking¹, Jonah Byrne³, Rachel Davis¹, Rodrigo Bressan⁴, Patrick McGorry⁵, Cristiano Noto⁶, G. Paul Amminger⁷, David Cotter⁸

¹Royal College of Surgeons in Ireland, ²Queen's University Belfast, ³RCSI University of Medicine and Health Sciences, ⁴Laboratório Interdisciplinar de Neurociências Clínicas(LiNC), Universidade Federal de São Paulo(UNIFESP); Programa de esquizofrenia-UNIFESP, São Paulo, ⁵Orygen, The National Centre of Excellence in Youth Mental Health, The University of Melbourne, ⁶Laboratório Interdisciplinar de Neurociências Clínicas(LiNC), Departamento de Psiquiatria, Universidade Federal de São Paulo, São Paulo, Brasil, ⁷Orygen, National Centre of Excellence in Youth Mental Health, Melbourne, Australia, ⁸Royal College of Surgeons in Ireland, Dept. Psychiatry, Education and Research Center, Beaumont Hospital, Dublin Ireland

Background: Our previous research have noticed the relationship between complement pathway proteins with psychopathology in clinical high-risk population (CHR). Based on these observations, we investigated the blood samples from cohorts of early psychosis and found that baseline complement pathway proteins not only associate with worsening of clinical symptoms in CHR but also useful in identifying responders to anti-psychotic treatment in first episode of psychosis (FEP) [doi: 10.1016/j.bbi.2021.09.018, doi:10.1016/j.bbi.2022.03.013 and DOI: 10.1093/schbul/sbac201]. Since these findings have high clinical value in early intervention of psychosis, in the current study we validated our previous observations in a different clinical cohort of CHR and drug naïve FEP patients.

Hypothesis: The current study hypothesizes that high levels of baseline complement pathway proteins in the blood predicts the worsening of functioning in CHR patients and predict the good clinical response to antipsychotics in FEP patients. To test these hypotheses, first we explored the relationship between complement pathway proteins at baseline and functional scores at follow-up in CHR population; Second in FEP patients, we tested whether the baseline

complement proteins associate with change in functioning or change in psychotic symptom severity before and after treatment.

Methods: Our team performed protein quantification of the blood samples from two clinically unique cohorts namely the STEP (n~175) clinical trial of CHR patients from Australia and the Gapi (n~85) clinical trial of FEP patients from Brazil. The complement pathway proteins were quantified using immune-assays and state of the art Mass-Spectrometry (MS) approaches. Linear regression models were used to investigate the relationship between protein levels and clinical symptom scores for the analyses. These models were adjusted for potential covariates.

Results: First, discovery based mass spectrometry study revealed that in UHR population (STEP study) showed a positive association of complement proteins with psychotic symptoms and inverse association with functional status. Second, in the GAPI clinical trial, we noticed a similar cross sectional association for complement proteins with psychopathology at baseline. Above all, these baseline complement proteins C4a and C1r demonstrated a significant relationship with improvement in psychotic symptoms and functioning after 2 months of risperidone. Overall, these findings strongly validated our previous observations in both CHR and FEP patients.

Discussion: We for the first time identified the relationship of complement proteins with functional deterioration in CHR subjects and with functional improvement after anti-psychotics. We have now replicated in three independent cohorts of psychosis patients by showing the relationship of complement proteins especially C4a with psychotic symptoms and functioning. These findings suggest that complement protein levels could be a strong markers for predicting the course of the disease in high-risk state. Furthermore, in FEP patients, these baseline complement protein levels could be clinically useful to identify the responders from non-responders to anti-psychotics. Since anti-psychotics are effective only in 50-60% of the patients, these markers of treatment response would be novel to modify the early intervention strategies to maximize the treatment response in psychosis. Further validation studies are underway which are funded by HRB, ORYGEN and Future Neuro-2.

F44. METABOLIC PARAMETERS AS A PREDICTOR FOR RELAPSE IN PATIENTS WITH SCHIZOPHRENIA TAPERING ANTIPSYCHOTICS

Sofie Mølgaard*¹, Alexander Nøstdal², Mette Ødegaard³, Jimmi Nielsen²

¹Psychiatric Center Glostrup, Unit for Complicated Schizophrenia, Mental Health Services in the Capital Region of Denmark, ²Psychiatric Centre Glostrup, Unit for Complicated Schizophrenia, Mental Health Services in the Capital Region of Denmark, ³Mental Health Centre Glostrup, Mental Health Services of the Capital Region, Unit for Complicated Schizophrenia

Background: Patients suffering from schizophrenia are at risk of relapse when tapering off their antipsychotic medication. Long-term observations report that following each relapse, patients become more difficult to treat. However, early interference during psychotic relapses seems to be of great importance since a brief relapse in well-monitored patients may have less severe consequences for long-term morbidity. To avoid severe psychotic relapses, markers predicting relapses have been requested. Only a few studies have investigated whether biological markers may predict psychotic relapses. Based on recent findings of a distinct molecular signature in serum in patients with schizophrenia compared to healthy controls, it has been suggested that the level of HDL and LDL may be used to predict symptom

improvement and time to relapse. An increase in serum lipids during initial antipsychotic treatment has been associated with symptom improvement, and one study found baseline HDL to predict later relapse despite continuous treatment with long-acting injectables. In the present study, we aim to investigate whether baseline metabolic parameters, such as LDL and HDL, can predict psychotic relapses in the tapering process.

Methods: The data are from an uncontrolled intervention study including patients undergoing gradual, closely monitored, antipsychotic dose reduction. The antipsychotic medication was tapered for 6 months, after which patients were followed up for an additional 6 months. Relapse status was defined according to hospital admission, symptomatic worsening on the Positive and Negative symptoms scale (PANSS), or a decline in Global Assessment of Function (GAF). Baseline values were compared between stable and relapsed patients using independent t-test. Hypothesized predictors, in this case HDL and LDL were analyzed using binary logistic regression, including other parameters with group differences. Thus, we ended up with a model with relapse status as the dependent variable, and LDL, HDL, and Chlorpromazine equivalent doses as independent variables.

Results: Of the 88 patients who entered the program, blood samples and relapse status after one year were available for 78 individuals (43 females). Their mean age was 37 (range 20 – 64) years. baseline PANSS total score was 62 (34-106), and GAF was 46 (31-82). They received on average 403 (32 – 1267) mg Chlorpromazine equivalent.

After 12 months, 29 (37 %) of the patients had experienced a psychotic relapse. This group of patients had a higher level of LDL ($3.15 \text{ nmol/L} \pm 0.94$) than the stable patients ($2.51 \text{ nmol/L} \pm 0.79$, $t_{76}=3.4$, $P=0.001$). Further, stable patients received higher Chlorpromazine equivalent doses (466 ± 322) at baseline than the patients relapsing (296 ± 259 , $t_{76}=2.4$, $P=0.009$). Our predictive model was significant ($P=0.025$) explaining 27% of the variance, with a significant effect of LDL ($P=0.002$) and Chlorpromazine equivalent doses ($P=0.018$)

Discussion: In the present post hoc analyses of data from an observational cohort, we found a higher baseline level of LDL in patients experiencing a relapse during tapering of antipsychotic medication. Previous studies have reported an antipsychotic-induced increase in serum LDL, particularly in patients responding to antipsychotic treatment, but the underlying mechanism behind this association is still poorly understood. It may, however, be the same mechanism that can explain why patients with increased LDL levels were more likely to relapse during tapering of antipsychotics. To increase the understanding of the association between biomarkers, and relapse during antipsychotic tapering we need longitudinal measures which we are now collecting in our new tapering cohort.

F45. METABOLOMIC SIGNATURES DIFFERENTIATING PSYCHOSIS SPECTRUM DISORDERS FROM HEALTHY CONTROLS AND ASSOCIATION WITH WEIGHT GAIN

Kristoffer Panganiban^{*1}, Jiwon Lee¹, Kenya Costa-Dookhan¹, Nicole MacKenzie², Quinn Casuccio-Treen², Araba Chintoh¹, Gary Remington¹, Daniel J. Mueller¹, Sanjeev Sockalingam¹, Philip Gerretsen¹, Marcos Sanches², Alla Karnovsky³, Kathleen Stringer³, Vicki Ellingrod³, Ivy Tso³, Stephan Taylor³, Sri Mahavir Agarwal¹, Margaret K. Hahn¹, Kristen Ward³

¹Centre for Addiction and Mental Health, University of Toronto, ²Centre for Addiction and Mental Health, ³University of Michigan - Ann Arbor

Background: Psychosis spectrum disorders (PSDs) are a series of debilitating mental illnesses associated with intrinsic metabolic dysfunction, with the pathophysiological mechanisms of both the mental and physical symptom domains being largely unknown. Antipsychotics, the main treatment of PSDs, are known to exacerbate the metabolic problems seen in patients with PSDs. One approach to help understand these mechanisms is through metabolomics which is the study of the complete set of metabolites in the body called the metabolome.

Methods: This 12-week prospective naturalistic study used untargeted metabolomic data and included 37 minimally antipsychotic-treated PSD patients and 18 non-psychiatrically ill controls in the baseline analysis. 19 patients completed the study and changes between baseline and endpoint were compared. Finally, patients with PSDs were grouped based on whether they gained a clinically significant amount of weight (GREATER THAN 7%, N = 6) at endpoint when compared to baseline to identify whether metabolomic signatures could predict antipsychotic-induced weight gain.

Results: The baseline comparison between patients with PSDs and controls showed two reduced metabolites in patients with PSDs: lysophosphatidylcholine (20:0), and carnitine (20:0) (FDR LESS THAN 0.05). Fold change analysis at the 2.0x level showed that oleamide and serotonin were decreased in patients with PSDs. For the baseline-to-endpoint analysis, we found that for the 2.0x fold change levels, oleamide and inosine were lower at endpoint. For patients who gained a clinically significant amount of weight (GREATER THAN 7%), we found 5 metabolites that had an increased 2.0x fold change in patients who gained GREATER THAN 7% weight: 3-hydroxyphenyl valeric acid, monoacylglycerol 16:0, oleamide, 2-piperidinone and bilirubin. We also found that 3 metabolites had a decreased 2.0x fold change in patients who gained GREATER THAN 7% weight: L-urobilin, 2-acetylpyrrolidine, and glycohyodeoxycholic acid.

Discussion: Using metabolomics to understand the pathophysiological mechanisms that underly the mental and physical symptoms of PSDs is a promising technique. Identifying early changes in metabolomic signatures may be able to help predict which patients with PSDs are prone to antipsychotic-induced weight gain and possibly clinical/functional outcomes. However, more research is needed to help identify these potential signatures.

F46. EVENT-RELATED SPECTRAL PERTURBATION AND SPECTRAL ANALYSIS OF TREATMENT RESISTANT AND ULTRA-TREATMENT RESISTANT SCHIZOPHRENIA

Andor Bodnár^{*1}, Yifan Mo¹, Claire McCaulley¹, Arlene Cuerdo¹, Lilian Zhong¹, Chloe Bethany¹, Malaka Harper¹, Jay Leonard¹, Frederick Nucifora¹, Christopher Ross¹, Russell Margolis¹

¹*Johns Hopkins University School of Medicine*

Background: Approximately 30% of patients with schizophrenia do not respond to standard antipsychotic medicines (treatment-resistant schizophrenia, TRS), and of these, 30% or more do not respond to clozapine (ultra-treatment-resistant schizophrenia, UTRS). We hypothesize that neurobiological differences underlie these subtypes.

Methods: To explore potential neural correlates distinguishing these patient categories, we conducted electroencephalographic (EEG) recordings during rest-state and various cognitive tasks involving visual and auditory stimuli. 32 electrodes were mounted in a fitted cap with a standard 10-20 layout. Electrodes on the cap were referenced to the electrode at the vertex (FCz). Average electrode impedance was LESS THAN 20 kΩ. The EEG data were sampled at 1000 Hz. In EEG preprocessing steps, electrodes were average referenced, and spherical

interpolation was limited to 10-15% of electrodes. After epoch rejection, high (0.5 Hz) and low (60Hz) pass filtering was applied to the EEG data.

Results: Eyes-closed resting-state EEG revealed significantly increased gamma band activity at frontal electrodes in UTRS patients compared to TRS patients. Disparity in gamma band activity between eyes-open and eyes-closed states was only significant in TRS patients. In the visual Stroop experiment, UTRS patients exhibited diminished gamma power at frontal-central and occipital electrode sites from stimulus onset to 800ms post-stimulus. Reduction in theta power at occipital electrode sites was also observed from stimulus onset to 100ms. In the auditory oddball experiment, UTRS patients displayed significantly reduced theta and alpha band activity during oddball sounds at frontal and parietal electrodes within the 0-200ms post-stimulus onset time window. Central electrodes recorded diminished alpha power from 50-600ms post-stimulus onset while passively listening to oddball sounds.

Discussion: In summary, our preliminary findings suggest that UTRS patients exhibit decreased neural oscillations across both auditory and visual stimulation, encompassing both high-frequency (gamma-band) and low-frequency (alpha/theta) bands when compared to TRS patients. Conversely, during resting-state EEG recordings, UTRS patients demonstrate heightened gamma band activity. These observations open avenues for further investigation into the neurobiological underpinnings of treatment-resistant schizophrenia subtypes and may inform potential targets for therapeutic interventions.

This work was funded by T32MH015330, the Abramson Fund, and ABCD Charitable Trust.

F47. LONGITUDINAL INFERENCE OF MULTIMODAL HIPPOCAMPAL AND CORTICAL NETWORK CONNECTIVITY IN PSYCHOTIC DISORDERS

Jana Totzek^{*1}, Mallar Chakravarty², Ridha Joobar², Ashok Malla², Jai Shah², Alexandra Young³, Martin Lepage², Katie Lavigne²

¹*McGill University*, ²*McGill University, Douglas Mental Health University Institute*,

³*University College London*

Background: The hippocampus shows the largest volume reduction in psychosis. Further, machine-learning approaches identify two subtypes of volume atrophy in psychosis distinctly related to antipsychotic treatment response, one of which begins in the hippocampus. Beyond volume, a dysconnectivity between the hippocampus and larger-scale brain networks is central to psychosis, and reductions in morphometric hippocampal-cortical connectivity predict negative symptoms as mediated by verbal memory impairments. However, it remains unclear whether multimodal hippocampal dysconnectivity precedes or follows deviations in large-scale cortical networks across subtypes of psychosis.

Methods: We measured morphometric and resting-state functional connectivity in 175 patients with first episode (FEP) and enduring psychosis, and 117 non-clinical controls. To derive morphometric connectivity, 18 hippocampal and adjacent white matter volumes were acquired through MAGeT, while cortical thickness was extracted through CIVET 2.1.1, and parcellated into 62 Desikan-Killiany-Tourville regions. Subject-specific structural covariance matrices were derived through the jackknife bias estimation procedure. To derive functional connectivity, we sampled resting-state functional MRI data from 66 FEP patients, and 51 controls. We used the CONN toolbox to extract correlation matrices between the 18 MAGeT regions and 46 cortical regions of the Harvard-Oxford atlas. In both modalities, the hippocampal regions were grouped into a hippocampal module while the cortical regions were grouped into the 7 Yeo modules, and we estimated the graph-theoretical participation

coefficient as a measure of intermodular connectivity. We used the average participation coefficients of all 8 morphometric and 8 functional modules as input for two separate Subtype and Stage Inference (SuStaIn) analyses. SuStaIn is a machine-learning algorithm which unites disease progression modeling and clustering, allowing us to derive connectivity progression patterns across psychosis subtypes.

Results: Following 10-fold cross-validation, SuStaIn resulted in two models with three subtypes each. In both analyses, Subtype 0 included individuals with normal-range connectivity on all markers. In the morphometric analysis, Subtype 1 progressed from decreased somatomotor network connectivity to decreased dorsal-attention (DAN), frontoparietal (FPN), visual, salience, and hippocampal network connectivity, followed by increased limbic and default mode network (DMN) connectivity, while Subtype 2 progressed from increased DMN and limbic network connectivity to decreased hippocampal, salience, DAN, FPN, visual, and somatomotor network connectivity. Different patterns emerged in the functional SuStaIn analysis. Subtype 1 progressed from decreased FPN, limbic, visual, DMN, and hippocampal network connectivity toward increased DAN, somatomotor, and salience network connectivity, while Subtype 2 progressed from increased somatomotor, salience, and DAN connectivity toward decreased hippocampal, DMN, visual, limbic, and FPN connectivity.

Discussion: We identified a subtype in which hippocampal connectivity was the first to decrease after an increase in cortical connectivity across both modalities. These findings extend prior work on volume atrophy into the field of multimodal connectivity, while underlining the role of bidirectional modeling in psychosis. Future work should address the relationship between the identified subtypes and clinical features of psychosis. In line with previous work, associations with antipsychotic treatment response would be of particular interest in order to evaluate the clinical utility of our connectivity subtypes.

F48. ANTIPSYCHOTIC-INDUCED PROLACTIN ELEVATIONS AND GONADAL HORMONES IN MEN WITH SCHIZOPHRENIA: DIVERGENT EFFECTS OF TESTOSTERONE AND ESTROGEN ON COGNITION AND SYMPTOM SEVERITY

Iris Hamers^{*1}, Bodyl Brand², Marieke Begemann², Cynthia Shannon Weickert³, Thomas W Weickert³, Iris Sommer²

¹University of Groningen, University Medical Center Groningen (UMCG), ² of Groningen, University Medical Center Groningen (UMCG), ³Neuroscience Research Australia, Schizophrenia Research Laboratory; School of Psychiatry, University of New South Wales, Upstate Medical University

Background: Schizophrenia spectrum disorders (SSD) exhibit important sex differences with males being more affected in terms of earlier onset, initial clinical progression, and treatment response. The gonadal hormones, testosterone and estrogen, have been implicated in these sex differences. Understanding the effects of gonadal hormones is complicated by the influence of antipsychotic medication, as it can increase prolactin levels, which in turn may result in a reduced production of gonadal hormones. Previous studies have mainly reported beneficial effects of testosterone on negative symptoms in men, but the effects on cognitive functioning remain inconsistent. In addition, it remains unclear whether the protective role of estrogen in women with SSD can also be extrapolated to men. Therefore, this study aims to investigate how antipsychotic-induced prolactin elevation influences levels of testosterone and estrogen, and how these levels affect symptom severity and cognitive functioning in men with SSD.

Methods: This cross-sectional study included baseline data from two clinical trials including 128 men with SSD and 44 healthy control men. Based on their medication use, patients were divided into a prolactin-sparing (n=53) and prolactin-raising group (n=75). Symptom severity was assessed with the Positive and Negative Syndrome Scale (PANSS) using the total score and five subscales: positive, negative, cognitive, depression/anxiety, and excitement/hostility. Cognitive functioning was measured using the Wechsler Adult Intelligence Scale-3rd edition (Wechsler, 1997) and the Brief Assessment of Cognition in Schizophrenia (Keefe et al., 2004) and combined into three domains: verbal fluency (VF), working memory (WM) and processing speed (PS). Hormone levels were compared between the prolactin-raising, prolactin-sparing and the control group. Then, the relationships between prolactin, testosterone and estrogen were investigated. Finally, backward linear regression analyses were conducted to examine the relationship between hormones, cognition and symptom severity.

Results: Prolactin levels were highest in the prolactin-raising group, followed by the control group, and lowest in the prolactin-sparing group ($H=45.279$, $p < .001$). We found no differences in testosterone and estrogen levels among the prolactin-raising, prolactin-sparing and the control group. Testosterone and estrogen were positively correlated in both the control group ($r(42)=.409$, $p=.006$) and in men with SSD ($r(126)=.240$, $p=.007$). In the prolactin-raising group, prolactin was negatively correlated with testosterone ($r(73)=-.32$, $p=.005$). In men with SSD, higher testosterone was a significant predictor for better cognitive functioning (WM: $\beta=.20$, $F(2, 119)=5.16$, $p=.007$, VF: $\beta=.30$, $F(3,118)=5.70$, $p=.001$) and lower symptom severity (total: $\beta=-.21$, $F(4, 117)=4.82$, $p=.001$, negative: $\beta=-.24$, $F(5, 116)=4.01$, $p=.002$). Conversely, higher estrogen levels were linked to slower processing speed ($\beta=-.22$, $F(5,116)=5.35$, $p < .001$) and higher symptom severity (total: $\beta=.23$, $F(4,117)=4.82$, $p=.001$, negative: $\beta=.25$, $F(5, 116)=4.01$, $p=.002$) in men with SSD.

Discussion: The results provide support for antipsychotic-induced prolactin elevations and suggest that prolactin-sparing medication may also result in lower prolactin levels compared to healthy controls. High prolactin levels could negatively impact testosterone levels and indirectly worsen cognition and symptom severity in males with SSD. This highlights the importance of maintaining optimal gonadal hormone levels in men with SSD, especially concerning negative and cognitive symptoms.

F49. IS ACCELERATED AGEING LINKED TO COGNITIVE IMPAIRMENTS IN SCHIZOPHRENIA?

Vid Mlakar^{*1}, Ibrahim Akkouch², Torill Ueland³, Viktoria Birkenæs⁴, Daniel S. Quintana⁵, Nils Eiel Steen⁶, Srdjan Djurovic⁷, Ole A. Andreassen², Monica Aas⁸

¹King's College London, Institute of Psychiatry, ²NORMENT Centre for Psychosis Research, Oslo University Hospital and University of ³NORMENT Centre for Psychosis Research, Oslo University Hospital and University of Oslo, University of Oslo, ⁴NORMENT Centre for Psychosis Research, Oslo University Hospital and University of Oslo, Norway., ⁵NORMENT Centre for Psychosis Research, Oslo University Hospital and University of Oslo, University of Oslo, NevSom, Oslo University Hospital, ⁶NORMENT Centre for Psychosis Research, Oslo University Hospital and University of Oslo, Diakonhjemmet Hospital, ⁷NORMENT Centre for Psychosis Research, Oslo University Hospital and University of Oslo, NevSom, Oslo University Hospital, Oslo University Hospital, ⁸SGDP, Institute of Psychiatry, Psychology, and Neuroscience King's College London

Background: Contemporary research suggests that individuals with schizophrenia spectrum disorders experience a biologically faster rate of ageing compared to age adjusted non-affected individuals. However, whether such accelerated ageing contributes to cognitive abnormalities seen in schizophrenia is yet to be established.

Methods: The study sample consisted of 758 participants (schizophrenia spectrum [$n = 357$] and healthy controls [$n = 401$]) collected as part of the Norwegian TOP study. All participants underwent a standardised neuropsychological test battery assessing five cognitive domains (working memory, verbal fluency, processing speed, verbal memory and verbal learning). Leukocyte telomere length was measured via blood and determined by quantitative real-time Polymerase Chain Reaction (qPCR) providing a telomere to single copy ratio (T/S ratio), used to estimate the mean telomere length of each participant. Telomerase activity was assessed by the expression levels of the Telomerase Reverse Transcriptase (TERT) and Telomerase RNA Component (TERC) genes. All analyses were adjusted for age, sex and ethnicity.

Results: Patients had shorter telomere lengths than healthy controls ($F = 6.22$, $p = 0.01$) and reduced expression levels of TERT ($F = 5.03$, $p = 0.03$), but not TERC ($F = 1.04$, $p = 0.31$). The mean age was twenty-nine years of age and sixty percent of the participants were males. Patients with shorter telomere lengths did nominally better on processing speed ($\beta = -0.17$, $p = 0.002$). For the remaining cognitive domains, no association was observed between telomere length or telomerase activity (working memory, verbal fluency, verbal memory and verbal learning, all p GREATER THAN 0.1). Compared to the controls group, patients performed lower on all cognitive domains (p LESS THAN 0.001).

Discussion: Patients had significantly shorter telomere lengths and reduced telomerase activity, compared to the control group. However, our preliminary results do not support telomere length or telomerase activity's involvement in the mechanisms underlying cognitive impairments in a relatively young group of patients with schizophrenia.

F50. SPEECH CONNECTIVITY IN SCHIZOPHRENIA: A STRUCTURAL APPROACH IN AN ITALIAN-SPEAKING COHORT

Francesca Magnani^{*1}, Matteo Tonna¹, Julianna Olah², Carlo Marchesi¹, Kelly Diederer², Thomas Spencer²

¹University of Parma, ²King's College London

Background: Language abnormalities in schizophrenia are putative pathogenic and risk biomarkers, often preceding clinical diagnosis. Clinical scales for language assessment, such as the Thought Language and Communication scale (TLC) and the Clinical Language Disorder Rating Scale (CLANG), have limitations, prompting the search for alternative methods. Mota's Speech Graph Analysis uses graph theory to objectively quantify structural features of speech connectedness, providing an indirect tool for characterizing thought through language, nearly independent of linguistic rules. The SpeechGraphs software converts text into graph and computes Speech Graph Attributes (SGA), which discriminate patients with schizophrenia from controls and predict diagnosis. It also allows to quantify structural disorganization of speech by comparing original verbal reports' graphs with purposely generated randomized graphs. This study applied Speech Graph Analysis for the first time in an Italian-speaking cohort using free-speech recordings, aiming to confirm its validity in detecting schizophrenia-related speech alterations, and to provide concurrent validity for SGA measures through correlations with clinical scales assessing language.

Methods: Thirty patients with schizophrenia (SCZ) and thirty healthy controls (HC) engaged in spontaneous dialogues, recorded and transcribed. SpeechGraphs software generated original

and random graphs for each transcript, producing connectedness measures (SGA). Participants underwent PANSS (Positive and Negative Syndrome Scale), CLANG and TLC Scales. Independent samples t-test and Mann-Whitney U test were used where appropriate to compare groups on all parameters, including similarity of verbal reports to randomized speech (Z-Scores). The Benjamini-Hochberg test controlled for multiple comparisons. Non-parametric correlations were performed between SGA measures and clinical scales scores in SCZ.

Results: SCZ showed lower levels of speech connectedness (p LESS THAN .001 for most SGA measures) and a higher number of loops and recurrent/parallel edges, suggesting increased repetition and redundancy. Differences between groups held after controlling for verbosity and multiple comparisons. SCZ' verbal reports were significantly more random-like than HC' (p LESS THAN .001 for most Z-Scores). There were significant between groups differences in CLANG and TLC scores (p LESS THAN .001). In patients, SGA measures of connectedness controlled for verbosity correlated negatively with CLANG/TLC total and production and disorganization subscales (p LESS THAN .001). SGA measures of recurrence correlated with higher CLANG/TLC total and disorganization subscales scores. Further correlations emerged between SGA and negative PANSS items.

Discussion: The significant differences in SGA between groups after controlling for verbosity, and the observed random-like speech pattern in SCZ, demonstrate the method's ability to detect subtle structural changes in patients experiencing language impoverishment or disorganization. These results confirm existing literature and hint for the applicability of Speech Graph Analysis for diagnostic discrimination and quantitative detection of speech alterations in schizophrenia, even with Italian language and free speech recordings. Correlations between SGA measures and CLANG/TLC scores suggest a link between thought impoverishment and reduced speech connectedness, extending beyond word production to structural thought qualities. SGA measures demonstrated concurrent validity with clinical scales, providing a complementary approach to the study of language in patients. Collaterally, we also confirmed the association between negative symptoms and reduced speech connectivity.

F51. EEG SENSORY GATING DEFICITS AND BLOOD REDOX MARKER DYSREGULATION: A KEY COMBINATION IN STRATIFYING AND PREDICTING MID-TERM OUTCOME IN EARLY PSYCHOSIS

Ines Khadimallah¹, Guillaume Marillier², Jean-François Knebel³, Chrysa Retsa³, Philippe Golay², Martine Cleusix², Luis Alameda², Micah Murray³, Paul Klauser¹, Kim Do⁴, Philippe Conus², Raoul Jenni*¹

¹Center for Psychiatric Neuroscience, Lausanne University Hospital and University of Lausanne, ²Service of General Psychiatry, Lausanne University Hospital and University of Lausanne, ³Radiodiagnostic Service, Lausanne University Hospital and University of Lausanne, ⁴University of Lausanne

Background: Electroencephalographic (EEG) low-level sensory processing alterations in psychosis may be an important state biomarker. Sensory gating is a crucial mechanism filtering out unnecessary or redundant information, certainly avoiding the overloading of high-level functions. Whereas auditory evoked potentials (AEPs) to sensory gating (mainly indexed by the P50 component in paired-click paradigms) have shown prominent abnormalities in chronic psychosis, inconsistent results have been reported in early psychosis. Isolated biomarkers certainly do not account for the complexity of disease progression, suggesting the need to combine them to increase the predictive potential of clinical and functional outcome. Grouping

AEP sensory gating and redox markers may be relevant given the following triangulation: first, AEP sensory gating alterations have been related to cognitive dysfunction (particularly attentional deficits); second, redox dysregulation may interfere with cognitive outcomes, notably through underpinned GABAergic activities; third, GABAergic interneuron activities are assumed to underlie the sensory gating effects. Thus, we explored the P50, N100 and P200 sensory gating AEPs in combination with COX6A2, as a marker of parvalbumin and redox status.

Methods: 43 early psychosis patients (EPP) and 46 age and gender matched healthy controls (HC) were recorded with high-density EEG during a passive sensory gating paradigm (paired-clicks); blood samples were collected from which exosome levels of COX6A2 were determined at baseline. For EPP, psychopathological, functional, and cognitive assessments were realized at baseline and longitudinally (up to 2.5 years). K-means clustering stratified EPP into two sub-groups based on EEG P50, N100 and P200 suppression values and COX6A2 levels.

Results: Considering all patients together, we observed a significant impairment of N100 suppression and COX6A2 compared to HC, but also negative correlations between N100 on one side and P50 and COX6A2 on the other. HC exhibited a strong positive correlation between P50 and COX6A2. EPP clustering based on P50*P200*COX6A2 differs from models including N100, by allowing patients to be stratified into two sub-groups with significant different cognitive profiles at baseline (including attention, processing speed, working memory). Interestingly, EPP clustering based on this model showed persistency of cognitive differences between groups in longitudinal analyses, but revealed also additional emerging significant differences at functional (GAF) and psychopathological levels (excitability, YMRS and CGI).

Discussion: EEG sensory-gating AEP and oxidative stress markers are key biomarkers in the pathophysiology of psychosis. Both theoretical underpinnings and current data suggest they should be considered together. Whereas P50 has been related to pre-attentional filtering of sensory information, the N100/P200 complex has been considered for triggering and allocating attention. In view of the present results, stratifying EPP by combining P50*P200*COX6A2 without N100 may help to point out current cognitive status, but also mid-latency clinical and functional outcome. By extension this raises questions about the underlying mechanisms subserving AEP. Defining specific sets of biomarkers on precise circuitry-based approaches are crucial for better identification and prediction of clinical, functional and cognitive outcome of EPP. This would have implication in optimizing management treatment.

F52. VISUAL BACKWARD MASKING IS A STABLE AND STATE-INDEPENDENT ENDOPHENOTYPE OF SCHIZOPHRENIA: RESULTS FROM A 10-YEAR LONG LONGITUDINAL STUDY

Melissa Faggella^{*1}, Simona Garobbio¹, Maya Roinishvili², Eka Chkonia³, Andreas Brand¹, Michael Herzog¹

¹Laboratory of Psychophysics, Brain Mind Institute, EPFL, ²Laboratory of Vision Physiology, Beritashvili Centre of Experimental Biomedicine and Institute of Cognitive Neurosciences, Free University of Tbilisi, ³Tbilisi State Medical University

Background: Endophenotypes are physiological, anatomical or cognitive traits that lie along the causal pathway between genetic risks and clinical syndromes. They are of great interest to investigate the pathology of psychiatric disorders as their closer proximity to the condition risk

factors allows to narrow down the heterogeneity and complexity of the phenotype. In previous studies, visual backward masking (VBM) has emerged as a promising candidate endophenotype of schizophrenia. Clear-cut VBM deficits and N1 differences were not only found in chronic patients but also in first-episodic patients, in unaffected first-degree relatives, and in schizotypal individuals. Here, we evaluate the stability of the deficit over a period of 10 years.

Methods: To this end, we examined VBM behavioural performance and EEG response from a cohort of 57 schizophrenia patients, 31 first-degree relatives, and 61 healthy controls. We retested those participants after 5 years and a subsample was retested again after 10 years.

Results: We found that group differences in behavioural performance between patients and controls were maintained over 10 years. In the EEG data, the group-averaged global field power (GFP) time series remained highly reliable over time for patients, relatives and controls. Moreover, we found pronounced inter-individual differences but high intra-individual reliability in the ERP waveforms. Finally, our results suggest that VBM behavioural performance and ERP response is independent from disorder covariates such as disorder duration, medication, and symptom severity.

Discussion: To our knowledge, this is the first time that a candidate endophenotype of schizophrenia is successfully shown to be state-independent and stable over such a long time period.

F53. ANTIPSYCHOTIC-INDUCED PROLACTIN ELEVATION IN PREMENOPAUSAL WOMEN WITH SCHIZOPHRENIA: ASSOCIATIONS WITH ESTROGEN, DISEASE SEVERITY, AND COGNITION

Bodyl Brand*¹, Janna de Boer¹, Elske Willemse², Cynthia Shannon Weickert³, Iris Sommer⁴, Thomas Weickert⁵

¹University Medical Center Groningen, ²University of Groningen, University Medical Center Groningen, ³Neuroscience Research Australia: Schizophrenia Research Laboratory, ⁴UMC Groningen, ⁵State University of New York Upstate Medical University

Background: Antipsychotic-induced prolactin elevation may impede protective effects of estrogens in women with schizophrenia-spectrum disorders (SSD). Our study sought to confirm whether the use of prolactin-raising antipsychotics is associated with lower estrogen levels, and to investigate how estrogen and prolactin levels relate to symptom severity and cognition in premenopausal women with SSD. To disentangle antipsychotic-induced hormone alterations from those that may be inherent to SSD itself, a sample of women receiving prolactin-sparing antipsychotics and a sample of women receiving prolactin-raising antipsychotics were compared. In addition, we include a sample of age-matched women without SSD for comparison.

Methods: This cross-sectional study included 79 premenopausal women. We separated women with SSD into those treated with prolactin-sparing antipsychotics (n=21) or prolactin-raising antipsychotics (n=27), and we included age-matched women without SSD (n=31). Circulating 17 β -estradiol was compared between groups. In patients, we assessed the relationship between prolactin and 17 β -estradiol, and the relationships of these hormones to symptom severity and cognition, using correlation analyses and regression models.

Results: In women receiving prolactin-raising antipsychotics, 17 β -estradiol levels were lower as compared to both other groups ($H(2) = 8.34$; $p = 0.015$), and prolactin was inversely correlated with 17 β -estradiol ($r = -0.42$, $p = 0.030$). In the prolactin-raising group, 17 β -estradiol

correlated positively with verbal fluency ($r = 0.52$, $p = 0.009$), and 17β -estradiol and prolactin together explained 29% of the variation in processing speed ($\beta(17\beta\text{-estradiol}) = 0.238$; $\beta(\text{prolactin}) = -0.446$; $F(2,25) = 5.98$, $p = 0.008$). In the prolactin-sparing group, 17β -estradiol correlated negatively with depression/anxiety ($r = -0.57$, $p = 0.014$), and explained 26% of the variation in total symptom severity together with prolactin ($\beta(17\beta\text{-estradiol}) = -0.406$; $\beta(\text{prolactin}) = 0.324$; $F(2,18) = 4.44$, $p = 0.027$).

Discussion: In premenopausal women with SSD, antipsychotic-induced prolactin elevation was related to lower estrogen levels. Further, estrogens negatively correlated with symptom severity and positively with cognition. Our findings indicate that while premenopausal women should benefit from the natural protective actions of estrogens, those beneficial effects may be impeded by prolactin-raising antipsychotics. Our findings emphasize the clinical importance of maintaining healthy prolactin and estrogen levels in women with SSD of premenopausal age.

F54. OLFACTORY FUNCTION AND ADVANCED BRAIN AGE IN CLINICAL HIGH RISK AND FIRST-EPISODE PSYCHOSIS

Lejia Fan^{*1}, xiaoqian Ma², Liangbing Liang³, Liu Yuan², Lijun Ouyang², Yujue Wang², Xiaogang Chen², Lena Palaniyappan⁴

¹Central South University, Changsha, ²The Second Xiangya Hospital, Central South University, ³Western University, ⁴Douglas Mental Health University Institute

Background: Schizophrenia is an illness where both aberrant olfactory function and accelerated brain aging are seen. We require further exploration, particularly in the context of pre-psychotic clinical high risk (CHR) state for psychosis before the onset of the first psychotic episode. This study aims to investigate olfactory identification function and brain age in individuals with first episode schizophrenia (FES) and those at CHR, examining the interplay between these factors.

Methods: A total of 215 participants, comprising 77 drug-naïve individuals with FES, 71 CHR, and 67 healthy controls (HC), underwent assessment of olfactory identification function using the odor stick identification test. T1-weighted anatomical images were obtained, and the XGboost method was employed to estimate individual brain age. Brain age, corrected by chronological age, was quantified as the brain age gap (BAG), representing the difference between predicted brain age and chronological age. A General Linear Model was applied, with olfactory function and BAG as independent variables, considering education levels and gender as covariates for BAG, and education levels and age as covariates for olfactory function. The relationship between olfactory function and BAG was also explored.

Results: Individuals with FES exhibited lower olfactory function ($F(2,210) = 5.66$, $p = 0.014$, partial $\eta^2 = 0.036$; mean(SD) in FES = 6.06(2.20); CHR = 6.88(2.35); HC = 7.69(1.83)) and higher BAG ($F(2,210) = 3.86$, $p = 0.022$, partial $\eta^2 = 0.051$; mean(SD) in FES = 3.17(8.88); CHR = 1.46(7.76); HC = 0.001(7.38)) compared to HC, with CHR showing no significant difference from the other two groups. Lower olfactory function was associated with higher BAG for HC ($r = -0.37$, $p = 0.002$), CHR ($r = 0.26$, $p = 0.031$), and CHR plus HC ($r = -0.31$, $p < 0.001$), but not for FES ($r = 0.04$, $p = 0.711$) or FES plus CHR ($r = -0.13$, $p = 0.116$).

Discussion: Impaired olfactory functions and advanced brain aging are characteristic of schizophrenia, distinguishing it from CHR. The observed association between lower olfactory function and higher BAG remains consistent in individuals with normal olfactory function and brain age. However, this relationship is disrupted once abnormalities emerge.

F55. RETINAL NERVE FIBER LAYER AND ITS RELATIONSHIP WITH COGNITIVE VARIABLES IN YOUNG SPANISH PATIENTS WITH EARLY-COURSE SCHIZOPHRENIA SPECTRUM DISORDERS

Background: Several studies have suggested that the retina structure is affected in schizophrenia spectrum disorders (SSD). However, most of these studies have included patients with mean ages 36-44 years and disease duration GREATER THAN 12 years (González-Díaz et al., 2022). This study aims to validate the hypothesis that Spanish individuals diagnosed with SSD within five years after diagnosis exhibit distinct retinal structures compared to matched healthy controls. These structural differences are expected to correlate with various cognitive-related variables.

Methods: Employing a cross-sectional design, individuals diagnosed with SSD were compared to age- and gender-matched healthy controls (HCs). Participants with pre-existing retinal/ocular pathology, a history of craniocerebral or ocular trauma, previous ocular surgery, diabetes, or high blood pressure were excluded. The Peripapillary Retinal Nerve Fiber Layer (pRNFL) was assessed with Optical Coherence Tomography, and data from each eye (i.e., right eye [OD] and left eye [OS]) were analyzed independently. The relationship between cognitive performance and pRNFL thickness was only analyzed in cases. The neuropsychological battery measured the following cognitive domains: 1. Estimated intelligence quotient (IQ), assessed with the Wechsler Adult Intelligence Scale (WAIS-III) (Wechsler, 1955) vocabulary subtest; 2. Working memory index of the WAIS-III, derived from the performance on the Digit Span, Arithmetic, and Letter-Number Sequencing subtests; 3. Processing speed index of the WAIS-III (Digit Symbol and Symbol Search subtests); 4. Verbal learning and memory, assessed with the California Verbal Learning Test (CVLT) (Delis et al., 1993); 5. Logical memory was evaluated using the Wechsler Memory Scale, 3rd edition (WMS-III) (Wechsler, 1997); 6. Executive function was assessed using the Wisconsin Card Sorting Test (WCST) (Berg, 1948);

7. Sustained attention, tested with the Continuous Performance Test–II (CPT-II), version 5 (Conners, 2005); and 8. Verbal fluency (phonemic and semantic) was assessed with the Controlled Oral Word Association Test (COWAT) (Benton, 1967). All scores were standardized by the patient's age/educational level. Higher scores correspond to better performance in all cognitive domains except for attention.

Results: Two HCs were included for each case to increase the power of the study (n=18 vs 36), with a similar proportion of genders in each group (n male cases: 10 (55.6%) vs. n male HCs: 20 (55.6%); $p=0.61$) and comparable age (Cases Mean age in years (SD): 30.17 (1.36) vs. Cases Mean age in years (SD): 30.11 (0.96); $p=0.96$). Surprisingly, a statistically significant thickening in global pRNFL was observed in SSD patients compared to healthy controls (OD: Mean (SD): 106.89 μm (9.64) vs. 100.11 μm (8.10), $t=2.720$, $p=0.009$; OS: 04.89 μm (9.00) vs. 99.08 μm (8.21), $t=2.373$, $p=0.021$). Negative correlations were found between global pRNFL thickness and Estimated IQ (OD: $r=-0.54$, $p=0.030$; OS: $r=-0.48$, $p=0.057$), Processing Speed (OD: $r=-0.72$, $p=0.002$; OS: $r=-0.63$, $p=0.008$), Working Memory (OD: $r=-0.55$, $p=0.032$; OS: $r=-0.52$, $p=0.048$), Verbal Memory (OD: $r=-0.59$, $p=0.015$; OS: $r=-0.54$, $p=0.031$), Logical Memory (OD: $r=-0.58$, $p=0.039$; OS: $r=-0.69$, $p=0.008$), and Sustained Attention (OD: $r=0.56$, $p=0.026$; OS: $r=0.63$, $p=0.009$). Other cognitive variables showed no correlation with pRNFL thickness.

Discussion: Previous studies in the Spanish population have yielded analogous paradoxical findings, suggesting the absence of thinning in recent psychotic episodes (compared with HCs) and implicating potential localized retinal inflammation. Our results suggest characteristics resembling papilledema, indicating possible retinal inflammation at the first stages of the illness in young patients. In this way, several significant correlations between cognitive variables and retina structure in a homogeneous sample suggest that pRNFL might aid in identifying cognitive dysfunction as it has been proposed in other diseases such as Multiple Sclerosis, Alzheimer's, and Parkinson's. These findings underscore the complexity of retinal alterations in early-stage SSD, highlighting unexpected pRNFL thickening and its relationship with cognitive performance.

F56. HEAD CIRCUMFERENCE TRAJECTORIES ASSOCIATED WITH PSYCHOTIC EXPERIENCES

Sarah Ashley¹, Kate Merritt², Francesca Solmi¹, Yanakan Logeswaran¹, Pedro Luque Laguna³, Avi Reichenberg⁴, Anthony David^{*5}

¹UCL, London, ²Institute of Mental Health, UCL, ³CUBRIC, Cardiff, ⁴Icahn School of Medicine At Mount Sinai, ⁵University College London

Background: Schizophrenia is associated with reduced total brain volume in adulthood, however the timing and trajectory of these volume changes are not well understood. Head circumference offers a simple but highly effective proxy measure of brain size, and when studied longitudinally it may provide important insights into developmental biomarkers of psychosis.

Methods: Using longitudinal data from a UK-based birth cohort (Avon Longitudinal Study of Parents and Children: ALSPAC), we modelled head circumference trajectories for the first time in relation to psychotic experiences across 22 timepoints from birth to age 15 years. We compared trajectories in those with subclinical psychotic experiences (N = 339) elicited at interview at age 18, and to those of controls without such experiences from the same cohort (N = 3,527). We used multilevel linear mixed regressions, iteratively controlling for a series of important confounders and provide results split by sex. To assess whether differences in head

circumference are related to generic growth factors, height was included as a covariate of interest.

Results: Psychotic experiences in females (n=218) were associated with reduced head circumference across childhood and adolescence compared to controls in univariable (mean difference = -0.27, 95% CI: -0.49 to -0.05) and multivariable models (fully adjusted: mean difference = -0.25, 95% CI: -0.46 to -0.04, $p = 0.02$). In contrast, psychotic experiences in males (n=121) were associated with increased head circumference across this period in univariable (mean difference = 0.35, 95% CI: 0.05 to 0.65, $p = 0.02$) and multivariable models (fully adjusted: mean difference = 0.40, 95% CI: 0.12 to 0.69, $p = 0.006$). When height was included in the model, results remained significant for males (increased head circumference), whereas there were no significant group differences in females. This suggests there may be divergent growth-related factors associated with psychotic experiences in males compared to females.

Discussion: Head growth is atypical in individuals who have psychotic experiences, suggesting that brain development may also be atypical early in development. Psychotic experiences occur in 5-10% of the general population and are associated with an increased risk for developing a range of adverse mental health outcomes including clinical psychotic disorder. Results differed by sex, with reduced head circumference in females and increased head circumference in males. Our results provide support for the neurodevelopmental hypothesis of schizophrenia, and highlight the possibility of opposing growth-related risk factors based on sex associated with the development of psychotic experiences.

F57. BIOLOGICAL SUBSTRATE OF COGNITIVE FUNCTIONS IN ADOLESCENT POPULATION WITH EARLY ONSET PSYCHOSIS: N-ACETYL ASPARTATE LEVELS DURING THE FIRST 5 YEARS OF ILLNESS

Belén Taulero^{*1}, Marta de la Torre², Chao Suo³, Joost Janssen², Josefina Castro-Fornieles⁴, Elena de la Serna⁴, Mara Parellada², Dolores Moreno⁵, Montse Graell⁶, Inmaculada Baeza⁴, Manuel Desco³, Andreas Meyer-Linderberg⁷, Murat Yucel³, Celso Arango², Marta Rapado-Castro⁸

Complutense University, ³School of Psychological Sciences, Monash Clinical and Imaging Neuroscience (MCIN) Laboratory, MONASH University, ⁴Neurosciences Institute, Hospital Clinic de Barcelona, IDIBAPS, CIBERSAM, University of Barcelona, ⁵Hospital General Universitario Gregorio Marañón. Complutense University. Hospital Universitario del Sureste, ⁶Hospital Infantil Universitario Niño Jesús, CIBERSAM, ⁷CIMH Medical Faculty Mannheim, Heidelberg University (Germany), ⁸Hospital General Universitario Gregorio Marañón. Complutense University, Melbourne Neuropsychiatry Centre, The University of Melbourne and Melbourne Health,

Background: Subjects with Early Onset Psychosis (EOP) present with alterations in early cognitive development [4]. These cognitive impairments are indicators for severity of the illness which are strongly associated with poor community outcome [1], and one of the most important prognostic variables [2]. While these cognitive deficits tend to remain stable over time in subjects with EOP, their cognitive functions have shown to continue to develop at a lower rate than their control counterparts [3][4][5]. Cognitive functions that have consistently shown to be most disrupted include executive functions, global attention, verbal and visual-spatial working memory, most of them have been related to functions of the dorsolateral

prefrontal cortex (DLPFC) region [5]. However, there is scarce knowledge about the biological substrate of cognitive function in psychoses. Some studies have pointed to biochemical alterations as the underlying causes of cognitive dysfunction. For instance, lower concentrations of N-Acetyl-Aspartate (NAA), a marker for neural integrity, have been found in psychosis [6]. In particular, previous studies have shown reduced levels of NAA/water ratio in the DLPFC in subjects with EOP compared to their control counterparts [7, 8]. The search for associations between biological substrate and neuropsychological functioning is essential for the pathophysiology of the psychotic disorders. Therefore, the main objective of this study is to analyse the relationship between the variation in NAA levels in the DLPFC in adolescents with EOP and cognitive functions over the first five years after the onset of the disease, compared to a paired sample of controls.

Methods: The study sample consisted of 65 subjects with EOP and 67 controls derived from the original sample (N=110 EOP and N=98 controls) of the Child and Adolescent First Episode Psychosis Study (CAFEPS) [9], who completed both neuroimaging and cognitive assessments over time with a mean age of 15.59 ± 1.82 . The study of neuropsychological domains function was performed by neuropsychological assessment at baseline, 2 years and 5 years follow up. The cognitive functions related to DLPFC region were grouped in DLPFC index: global attention (Continuous Performance Test; Wechsler Adult Intelligence Scale; Trail Making Test A; Stroop Test 1 and 2), verbal and visual-spatial working memory (WAIS-III digits backward and letter-number sequencing) and executive functioning (Trail Making Test B; Stroop Test 3; Verbal Fluency and Wisconsin Card Sorting Test). In vivo NAA levels were obtained by single-voxel MR spectroscopy in the left DLPFC region at baseline, 2 years and 5 years follow up. The statistical analysis was performed using a mixed model, in which the variation of NAA levels over the five years follow-up was introduced as covariate to determine its plausible effect on cognitive function. The direction of the associations was analysed using Pearson's correlation.

Results: The index of cognitive functions associated with the DLPFC region: global attention, verbal and visual-spatial working memory and executive functioning, was higher in controls counterparts compared to EOP subjects, throughout the follow-up. In controls, there was a significant rise of cognitive index when NAA was considered as covariate, from baseline to 5-years follow-up (difference: 0.406, $p < 0.01$) and from 2-years to 5-years (difference: 0.327, $p=0.002$). The difference of cognitive index at 5 years follow-up, between EOP subjects and their counterparts, became statistically significant taking into account NAA (difference: 0.458, $p=0.007$ NAA). In terms of global attention, the difference between groups at 5-years follow-up became statistically significant with NAA (difference: 0.722, $p=0.002$). The same applied to the difference in working memory in controls from baseline to 5-years (difference: 0.437, $p=0.010$ NAA). Finally, executive functions variation from baseline to 5 years in EOP subjects was associated with NAA (coefficient: 0.24, $p=0.05$), and did not show it in controls (coefficient: 0.139, $p=0.198$).

Discussion: The decrease of NAA levels in the DLPFC area in EOP subjects is related to a deficit in the development of cognitive functions over the 5-years follow-up. This brain metabolite would be a specific marker of deficit of neurodevelopment or continued cellular disruption that may contribute to the impairment of cognitive functions. It may be explained on the basis of an abnormal maturation process before or in the first steps towards the onset of the disease.

F58. CORTICAL REACTIVITY AND TASK-RELATED ACTIVITY MODULATION IN SCHIZOPHRENIA AND HEALTHY CONTROLS: A TMS-EEG STUDY

Inés Fernández-Linsenbarth*¹, Gema Mijancos-Martínez², Alejandro Bachiller², Rosa M. Beño-Ruiz-de-la-Sierra¹, Antonio Arjona-Valladares¹, Alejandro Roig-Herrero¹, Miguel Ángel Mañanas², Vicente Molina¹

¹Universidad de Valladolid, ²Polytechnic University of Catalonia

Background: Schizophrenia has been associated with a reduced task-related modulation of cortical activity assessed through electroencephalography (EEG) by means of Shannon Entropy, i.e., a global index of EEG signal irregularity [1–3]. However, to the best of our knowledge, no study so far has assessed the underpinnings of this decreased EEG modulation in schizophrenia. This lower modulation has been associated with higher pre-stimulus connectivity strength, revealing a basal hypersynchrony [4, 5], and with an increased density of theta spectral power at baseline [6]. A possible substrate of these findings could be a decreased inhibitory function, a replicated finding in the field [7–9]. In recent years, the combination of transcranial magnetic stimulation (TMS) and EEG has emerged as a powerful tool for assessing inhibitory and excitatory functions of the cerebral cortex. In this study, our aim was to explore the association between EEG modulation during a cognitive task and the inhibitory system function in a sample including healthy controls and schizophrenia patients. We hypothesized that the replicated decreased task-related activity modulation during a cognitive task in schizophrenia would be related to a hypofunction of the inhibitory system.

Methods: 27 healthy controls and 22 patients with schizophrenia (of them 13 first episodes) performed a three-condition auditory oddball task from which the spectral entropy modulation was calculated. Additionally, cortical reactivity -as an indirect index of the inhibitory function- was assessed by the administration of 75 monophasic transcranial magnetic stimulation single pulses over the left dorsolateral prefrontal cortex. Finally, to assess potential auditory-evoked potentials that could confound the genuine TMS cortical reactivity findings, 40 participants (of them 20 healthy controls) received sham TMS pulses.

Results: In line with previous studies, schizophrenia patients showed significantly lower spectral entropy modulation compared to healthy controls during the three-condition auditory oddball task ($t = 2.87$, $p = 0.006$). Moreover, our study revealed that patients displayed higher cortical reactivity following TMS single pulses applied over the left dorsolateral prefrontal cortex than healthy controls ($t = 3.01$, $p = 0.004$). Active stimulation resulted in significantly higher cortical reactivity compared with sham stimulation ($t = 10.21$, $p < 0.001$). Finally, our data revealed that cortical reactivity was significantly related to spectral entropy modulation ($r = 0.336$, $p = 0.018$) when considering both healthy controls and schizophrenia patients.

Discussion: Compared to healthy controls, schizophrenia patients showed a deficit in EEG activity modulation during a cognitive task and higher cortical reactivity following TMS single pulses. Our key finding implies that spectral entropy modulation is associated with the amplitude of the evoked response to TMS single pulses in the left dorsolateral prefrontal cortex when considering the entire sample. This may suggest the idea that this relationship would be better considered dimensional rather than categorical. These findings provide novel insight into the neurophysiological underpinnings of potentially different subgroups of schizophrenia patients.

F59. COGNITIVE PROFILING IN SCHIZOPHRENIA: WHO IS TO BLAME BETWEEN INFLAMMATORY AND KYNURENINE PATHWAY MARKERS?

Giulia Agostoni^{*1}, Jacopo Sapienza², Stefano Comai³, Sofia Nasini³, Stefano Dell'Acqua³, Stefania Sut³, Margherita Bechi², Marco Spangaro², Francesca Martini², Roberto Cavallaro¹, Marta Bosia¹

¹Vita-Salute San Raffaele University, ²IRCCS San Raffaele Hospital, ³University of Padua

Background: Cognitive impairment is a core feature of schizophrenia and its heterogeneity is a typical hallmark, both from the biological and clinical point of view. Several biomarkers of cognitive impairment have been described, including neuroinflammatory indexes and metabolites derived from the kynurenine pathway (KP), which gained attention as they are at the crossroad between inflammation and neurotransmission. However, the specific interplay between cognitive deficits and both neuroinflammatory biomarkers and KP metabolites is far from being elucidated. Our aim is to disentangle the specific neuroinflammatory and KP markers related to different cognitive profiles in schizophrenia.

Methods: 68 patients with schizophrenia were enrolled and evaluated for cognition (MATRICS). Serum levels of inflammatory factors (i.e., IL-6, IL-1 β , IL-1ra, IL-8, IL-9, IL-10, IL-13, IL-17A, IFN α , IP-10, MCP-1, MIP1 α , MIP1 β , PDGF-BB, RANTES e TNF- α e ANP) and KP metabolites (i.e., Trp, KYN, KYNA, 3-HK, QUIN, KYN/Trp ratio, KYNA/KYN ratio, and 3-HK/KYN ratio) were extracted. To characterize different cognitive profiles, we performed a two-step cluster analysis, considering MATRICS subscores as clustering variables. Then, we separately performed Pearson's correlations in each cluster, to evaluate the interplay between cognitive domains and both the plasma levels of inflammatory markers and KP metabolites.

Results: Cluster analysis produced two groups of patients: Cluster 1 (low neurocognitive profile) and Cluster 2 (high neurocognitive profile).

As for Cluster 1, correlations were found between processing speed and ANP levels ($r=0.566$; $p=.003$), KYN ($r=-0.4$; $p=.02$), KYNA ($r=0.40$; $p=.023$), 3-HK ($r=-0.42$; $p=.015$), and KYN/Trp ratio ($r=-0.44$; $p=0.01$). Visual learning resulted associated to 3-HK ($r=-0.40$; $p=.002$) and KYN levels ($r=-0.40$; $p=.002$). Lastly, attention was related to 3-HK/KYN ratio ($r=0.52$; $p=.01$). Concerning Cluster 2, correlations showed associations between working memory and IL-17A ($r=-0.56$; $p=.04$), IL-9 ($r=-0.56$; $p=.04$), TNF- α ($r=-0.64$; $p=.01$), MIP1 α ($r=-0.58$; $p=.035$), PDGF-BB ($r=-0.69$; $p=.009$) and RANTES ($r=-0.62$; $p=.02$). Attention was related to MIP1 α ($r=-0.58$; $p=.04$) and QUIN ($r=-0.56$; $p=.018$), while reasoning resulted related to KYNA ($r=-0.40$; $p=.04$).

Discussion: Results support previous literature showing correlations between both inflammatory and KP markers and cognitive abilities in schizophrenia. Noteworthy, they shed new light on possible differential impact of the two pathways, suggesting specific patterns of association according to the cognitive profile. In patients with a higher cognitive profile (Cluster 2), neuroinflammatory cytokines are mostly and adversely related to cognition, with limited effects of KP metabolites. These results may be due to a greater susceptibility to the oxidative stress and cytotoxicity exerted by neuroinflammation in patients with a more preserved cognition. In contrast, in patients with a lower cognitive profile (Cluster 1), KP metabolites have a greater impact on cognition compared to cytokines. We can argue that in patients already cognitively compromised, KP metabolites might impact cognition due to a wide range of neuromodulatory, neurotoxic and neuroprotective properties, while the action of inflammatory factors seemed less impactful. Although preliminary, our findings highlight the dissociated effects of inflammatory and KP markers on cognition, depending on the patients' cognitive profile. In particular, a predominant effect of inflammation is observed among patients with relatively preserved cognitive abilities, while the KP plays a major role in patients with more severe deficits.

F60. IMMUNOPHENOTYPING SCHIZOPHRENIA SUBTYPES STRATIFIED BY ANTIPSYCHOTIC RESPONSE

Yanhui Li^{*1}, Jocelyn Wen Xin Ong², Yuen Mei See¹, Jie Yin Yee¹, Charmaine Tang¹, Shushan Zheng¹, Boon Tat Ng¹, Bernett Teck Kwong Lee³, Anand Kumar Andiappan², Jimmy Lee¹

¹*Institute of Mental Health, Singapore*, ²*Singapore Immunology Network (SIgN), Agency for Science, Technology and Research (A*STAR), Singapore*, ³*Lee Kong Chian School of Medicine, Nanyang Technological University, Singapore*

Background: Immune dysfunction has been proposed to play a role in the pathophysiology behind the development and persistence of psychosis, apart from well-established dopaminergic mechanisms. Studies have shown immunological changes in schizophrenia ranging from proteins to genomics and immune cell types. However, current immunophenotyping studies are limited by small sample sizes and the number of immune markers investigated. In this study, we perform comprehensive immunophenotyping of 196 subjects comprising 147 schizophrenia patients stratified by antipsychotic response (49 antipsychotic-responsive, 70 clozapine-responsive, 28 clozapine-resistant) and 49 healthy controls. We aim to identify significant immune cell populations associated with schizophrenia and increasing treatment resistance, as potential modulators of underlying psychosis.

Methods: Patients with schizophrenia were recruited from inpatient and outpatient settings at the Institute of Mental Health, Singapore. Patients were categorised based on antipsychotic response, defined as positive symptom remission after at least 8 weeks of respective antipsychotic treatment. 49 healthy controls with no prior medical and psychiatric history were recruited from the community. Demographic data including age, sex, ethnicity, body mass index and smoking status were collected. Data regarding antipsychotic treatment history was collected via patient interviews and medical records. All participants were assessed on the Positive and Negative Symptom Scale (PANSS) while schizophrenia patients were rated on the Clinical Global Impression (CGI) scale by trained clinicians. Peripheral blood mononuclear cells (PBMCs) were collected from participants, stained with antibodies from a panel of 34 immune markers and put through flow cytometry. Manual gating was performed on flow cytometry data and proportions of each cell population relative to CD45⁺ cells (total leukocyte population) were analysed. Median centering was performed to correct for batch effects and cell population proportions across all 4 groups were compared using the Kruskal-wallis test. Post-hoc Dunn tests and Bonferroni correction were subsequently performed for pairwise comparisons between groups.

Results: As expected, PANSS and CGI scales increased with increasing treatment resistance. Mucosal-associated invariant T (MAIT) cells ($p = 3.20 \times 10^{-5}$), plasmablasts ($p = 3.60 \times 10^{-4}$), IgG⁺ B cells ($p = 7.38 \times 10^{-3}$), IgD⁺ CD27⁺ Memory B cells ($p = 0.042$), CD8⁺ T cells ($p = 2.60 \times 10^{-3}$), exhausted CD8⁺ T cells (CD57⁺ CD8⁺) ($p = 9.35 \times 10^{-3}$), (CD69⁺ KLRG1⁺ CD8⁺) ($p = 1.20 \times 10^{-3}$) and CD8⁺ memory T cells (CD45RA⁺ CD27⁺ CD8⁺) ($p = 0.0286$), were among the top cell populations to be downregulated in schizophrenia, with lower proportions seen with increasing treatment resistance. Conversely, CD4⁺ memory T cells (CD69⁺ KLRG1⁺ CD4⁺) ($p = 0.0331$) and naïve CD4⁺ T cells (CD45Ra⁺ CD27⁺ CD4⁺) ($p = 0.0336$) were found to be upregulated in schizophrenia, with higher proportions seen with increasing treatment resistance.

Discussion: Our results corroborate higher CD4⁺/CD8⁺ ratios previously found in psychosis. We have also explored immune cell populations not previously investigated, and present novel findings. Most significant populations were downregulated rather than upregulated in

schizophrenia, suggesting attenuated immune function modulated by those cell populations in psychosis. This study represents a first attempt at comprehensive immunophenotyping of patients with varying antipsychotic response. Future research may build on our findings with further mechanistic studies, and immune markers identified may serve as potential biomarkers of treatment resistance and disease severity.

F61. IDENTIFYING INDIVIDUALS AT RISK OF PSYCHOSIS USING MODELLED DECISION-MAKING PARAMETERS

Franziska Knolle*¹, Elisabeth F. Sterner¹, Rick Adams², Michael Moutoussis², Graham Murray³

¹Technical University of Munich, ²University College London, ³University of Cambridge

Background: In psychosis, alterations in value-based action selection and action-outcome learning can be observed often even before disease onset. Computational models of decision-making allow the investigation of whether and how these impairments contribute mechanistically to psychotic symptoms and, thus, have great potential to improve early identification and intervention. The active inference framework conceptualizes decision-making as a process of Bayesian inference in which the brain predicts the consequences of an action based on both past experiences and the structure of the task to choose the action to produce the most preferred outcomes. Using active inference modelling, we wanted to explore (1) whether AI parameters of a modelled orthogonalized Go/NoGo task differ between at-risk-mental-state (ARMS) individuals, first-episode psychosis (FEP) patients and healthy controls and (2) whether task performance and modelling parameters would be suitable for identifying group associations.

Methods: 23 ARMS individuals, 26 patients with FEP and 31 healthy controls completed a probabilistic decision making task in which action choice (go/no-go) was dissociated from outcome valence (gain or loss). We evaluated group differences in performance and active inference model parameters and performed receiver operating characteristic (ROC) analyses to assess group classification.

Results: We observed reduced performance in patients with specific deficits in punishment learning. In addition, active inference modelling showed that FEP patients displayed increased forgetting and less optimal general choice behavior, with poorer action-state association (1). Using ROC analysis, we were able to demonstrate that combining the specific expression of modelling parameters and the individual performances measures revealed fair-to-good classification performances of all groups which is especially relevant for the distinction of controls and ARMS individuals (2).

Discussion: Taken together, our findings show that active inference modelling of an orthogonalized Go/No-Go task does not only provide further explanation for dysfunctional mechanisms underlying decision-making in psychosis, but may also be highly relevant for future research on the development of diagnostic biomarkers.

F62. DECIPHERING SEX-SPECIFIC NEURODEVELOPMENTAL TRAJECTORIES VIA THE SULCAL PITS

Noemí Hostalet¹, Pilar Salgado-Pineda², Yasser Alemán-Gómez³, Erick J Canales-Rodríguez⁴, Raymond Salvador⁵, Edith Pomarol- Clotet⁵, Mar Fatjó-Vilas*⁵

¹FIDMAG Sisters Hospitaliers Research Foundation and CIBERSAM, ²FIDMAG Research Foundation and CIBERSAM, ³Connectomics Lab, Centre Hospitalier Universitaire Vaudois (CHUV) and University of Lausanne (UNIL), ⁴Signal Processing Lab (LTS5), École Polytechnique Fédérale de Lausanne, ⁵FIDMAG Research Foundation and CIBERSAM

Background: Sulcal pits are the deepest points of the brain cortex. They are located in each sulcal basin along the bottom sulcal lines, regularly arranged in chains of shallower and deeper pits. Their apparition begins prenatally, with the first cortical folds, and they span with the formation of the secondary and the tertiary sulci through gestation and early childhood. The spatial distribution of sulcal pits is stable once they are formed and highly reproducible across individuals. Therefore, sulcal pits are proposed as suitable markers of neurodevelopmental alterations that occur during the first stages of embryo development. Neurodevelopmental disorders, such as autism, attention deficit hyperactivity disorder and bipolar disorder, have been associated with specific patterns of sulcal pits. However, no study has evaluated sex-specific differences related to the patterns of sulcal pits in healthy adult individuals. We aimed to explore differences in the quantitative patterns of sulcal pits between males and females, separately in each hemisphere. This novel approach can shed light on the biological mechanisms underlying neurodevelopmental sex differences in the health-psychopathology spectrum.

Methods: The sample was composed of 93 healthy males and 97 healthy females whose age range was between 18 and 65 years old. No significant differences in age between groups were found. For all participants, structural magnetic resonance images (MRI) were acquired in a 1.5T scanner. First, we proceeded to segment white matter surfaces from the MRI using the FreeSurfer pipeline. From the white matter surfaces, sulcal pits were extracted using the implemented function in BrainVisa “Sulcal pits Extraction”. Subsequently, individual sulcal pits were projected to fsaverage FreeSurfer template to perform group comparisons and obtain a group parcellations map applying a watershed algorithm. The maximum depth of the sulcal pits was calculated using the depth potential function (DPF) and the parcels were clustered in three groups (shallow, middle, deep) using a k-means algorithm based on sulcal pits depth. The frequency of sulcal pits was assessed in males and females considering the total number of sulcal pits separately in each hemisphere (hemispheric level) and the total number of pits on each depth cluster (cluster level). Furthermore, differences in the depth of sulcal pits were also assessed in each parcel (parcel level). Comparisons between groups were performed by applying linear regressions including IQ as a covariate. Regional comparisons were corrected by applying False Discovery Rate (FDR).

Results: At the hemispheric level, males showed a higher frequency of sulcal pits in both hemispheres (right: $p=0.0002$; left: $p=2.47 \times 10^{-8}$). At the cluster level, males showed more sulcal pits than females in the deep clusters of both hemispheres and in the shallow cluster of the left hemisphere ($p < 0.05$). At the parcel level, females had significantly deeper pits than males ($pFDR < 0.05$) in two deep parcels of the left hemisphere comprising the insula and the central sulci. On the other hand, males had deeper pits than females in two shallow parcels of the right hemisphere comprising the marginal and pericallosal sulci.

Discussion: Our findings suggest the potential role of sulcal pits as suitable markers of neurodevelopmental sex differences. Furthermore, differences between hemispheres suggest asymmetrical neurodevelopmental trajectories between sexes. These results underscore the need to adopt a perspective considering sex when analysing neurodevelopmental disorders.

F63. MECHANISM OF AUTOANTIBODIES IN SCHIZOPHRENIA

Ryan McLean^{*1}, Nicole Brace¹, Philomena Halford¹, Jun Wei¹, Antonia Pritchard¹

¹*University of the Highlands and Islands*

Background: The causes and pathomechanisms of schizophrenia are unclear despite many years of dedicated research. A series of observations has indicated autoimmune dysregulation is present in people with schizophrenia, including increased levels of specific circulating antibodies. The targets for the antibodies identified to date include neurotransmitter receptors such as the N-Methyl-D-Aspartate Receptor (NMDAR), intracellular proteins such as TRANK-1 and dietary proteins such as gliadin (from gluten). The role of schizophrenia-associated antibodies in the development of schizophrenia is, however, not yet understood. Studies of Anti-NMDA-Receptor Encephalitis suggest that autoantibody binding may disrupt receptor function and result in psychiatric symptoms, however the contribution of autoantibodies to neuroinflammation, immune cell activation and complement-mediated synaptic pruning, all with relevance to Schizophrenia, have not been examined. The contribution of an autoantibody to these processes are likely to depend on antibody isotype, possibly more importantly than antibody target. This study examined the hypothesis that antibody target and IgG subtype has different effects on a range of Schizophrenia-relevant cellular processes in mixed CNS cultures derived from Mouse neural precursor cells (NPC).

Methods: Mouse NPCs were differentiated into mixed populations of neurons, oligodendrocytes and astrocytes, using standard protocols. Differentiation was confirmed using Flow Cytometry markers against O4, Nestin and GFAP respectively. Commercially available monoclonal antibodies against a range of targets, including schizophrenia-relevant receptors including NMDAR and Voltage-Gated Calcium Ion Channels, were selected on the basis of the availability of different IgG isotypes, against these targets. The antibodies were incubated with mouse mixed mouse neuronal populations, for 24 hours before the impact of different IgG isotypes and different IgG targets on Schizophrenia-relevant cellular processes were examined. As complement-mediated synaptic elimination is a plausible mechanism by which autoantibodies may contribute to the pathology of Schizophrenia, the impact of IgG, by target and isotype, on Complement Protein expression was examined using immunohistochemistry with antibodies against C3 and C4.

Results: The NPC derived mixed population neuronal cells were confirmed as being of three different types, with median percentage populations of 61% neurons, 29% oligodendrocytes and 9% astrocytes. While results are still being collected, to date the impact of IgG target and IgG isotype on cell death has been examined in the first of three independent replicates of the in vitro experiments. Flow cytometry with Annexin-V-APC/PI in conjunction with O4, Nestin and GFAP have been used to characterise the impact of IgG incubation on apoptosis in individual cell types. Immunohistochemistry comparison of C3 and C4 expression elicited by each cell type has similarly been performed on the first of the replicate experiments.

Discussion: This study is testing the hypothesis that antibodies contribute to Schizophrenia-processes in a class specific manner, which has as an important of an impact as the antibody target, -As this study required multiple different classes of antibodies raised to a specific target, this approach required the use of murine derived antibodies and cell line. This does, however, present the opportunity to assess target-independent mechanisms of antibody classes, as well as relevant target antibody effects on vital cells of the central nervous system, using mixed populations of central nervous system cells.

F64. EARLY LIFE ADVERSITY AND HIPPOCAMPAL VOLUME AS RISK FACTORS FOR PSYCHOTIC-LIKE EXPERIENCES IN ADOLESCENTS

Background: Sub-clinical psychotic-like experiences are relatively common in the general population, and in young people they have been established as a risk factor for a wide range of mental health problems. Early life adversities (ELA), capturing negative and stressful experiences in childhood, have been consistently associated with the onset of psychosis later in life. Furthermore, a history of ELA has also been associated with volumetric reductions in the hippocampus, and lower hippocampal volumes have been reported in psychiatric disorders, including early-onset psychosis. Yet, it is unclear whether exposure to ELA and reductions in hippocampal volume interact to increase the risk towards psychotic-like experiences in young people. Here, we investigated ELA and hippocampal volume as risk factors that potentially interact to heighten the vulnerability to psychotic-like experiences in young adolescents.

Methods: We recruited n=228 adolescents (mean age=12.4 years, SD=1; 54% female). We assessed ELA experiences using the Adolescent Life Experiences questionnaire, and psychotic-like experiences with the Adolescent Psychotic Symptom Screener, creating a weighted score of frequency and perceived distress. We acquired structural MRI in a 3T GE scanner (IR-SPGR, 32Ch head coil, res=1.2x1x1mm). T1-weighted images were processed with Freesurfer (v7.3.2) to estimate hippocampal volume. We used linear regression models predicting psychotic-like experiences, modelling main effects of ELA and total hippocampus volume, and an interaction between the two predictors. We adjusted all models for age, sex, and estimated Total Intracranial Volume (eTIV) as potential covariates.

Results: A linear regression model with total score of ELA and total hippocampal volume explained variance in psychotic-like experiences ($F(5,222)=5.44$, $p < .001$; adjusted $R^2=0.09$), above and beyond the covariates (change in adjusted $R^2=0.08$; model comparison $F(2,222)=10.92$, $p < .001$). ELA had a positive association with

psychotic-like experiences ($\beta=0.45$, 95%CI [0.33;0.57], p LESS THAN .001), whereas total hippocampus volume was negatively associated with psychotic-like experiences ($\beta=-0.36$, 95%CI [-0.5;-0.21], $p=.014$). The interaction between ELA and total hippocampus volume did not significantly improve model performance (change in adjusted $R^2=0.01$; model comparison $F(1,221)=2.13$, $p=.146$).

Discussion: Exposure to adverse and stressful experiences in childhood and adolescence and hippocampal volume were independently associated with higher weighted scores of frequency and distress of psychotic-like experiences. This suggests that both, ELA and hippocampal structure represent risk factors for psychotic-like experiences that develop early in life. The hippocampus is a structure highly sensitive to neurodegenerative effects of chronic stress, such as that induced by ELA, and plays a main role in regulating the stress responses through a negative feedback loop with the hypothalamic-pituitary-adrenal (HPA) axis. Hippocampal volume reductions may be related to dysregulated HPA-axis activity, representing a shared mechanism relevant to development and maintenance of psychiatric disorders. Future longitudinal investigations capturing a wider age range could explore whether there is an interaction at specific developmental periods, or if ELA and hippocampal structure could be considered independent risk factors.

F65. ANTENATAL PSYCHOPATHOLOGY AND INFANT OUTCOMES: THE ROLE OF MATERNAL ANTENATAL IMMUNE SYSTEM

Catriona Curl^{*1}, Katie Hazelgrove¹, Alessandra Biaggi¹, Rebecca Bind¹, Susan Conroy¹, Susan Pawlby¹, Lavinia Rebecchini¹, Kristi Sawyer¹, Carmine Pariante¹, Vaheshta Sethna¹, Paola Dazzan¹

¹*King's College London, Institute of Psychiatry*

Background: Prospective cohort studies have shown that maternal mental illness during pregnancy can have long lasting negative consequences on the developing child. Research to understand the potential mechanisms underlying this association, such as developmental programming, has begun to attract attention. More specifically, immune activation, indicated by higher levels of Interleukin-6 (IL-6) has been reported in association with risk for major psychiatric disorders. Here, we investigated the relationship between maternal antenatal psychopathology and infant outcomes, and whether maternal antenatal IL-6 levels might help explain this relationship.

Methods: We included 253 women comprising $n=103$ healthy controls; $n=32$ women with a history of Major Depressive Disorder (MDD); $n=67$ women with MDD in current pregnancy; and $n=51$ women at risk of Postpartum Psychosis (PP). They were recruited in pregnancy and followed up until 12 months postnatally. Blood was obtained from the mothers during the early third trimester of pregnancy to measure a biological marker of immune system function, serum interleukin 6 (IL-6). Neonatal behaviour and infant development were assessed at 6 days and 12 months postpartum respectively across all four groups using the Neonatal Behavioural Assessment Scale (NBAS) and the Bayley Scales of Infant Development (BSID).

Results: Mothers in the “history of MDD” and “MDD in pregnancy” groups had significantly higher levels of serum IL-6 during pregnancy than controls and “at risk of PP” women ($p=$ LESS THAN .05).

At 6 days postpartum, newborns of women in the “MDD in pregnancy” and “at risk of PP” groups scored significantly lower than controls ($p=$ LESS THAN .001) in the autonomic stability cluster which records signs of stress related to the homeostatic adjustments of the

central nervous system. Newborns of women in the “MDD in pregnancy” group also scored significantly lower than those of controls for social interaction ($p=.008$). At 12 months postpartum, infants of mothers in the “at risk of PP” scored lower than controls for cognitive development ($p=.015$), and lower than all groups for motor development ($p=.004$). Infants of mothers “at risk of PP” also scored lower for language development than controls and “MDD in pregnancy” ($p= \text{LESS THAN } .001$). Finally, higher levels of serum IL-6 during pregnancy were negatively correlated with infant cognitive scores at 12 months postnatal across all groups ($r= -.185$, $p= .01$).

Discussion: Maternal antenatal psychopathology is associated with activation of the immune system in pregnancy and less optimal neonatal and infant development. It is possible that higher maternal levels of immune system function could be due to poor regulation of cytokine-glucocorticoid feedback, leading to overactive Hypothalamic-Pituitary-Adrenal (HPA) Axis regulation of immune response. These are in turn associated with poorer infant cognitive development, which supports the premise that stress-induced maternal immune activation may contribute in part to prenatal programming of risk. Future regression models will test whether these associations represent mechanistic pathways.

F66. PARENTAL STRESS AND GENERAL FAMILY FUNCTIONING IN FIRST-ONSET CHILD AND ADOLESCENT PSYCHOSIS: PRELIMINARY RESULTS FROM THE OPUS YOUNG TRIAL

Background: Few studies have investigated the stress and burden on parents associated with having a child or adolescent experiencing first-onset of a psychotic disorder. However, studies in adult psychosis has demonstrated the need for Early Intervention Services (EIS) to target the burden of disease that parents and families experience. Parental stress and family function is therefore expected to correlate with changes in child illness severity and functioning during the course of treatment. OPUS YOUNG (OY) is a randomised clinical trial comparing the effects of two years of EIS (the OY intervention) to treatment as usual (TAU). The present study outlines parent stress and family functioning at baseline before treatment is initiated.

Methods: Parents of 290 youths aged 12-17 years participating in the OY trial were invited for baseline assessment with Parental Stress Scale (PSS) and the McMaster Family Assessment Device – General Functioning Subscale (FAD-GF). The PSS measures stress as experienced by the parents. The questionnaire includes 18 statements to which the parent rate their response on a 5 point Likert scale from strongly disagree to strongly agree. Ten of the statements address negative and stressful aspects of parenting, while 8 statements address positive aspects of

parenting. The FAD-GF measures the overall general family function assessed by 12 questions addressed to the parents. Responses are rated on a 4 point Likert scale from strongly disagree to strongly agree.

Results: We will present characteristics of the patient sample and preliminary results of PSS and FAD-GF of the OY sample at baseline.

Discussion: We will discuss our findings of the perceived level of burden compared to findings from other similar and other patient samples.

F67. THE ROLE OF IL-18 AND CHILDHOOD TRAUMA IN EARLY-ONSET PSYCHOSIS

Cecilie Funderud^{*1}, Anette Fjeldstad², Ingrid Agartz³, Nils Eiel Steen⁴, Ole Andreassen⁵, Monica Aas⁶, Anne Margrethe Myhre⁴

¹Østfold Hospital Trust, ²NORMENT Centre for Psychosis Research, Oslo University Hospital and University of Oslo, ³Østfold Hospital Trust, Norway, ⁴Centre for Psychiatry Research, Department of Clinical Neuroscience, Karolinska Institutet and Stockholm Health Care Services, Region Stockholm, Norwegian Centre for Mental Disorders Research (NORMENT), Institute of Clinical Medicine, University of Oslo, Diakonhjemmet Hospital, ⁵NORMENT Centre for Psychosis Research, Oslo University Hospital and University of Oslo, ⁶NORMENT, KG Jebsen Centre for Psychosis Research, Institute of Clinical Medicine, University of Oslo and Division of Mental Health and Addiction, Oslo University Hospital, University of California, San Diego, Oslo University Hospital and University of Oslo, , ⁶Institute of Psychiatry, Psychology, and Neuroscience, Kings College London

Background: There is evidence for immunological dysregulation and low-grade inflammation as a part of the pathogenesis of psychosis-spectrum disorders. Furthermore, studies in adults indicate a link between low-grade inflammation and early trauma. The proinflammatory interleukin-18 (IL-18) has been found elevated in psychosis-spectrum disorders. IL-18 is to a large degree bound to IL-18's binding protein (IL-18BP), forming a complex which blocks IL-18's biological activity. This interleukin is an important modulator of the immune system, but there are few studies examining IL-18 in adolescents with Early-Onset Psychosis. The purpose of this study is increased understanding of the association between childhood trauma and low-grade inflammation (IL-18) in adolescents with an Early-Onset Psychosis. We will specifically investigate whether childhood trauma exposure and higher levels of IL-18 and IL-18/IL-18BP-ratio are more often observed in adolescents (aged between 13-18 years) with an Early-Onset Psychosis, compared to age- and sex-matched healthy controls (HC).

Methods: Serum levels of IL-18 and IL-18BP were measured using venous blood samples from adolescents with Early-Onset Psychosis (n=22) and HC (n=44). Childhood trauma was assessed with the Childhood Trauma Questionnaire (CTQ) and analyzed as a continuous variable (total and subgroup CTQ-score). As the immune markers (IL-18 and IL-18/IL-18BP-ratio) were skewed, they were log transformed prior to being entered into the statistical models. Logistic regression was used to investigate differences in trauma exposure and IL-18 levels in patients and controls. Linear regression was used to investigate the relationship between IL-18 and childhood trauma experiences in patients and controls separately. All analyses were controlled for age and sex.

Results: Patients experienced significantly more childhood trauma (Odds ratio, OR: 1.25; 95% CI: 1.08-1.45; p=.003) and had higher IL-18-levels (OR: 2.28; 95% CI: 1.08-4.82; p=.03) compared to the controls, but no significant differences were observed for IL-18/IL-18BP-ratio

(p GREATER THAN .1). We did not find a significant association between reported childhood trauma experiences (total CTQ-score) and serum IL-18 in either group (p GREATER THAN .1). However, there was a trend-level association between reported childhood trauma (total CTQ-score) and the IL-18/IL-18BP-ratio within the patient group ($\beta=.40$, $t = 1.77$, $p=.09$). Investigating trauma-subscales, we found within the patients a significant association between emotional abuse and the IL-18/IL-18BP-ratio ($\beta=.47$, $t = 2.40$, $p=.03$). No association was observed between childhood trauma and the immune markers (IL-18 and IL-18/IL-18BP ratio) in the control group (p GREATER THAN .1).

Discussion: Our findings support an association between childhood trauma and low-grade inflammation (IL-18) in adolescents with an Early-Onset Psychosis. Our preliminary analyses suggest higher occurrence of childhood trauma in patients with an Early-Onset Psychosis than in the age- and sex-matched healthy adolescence group. Our preliminary findings may suggest an association between the IL-18 system and specific types of childhood trauma experiences in the Early-Onset Psychosis group, but not in the healthy adolescents. While taking the small sample of these preliminary analyses into consideration, our findings indicate an interplay between low-grade inflammation and childhood trauma in adolescent psychosis deserving further attention.

F68. EXAMINING THE ASSOCIATION BETWEEN PRENATAL AND PERINATAL ADVERSITY AND THE PSYCHOTIC EXPERIENCES IN CHILDHOOD

Lorna Staines*¹, Niamh Dooley¹, Colm Healy², Ian Kelleher², David Cotter¹, Mary Cannon¹

¹Royal College of Surgeons in Ireland, ²University of Edinburgh

Background: Prenatal and perinatal complications are an established risk factor for psychotic disorder, but far less is known about the association between prenatal and perinatal complications and psychotic experiences (PEs). PEs in childhood are relatively common, but distressing and/or repeated PEs (persistence), have been associated with adverse outcomes including higher rates of mental disorders and substance disorders. We aimed to examine the longitudinal effects of prenatal/perinatal risk factors on frequency and persistence of distressing PEs across late childhood (age 9/10 - 11/12). Prenatal risk factors were maternal behaviours during pregnancy (smoking/substance use/alcohol consumption) and eleven medical complications (e.g. pre-eclampsia, maternal diabetes). Perinatal risk factors included birth weight and eight medical complications (e.g. born jaundiced, convulsions at birth). We examined the cumulative risk of prenatal/perinatal risk factors on frequency of distressing childhood PLE, and differences between transient PEs, persistent PEs, and controls.

Methods: The Adolescent Brain Cognitive Development study is a large USA based child cohort (age 9-10 at baseline; n=11872 with PE data). PEs were measured at 3 time points (baseline, T1, T2) using the Prodromal Questionnaire-Brief, Child version, and included only if reported as distressing (score $\geq 3/5$). Mixed effect models were used for analysis, controlling for random-effects, and a substantial number of fixed-effects covariates which have been previously associated with PEs, including; family history, socio-economic status, maternal health and age.

Results: Urinary tract infection ($\beta=0.11, 95\%CI[0.03, 0.19]$), and severe anaemia ($\beta=0.18, 95\%CI[0.07, 0.29]$) increased frequency of distressing PEs in childhood. Number of prenatal complications increased frequency of PE ($\beta=0.03, 95\%CI[0.01, 0.06]$) and risk of persistent PEs (OR=1.08, 95%CI[1.01, 1.15]). Maternal smoking was associated with an increased frequency of PEs ($\beta=0.11, 95\%CI[0.04, 0.18]$), and were 31% more likely to report

persistent PEs (OR=1.31,95CI[1.04,1.66]). Maternal substance use was associated with a 48% increased risk of persistent PEs (OR=1.48,95%CI[1.08,2.01]). Perinatal complications showed no effect on frequency or persistence of distressing childhood PEs.

Discussion: This study provides evidence that specific prenatal medical complications (urinary tract infection, severe anaemia) and maternal behaviours (smoking during pregnancy), increased frequency of distressing PEs in childhood. Cumulative number of prenatal medical complications also increased frequency of PEs. Maternal smoking and substance use, as well as cumulative number of prenatal complications, increased risk of persistent PEs. These findings support the evidence of the importance of addressing maternal behaviours for the long term health of the child. Additionally, it demonstrates that public health services currently not freely available in the USA (e.g. sexual health services for pregnant people) could have long-term adverse consequences on children.

F69. DEVELOPMENT OF PSYCHOPATHOLOGY IN ADOLESCENTS BORN TO PARENTS WITH SCHIZOPHRENIA OR BIPOLAR DISORDER

Doris Helena Bjarnadóttir Olsen^{*1}, Maja Gregersen², Mette Falkenberg Krantz², Carsten Hjorthøj³, Sinnika Birkehøj Rohd⁴, Marta Schiavon⁴, Anette Faurskov Bundgaard⁵, Andreas Færgemand Laursen⁵, Jessica Ohland⁴, Aja Greve⁵, Ole Mors⁵, Nicoline Hemager², Merete Nordentoft⁶, Anne Amalie Elgaard Thorup⁷

¹CORE- Copenhagen Research Centre for Mental Health, Mental Health Center Copenhagen, Capital Region of Denmark, ²CORE- Copenhagen Research Centre for Mental Health, Mental Health Center Copenhagen, Capital Region of Denmark; BFOR - Child and Adolescent Mental Health Centre, ³CORE- Copenhagen Research Centre for Mental Health, Mental Health Center Copenhagen, Capital Region of Denmark; University of Copenhagen, Section of Epidemiology, ⁴CORE- Copenhagen Research Centre for Mental Health, Mental Health Center Copenhagen, Capital Region of Denmark; ⁵Psychosis Research Unit, Aarhus University Hospital Psychiatry, ⁶CORE- Copenhagen Research Centre for Mental Health, Mental Health Center Copenhagen, Capital Region of Denmark; Faculty of Health and Medical Sciences, University of Copenhagen, ⁷CORE- Copenhagen Research Centre for Mental Health, Mental Health Center Copenhagen, Capital Region of Denmark; BFOR - Child and Adolescent Mental Health Centre; Department of Clinical Medicine, Faculty of Health and Medical Sciences, University of Copenhagen

Background: Schizophrenia spectrum disorder (SZ) and bipolar disorder (BP) are severe mental disorders. Although these disorders vary in terms of character and severity, they are highly associated with periods of disability and suffering on a personal as well as a societal level. SZ and BP tend to cluster in families in which familial high-risk (FHR) offspring constitute a vulnerable risk group. Compared to individuals without affected parents, FHR offspring of a parent with either a psychotic disorder or BP have a more than a five-fold risk of developing the same disorders as the parent. Furthermore, FHR offspring of SZ and BP have an increased risk of mental disorders already in childhood, indicating that vulnerability to psychopathology is founded early in life. However, it is not clear whether this vulnerability is significant for development of severe mental illness later in life. By comparing adolescents with familial high-risk of SZ and BP with population-based controls, we aim to examine and describe: 1. Mental disorders and psychiatric comorbidity, Prevalence of mental disorders and

psychiatric comorbidity by age 15, Cumulative incidence of mental disorders and psychiatric comorbidity from age 7 to age 15.

2.Diagnostic changes over time, Stability of mental disorders from age 7 to age 15, Proportion of offspring with persistent, incident, remittent, or no mental disorder at age 15.

3.Global functioning: Overall global functioning in FHR offspring from age 7 to age 15, Global functioning in relation to offspring psychopathology.

Methods: The Danish High Risk and Resilience Study is a nationwide prospective cohort study consisting of 522 children born to parents with SZ, BP, or none of these disorders (population-based controls). The families were recruited from the Danish registers and the population-based controls were matched to the children of FHR-SZ on municipality, sex, and age. The first assessment was performed from 2013–2016 when the children were 7 years old (the VIA 7 study). The second wave (the VIA 11 study) was carried out when the children were 11 years old from 2017-2020 with an 89% retention rate. In the third wave (the VIA 15 study) the children have turned 15 years old, data collection started in 2021 and will be finalized in spring 2024. Face-to-face interviews are conducted by trained professionals blinded to parental illness with the gold-standard diagnostic interview Kiddie Schedule for Affective Disorders and Schizophrenia for School-Age Children – Present and Lifetime Version (KSADS-PL). All diagnoses are confirmed at clinical conferences with a child and adolescent psychiatrist.

Results: Results are expected in autumn 2024.

Discussion: As our study is based on a large nationwide prospective sample observing the same individuals from early childhood to adolescence during three waves of comprehensive assessment, we expect it to provide valuable data of the development of psychopathology. Furthermore, we enhance the accuracy of data by including offspring within a narrow age range. As in our previous follow up study we expect a high retention rate. We use clinical interviews where data is based on the participants' memory, entailing a risk of reporting bias. Furthermore, we are aware of the risk of selection bias, as participants with poorer functioning may find it more difficult to participate in the project. To eliminate this, we facilitate flexible interview scheduling and durations. Cohort studies following FHR offspring contribute to an increased knowledge of which FHR offspring are at most risk of severe mental illness, and thus improving which FHR offspring to target for preventive services.

F70. COMPARING PARENT AND CHILD COGNITION IN FAMILIES WITH PARENTAL SCHIZOPHRENIA OR BIPOLAR DISORDER: A DEVELOPMENTAL PERSPECTIVE FROM SEVEN TO 11 TO 15 YEARS OF AGE

Anette Faurskov Bundgaard*¹, Arndis Simonsen², Andreas Færgemand Laursen², Nanna Lawaetz Steffensen², Merete Birk², Sinnika Birkehøj Rohd³, Martin Wilms³, Marta Schiavon³, Doris Helena Feodora Bjarnadóttir Olsen³, Jens Richardt Møllegaard Jepsen³, Nicoline Hemager³, Merete Nordentoft³, Anne Amalie Elgaard Thorup³, Ole Mors², Aja Neergaard Greve²

¹Psychosis Research Unit, Aarhus University Hospital Psychiatry, ²Psychosis Research Unit, Aarhus University Hospital Psychiatry, ³Copenhagen University Hospital

Background: Schizophrenia (SZ) and bipolar disorder (BD) are severe mental disorders, and offspring of parents with SZ or BD are at increased risk of developing the same or other mental disorders. Growing evidence has indicated that SZ and BD share clinical, cognitive,

neuroimaging, and genetic characteristics, an overlap which might also be present in their offspring. Neurocognitive deficits are core features of both SZ and BD. In both groups, neurocognitive impairments have been found to negatively impact the level of functioning and some studies have suggested that cognitive impairments are early vulnerability markers or endophenotypes for these disorders. Familial high-risk (FHR) studies have demonstrated that children born to parents with SZ or BD display a wide array of neurocognitive deficits that lie in between the respective patient group and healthy controls. These studies highlights the importance of assessing and understanding the presence and development of neurocognition in offspring at FHR. High heritability estimates of cognition have been demonstrated in SZ as well as in healthy populations. Heritability of general cognitive ability increases significantly and linearly with age, suggesting a genotype-environment correlation. However, the intergenerational transmission of cognitive abilities is still an under-researched field both in general and in families with severe mental disorders. Few studies have investigated the association and only cross-sectional data has been reported. This study aims to assess the transmission of intelligence, processing speed and verbal working memory from both biological parents to their offspring from the child was seven to 11 to 15 years of age in a cohort of families where a least one parent was diagnosed with schizophrenia og bipolar disorder, or none of these disorders.

Methods: This study is part of The Danish High Risk and Resilience Study – VIA, a longitudinal nationwide cohort of children with no (PBC; 200), one or two parents diagnosed with SZ (FHR-SZ; 202) or BP (FHR-BP; 120). At age seven, 522 children and both their biological parents were assessed (VIA 7). Parents and children underwent the same battery of tasks from validated neurocognitive measures. Intelligence was estimated using The Reynolds Intellectual Screening Test. Processing speed and verbal working memory was assessed respectively with Coding and Letter-Number Sequencing in children from Wechsler Intelligence Scale for Children – fourth edition, and in parents from Wechsler Adult Intelligence Scale – fourth edition. At age 11, the children were assessed using the same tests, with a follow-up rate of 89% (VIA 11). Now at age 15, the children are assessed for the third wave of the study (VIA 15).

Results: Data collection is ongoing and will be finalized in the spring of 2024.

Discussion: To our knowledge this is the first longitudinal study to assess cognition between parents and children in in the same study with the same measurements. This provides a unique opportunity to investigate the relationship between parent and child cognition and how cognition might be modulated by having a parent with a severe mental disorder such as SZ or BP. This will enrich our understanding of neurocognitive deficits as endophenotypes for SZ and BD which is important to enhance our understanding of the etiological mechanisms underlying the development of the disorders.

F71. AMPHETAMINE SENSITISATION IN HEALTHY VOLUNTEERS LEADS TO INTERNALISING ATTRIBUTION BIAS AND INCREASED STRESS SENSITIVITY TO LOSS OF CONTROL

Nace Mikus^{*1}, Federico Mancinelli², Claus Lamm³, Mathäus Willeit⁴, Christoph Mathys¹

¹Aarhus University, ²University of Bonn, ³University of Vienna, ⁴Medical University of Vienna

Background: Hypersensitivity of the dopaminergic system is believed to be the core biological abnormality in patients with psychosis and an important risk factor in various other

neuropsychiatric disorders. Endogenous dopamine sensitization is characterized by an increased response to dopamine-releasing drugs as well as stressful environments. Yet, the mechanisms through which dopamine dysregulation leads to increased stress sensitivity are largely unknown. Stressors that result from perceived uncontrollable negative events are particularly likely to elicit a larger response in vulnerable individuals, especially those that have a self-blaming causal attribution bias. Here, we present preliminary data from an experiment investigating the effects of dopamine sensitization on causal attribution in experimentally induced loss of control.

Methods: Healthy male volunteers were subjected to an amphetamine sensitisation procedure in which they received three repeated low doses of D-amphetamine ($n = 8$) or mannitol ($n = 2$) two days apart. After a two-week sensitisation period, both groups received another dose of D-amphetamine. Blood pressure and heart rate were measured several times during each experimental session. Stress sensitivity and attribution bias were measured using a novel behavioural task in which participants had to exert effort to either gain monetary rewards or avoid monetary losses. Throughout the task, the degree of control participants have over the outcome of each trial is reduced. After each trial, participants are asked about their subjective sense of control, perceived stress and whether they attribute the outcome of the trial to chance or to their performance. Participants perform the loss of control task several times during the experiment: at baseline (B1), after the first amphetamine administration (A1), after sensitisation without drug administration (B2) and after sensitisation with amphetamine administration (A2).

Results: We found stronger responses to amphetamine after the sensitisation procedure, as indicated by a significant difference in systolic blood pressure in response to amphetamine between the last and the first amphetamine administration ($p = 0.03$, mean difference = 8.75 mmHg). Using a linear model predicting self-reported stress from perceived control as a random and fixed effect, and sensitisation and amphetamine administration as fixed effects, we found that loss of control led to higher self-reported stress across the study ($p < 0.001$) and that this effect was more pronounced after sensitisation ($p < 0.001$). Looking at session comparisons within the sensitisation group only, we found that stress sensitivity was higher under amphetamine after sensitisation (A2) compared to before sensitisation (A1) and to baseline (B1, all $p < 0.01$). We defined attribution bias as a linear effect of success or failure in each trial on attribution. We found that participants generally show a positive attribution bias, by attributing failures to luck and successes to their own performance ($p < 0.001$), and that a positive attribution bias reduced the effect of loss of control on stress. A mixed linear model predicting attribution from trial outcome as a fixed and random effect and sensitisation and amphetamine administration as fixed effects, we found that sensitisation led to stronger internal attribution, regardless of trial outcome ($p < 0.001$).

Discussion: The preliminary results of this study support the notion that repeated exposure to psychostimulants leads to increased stress sensitivity in response to loss of control. Our data suggest that the psychological mechanism that underlies the heightened stress response is a higher internalising attribution style. The strength of this study is a novel paradigm that is administered repeatedly within subjects; however, the findings are preliminary, with low sample sizes, and should be interpreted with this in mind.

F72. PRELIMINARY DATA FROM THE CONNEX-X EXTENSION TRIAL EXAMINING THE LONG-TERM SAFETY OF ICLEPERTIN (BI 425809) IN

PATIENTS WITH SCHIZOPHRENIA WHO COMPLETED PHASE III CONNEX TRIALS

Corey Reuteman-Fowler^{*1}, Zuzana Blahova², Stephen R. Marder³, Satoru Ikezawa⁴, Peter Falkai⁵

¹Boehringer Ingelheim Pharmaceuticals, Inc., ²Boehringer Ingelheim RCV GmbH and Co. KG, ³Semel Institute for Neuroscience at UCLA, David Geffen School of Medicine, ⁴International University of Health and Welfare, Mita Hospital, ⁵Ludwig Maximilians University Munich

Background: Cognitive impairment associated with schizophrenia (CIAS) is an important unmet need as there are no effective treatments available. Iclepertin (BI 425809), a glycine transporter-1 inhibitor, has been shown to improve CIAS in Phase II trials, and Phase III trials are underway. The ongoing CONNEX-X extension study aims to collect additional safety data relating to iclepertin treatment in patients with CIAS.

Methods: CONNEX-X (NCT05211947/1346-0014) is a multinational, multicentre, open-label, single-arm extension study in patients with CIAS who completed 26 weeks of treatment (iclepertin 10 mg or placebo) in one of 3 Phase III CONNEX parent trials (NCT04846868/1346-0011, NCT04846881/1346-0012, NCT04860830/1346-0013). An estimated 1400 clinically stable outpatients will be treated (iclepertin 10 mg daily) for 1 year, irrespective of previous treatment (iclepertin/placebo). Patients are excluded if any of the following circumstances occur during the parent study and up to Visit 1 of CONNEX-X: suicidal behaviour or ideation (type 5 on the Columbia-Suicide Severity Rating Scale), diagnosis with moderate/severe substance use disorder, diagnosis other than schizophrenia (according to Diagnostic and Statistical Manual of Mental Disorders – Fifth Edition), development of any condition preventing participation, a haemoglobin level decrease (GREATER THAN 25% or LESS THAN 100g/L from baseline in parent trial) or haemoglobinopathies. The primary endpoint is the occurrence of treatment-emergent adverse events. The secondary endpoints include change from baseline (CfB) in Clinical Global Impressions-Severity (CGI-S) and CfB in haemoglobin. Further efficacy endpoints include CfB in MATRICS Consensus Cognitive Battery (MCCB) overall composite T-score, CfB in Schizophrenia Cognition Rating Scale total score and CfB in Virtual Reality Functional Capacity Assessment Tool (VRFCAT) total times.

Results: Currently, 460 patients have been enrolled and randomised from the parent trials with 0% screening failures (~80% roll-over rate, 30 August 2023). Current study status, including recruitment, screening failures and data collection experiences, are presented.

Discussion: Patient enrolment rates from the CONNEX trials to the CONNEX-X open-label extension study are stable. CONNEX-X will allow the exploration of long-term safety, as well as descriptive analyses of cognitive and functional endpoints of iclepertin in the treatment of CIAS.

This study is funded by Boehringer Ingelheim (NCT05211947/1346-0014).

F73. LEVEL AND CHANGE IN SYMPTOM CLUSTERS AND INSIGHT AFTER COMMENCING ANTIPSYCHOTIC TREATMENT

Lena Stabell^{*1}, Erik Johnsen¹, Rune Kroken¹, Else-Marie Løberg¹, Eirik Kjelby², Inge Joa³, Solveig Klæbo Reitan⁴, Rolf Gjestad⁵

¹Haukeland University Hospital, University of Bergen, ²ReHaukeland University Hospital, ³TIPS – Centre for Clinical Research in Psychosis, Stavanger University Hospital, Network for Medical Sciences, University of ⁴St. Olavs Hospital; Norwegian University of Science and Technology, ⁵Haukeland University Hospital, Centre for Research and Education in Forensic Psychiatry, Haukeland University Hospital

Background: Impaired clinical insight is common in schizophrenia spectrum disorders. Impaired insight may influence both treatment motivation and adherence. This has effects on prognosis. Most studies lack multiple assessments in the initial phase after commencing antipsychotic treatment to capture the relationship between insight and symptom changes. In this study, we aim to disentangle the effects of fluctuations in different symptom cluster on insight. We examined changes in symptoms and insight during the first six weeks of antipsychotic treatment.

Methods: Using data from the BeSt InTro trial, 144 patients were assessed with the Positive and Negative Syndrome Scale (PANSS) at baseline, week 1,3, and 6 after commencing antipsychotic treatment. We predicted change and end level of insight in separate latent growth curve models based on the following symptom clusters: Positive (P1, P3, G9, P5, P6), negative (N4, N2, N1, N3, G7, G16), disorganised/cognitive (G11, P2, N5, G10, N7, G13, G5), hostility (P7, G8, G4, G14), and a total PANSS score excluding the insight item (mPANSS).

Results: Mean insight improved from 3.4 at baseline to 2.5 after six weeks of AT, range 1-6 at both time points. However, more than one fifth of the participants had a score of four or more after six weeks use of antipsychotics. Change in several of the predictors corresponded with change in outcome within the following intervals: week 0-1, week 1-3 and week 3-6. The end level of insight was predicted by baseline level and change in the 3-6 weeks interval in all symptom models. Change in positive ($b = 2.06$, $p = 0.007$), hostility ($b = 1.62$, $p = 0.028$) and mPANSS ($b = 1.89$, $p = 0.014$) in the 1–3-week interval were also significant predictors of the end level of insight.

Discussion: Our analyses display time-specific relations between improvements in symptoms, and

improvements and the end level of clinical insight after six weeks of antipsychotic treatment. Accordingly, ongoing symptom reduction is associated with continuous improvement in insight. This aligns with previous findings based on longer follow-up or less frequent assessments in the initial phase. Lack of significant findings in negative and cognitive symptoms clusters in the week 1-3 interval, may be due to the internal relationships between the predictors in their individual models. Our results suggest close monitoring of treatment effects, including insight. Although mean insight was improved, a notable group of participants displayed persistent impaired insight after commencing antipsychotic treatment. This has been reported in previous studies, and the literature has identified both state and trait properties of insight. Therefore, some patients may benefit from other treatments aimed at improving insight, particularly the trait aspect. Lately, interventions aimed at improving metacognitive functions have shown promising results.

F74. LONG-TERM SAFETY OF KARXT (XANOMELINE AND TROSPIMUM) IN SCHIZOPHRENIA

Ronald Marcus¹, Rishi Kakar², Andrew C. Miller¹, Amy Claxton*¹, Steven M. Paul¹, Stephen K. Brannan¹, Inder Kaul¹

Background: A high unmet medical need exists for more effective, better tolerated treatments for schizophrenia with novel mechanisms of action. All currently approved treatments for schizophrenia have D2 dopamine receptor blocking activity; the efficacy and tolerability limitations of these therapies are well known. KarXT, an investigational medication, combines the dual M1/M4 preferring muscarinic acetylcholine receptor agonist xanomeline and the peripherally restricted muscarinic receptor antagonist trospium chloride. KarXT is designed to preserve the beneficial central nervous system effects of xanomeline while reducing adverse events (AEs) due to peripheral muscarinic receptor activation. The efficacy and safety of KarXT in schizophrenia was demonstrated in the 5-week, randomized, double-blind, placebo-controlled EMERGENT-1 (NCT03697252), EMERGENT-2 (NCT04659161), and EMERGENT-3 (NCT04738123) trials. Long-term safety and tolerability of KarXT in adults living with schizophrenia is being assessed in the Phase 3, multicenter, 52-week, outpatient, open-label extension EMERGENT-4 (NCT04659174) study and 52-week, open-label EMERGENT-5 (NCT04820309) study in de novo participants.

Methods: Safety and tolerability measures from EMERGENT-4 and EMERGENT-5 were pooled to assess the long-term safety and tolerability of KarXT in participants with schizophrenia. The EMERGENT-4 trial enrolled participants who previously completed the treatment period of one of the two Phase 3 double-blind studies, and the EMERGENT-5 trial enrolled de novo adult subjects with schizophrenia without prior exposure to KarXT and with a Positive and Negative Syndrome Scale total score ≤ 80 , a Clinical Global Impression–Severity score ≤ 4 . Data from an interim analysis of the EMERGENT-4 and EMERGENT-5 trials were pooled, and all safety analyses were conducted in the safety population, defined as all participants who received ≥ 1 dose of trial drug. Data are continuing to be recorded in these ongoing studies, and updated analyses will be available at the time of the meeting.

Results: A total of 674 participants were included in the long-term safety interim analyses. Across the EMERGENT-4 and EMERGENT-5 trials, approximately 60% of patients reported ≥ 1 treatment-related AE. The most common treatment-related AEs occurring in $\geq 5\%$ of participants receiving KarXT were nausea, vomiting, constipation, dry mouth, dyspepsia, dizziness, hypertension, and diarrhea. Of the most common treatment-related AEs the majority were mild or moderate in severity with low rates of severe AEs reported for nausea and vomiting. KarXT was not associated with clinically meaningful changes in prolactin levels and a mean decrease in weight was observed from baseline to Week 52.

Discussion: The interim pooled analyses from the long-term, open label trials indicated KarXT was generally well tolerated in individuals with schizophrenia in an outpatient setting across 52 weeks. These findings, together with the long-term efficacy results showing improvements in efficacy measures across the 52-week trial, support the potential of KarXT to be the first in a new class of antipsychotic medications based on muscarinic receptor agonism and a well-tolerated alternative to currently available antipsychotics.

F75. INCORPORATING DIGITAL HEALTH TECHNOLOGY TOOLS IN STUDY DESIGN TO ASSESS MEDICATION ADHERENCE IN SCHIZOPHRENIA TRIALS

Reuben Fan^{*1}, Elizabeth Hanson², Rich Christie³, Deshana Desai³, Tingting Ge¹, Leah Aluisio¹, Shaolei Feng³, Mahnaz Asgharnejad², Satjit Brar¹, Eduardo Dunayevich¹, Lei Guan³, Venkatesha Murthy², Jaskaran Singh¹, Ni Aye Khin¹

Background: In CNS trials, study design is crucial to mitigate high drop-out rates and poor treatment adherence. Digital health technology tools have been used as part of the study design to monitor and support medication adherence. A smartphone-based application (the Platform), that utilizes video analysis technology to monitor study medication intake was employed in a clinical study evaluating investigational TAK-831/NBI-844 (luvadaxistat) as an adjunctive treatment for negative symptoms of schizophrenia (the INTERACT Study). Here, we sought to understand the impact of including adherence support with the Platform in the single blind lead-in (SLBI) phase as part of the eligibility requirement for inclusion in the double-blind (DB) (post-randomization) period. We also investigated how DB Platform adherence values correlated with pill-count and detectable luvadaxistat plasma levels in subjects assigned to take luvadaxistat during the DB period.

Methods: The INTERACT Study was a phase 2, 12-week, randomized, DB, placebo-controlled, efficacy, safety, and pharmacokinetic study of 3 doses (50, 125 and 500 mg) of luvadaxistat. There was a 2-week (Day -14 to Day -1) SLBI period where adherence to study drug intake was measured using the Platform. During the SLBI period, all subjects received placebo tablets, that appeared identical to the study drug to be given during the 12-week DB period (Day 1 to Day 84). To enter the DB portion of the study, subjects needed to complete the SLBI period with at least 75% adherence to Platform use. Platform adherence is defined as the number of pills successfully logged on the Platform against the expected number of pills. Pill count adherence is defined as the number of pills dispensed corrected for number of returned pills. For measuring concordance between pill-count and Platform use, we set adherence thresholds of 90% and 75% respectively between the final two visits (Day 70 and Day 84). Concordance with detectable luvadaxistat plasma level is based on samples collected at final DB study visit (Day 84).

Results: Of the 304 enrolled subjects, 256 subjects were randomized and 169 subjects were assigned to take luvadaxistat. Of the 256 randomized subjects, 254 (83.5%; 254/304) have Platform data for analysis. Within the SLBI period, the average adherence to Platform use of those who did not qualify for the DB period was ~71%. The average SLBI adherence to Platform use of those who did qualify for the DB period was ~94%. The overall adherence to Platform use for subjects participating in both the SLBI and DB periods was ~92%. The adherence to Platform use for the DB portion alone was also ~92%. There were 160 subjects assigned to the take luvadaxistat in the DB that also maintained a $\geq 75\%$ overall Platform use adherence and 144 (90%; 144/160) of those subjects had quantifiable plasma concentrations of luvadaxistat. In addition, 154 subjects assigned to a luvadaxistat arm had Platform data to compare with pill count data and 151/154 (98.1%) of those subjects had both 75% adherence to Platform use and 90% or greater pill count adherence. Overall, among all 3 measures, we found 88% met all 3 thresholds ($\geq 75\%$ adherence to Platform use, $\geq 90\%$ pill-count adherence, and quantifiable plasma concentrations of luvadaxistat).

Discussion: Preliminary analysis indicates subjects who demonstrated adherent behaviors in the SLBI period tended to maintain such behaviors through the DB. This also indicates that thoughtful integration of a technology platform in the study design (that considers markers of medication adherence) can lead to a desirable confluence of measures indicative of subjects who are able to maintain intake of investigational product throughout a protocol. Further analysis to be discussed.

F76. METACOGNITIVE TRAINING FOR NEGATIVE SYMPTOMS

Linda Swanson*¹, Jonas Persson², Benjamin Rask², Simon Cervenka²

¹*Centre for Clinical Research Sörmland, Uppsala University SE, ,* ²*Uppsala University,*

Background: The cognitive model proposes that negative symptoms (NS) in schizophrenia might be caused/maintained by dysfunctional beliefs about social affiliations, performance, expectations of pleasure, success, and acceptance as a consequence of repeated failures and setbacks, where individuals adopt coping strategies by ‘shutting down’ the cognitive-affective experience. This allows individuals to cope with overwhelming situations in the short-term, but leads to a reliance on NS in the longer-term. Longitudinal studies have shown support for the model as defeatist performance attitudes and asocial beliefs are found to predict future NS. In addition, there is evidence that suggests a link between metacognition and NS as limitations in complex metacognitive processes are associated with concurrent and future NS. These limitations predict NS in first episode psychosis and in more chronic samples. This suggests that NS reduction may partially depend on improved metacognitive capacity, and that a metacognitive intervention specifically targeting the cognitions listed in the cognitive model may be beneficial. We (Swanson et al. 2022) therefore adapted a metacognitive training programme (MCT) to NS to examine variable change over the course of the intervention and to carry out a preliminary investigation of putative mechanisms of change.

Methods: We adopted a mixed methods case series design (N=15) where detailed quantitative data on changes over time were combined with exit interviews. The triangulation of quantitative and qualitative results also facilitated a thorough exploration of the feasibility of the intervention. The study used a combination of interviews (Brief Negative Symptom Scale; Positive and Negative Syndrome Scale; Calgary Depression Scale for Schizophrenia; Metacognition Assessment Scale; the Global Assessment of Functioning) and self-rated questionnaires (Personal Belief about Illness Questionnaire; Reflective Function Questionnaire). Non-parametric tests were used to evaluate changes at pre, post and follow-up due to the limited sample size and the repeated-measure nature of the data whilst multilevel modelling (MLM) was used to assess change over time and across cases and thematic analysis to analyse the qualitative data.

Results: Improvements on NS were observed following the intervention (with large effect sizes post intervention/follow-up) as well as on reflective functioning and stigma with similar patterns seen in the qualitative results. The intervention showed good feasibility as demonstrated by the attendance rate and the positive feedback from participants and the multidisciplinary team. MLM showed that depression, internalized stigma and reflective functioning best explained the variance in NS. In a follow-up analysis (Swanson et al. 2023), we found that there were two specific NS underlying the improvement: asociality and blunted affect. The overall results suggest that NS is related to intrapersonal functioning in terms of cognitive and emotional experience and that NS may develop in part as a consequence of diminished capacity for self-other mental state processing.

Discussion: The study shows that MCT could be adapted to target NS, thereby holding the promise of a brief and structured intervention to reduce NS. In addition, the analysis allowed us to identify potential mechanisms and how these could interact to influence NS expression, facilitating the future refinement of the intervention to target specific psychological processes that may underpin NS. The refined intervention will be systematically assessed in future research with a larger sample, utilizing a more robust randomized controlled design by including a control group, independent assessors as well as brain scans (see poster by Rask et al 2024).

F77. COMPARING COGNITIVE REMEDIATION APPROACHES IN SCHIZOPHRENIA: PRELIMINARY RESULTS FROM A RANDOMIZED, CONTROLLED TRIAL

Matthew Kurtz*¹, Bryan Gu¹, Maeve Hoffman¹, Grace Melville¹, Alexia Pollock¹, Jennifer Rose¹

¹*Wesleyan University*

Background: Cognitive remediation (CR) is a type of behavioral intervention that addresses cognitive deficits in schizophrenia by restoring lost cognitive skills or providing strategies for bypassing deficits through task practice. Meta-analyses (Vita et al., 2021; Lejeune et al., 2021) have revealed that cognitive remediation is a validated approach to improving cognitive function in schizophrenia, however a lack of precision regarding the active elements of the intervention have prevented its recommendation as a standard treatment for the illness (Dixon et al., 2010). The present study sought to identify cognitive training mechanisms that are most effective at improving cognitive function in schizophrenia by comparing two different systematic programs of CR with different foci: drill-and-practice exercises vs. compensatory strategies. Both programs have strong preliminary empirical support.

Methods: In this ongoing, single-blind, randomized, controlled and pragmatic clinical trial, participants were randomly assigned to one of three groups according to a 2 (drill-and-practice computerized CR): 2 (compensatory cognitive skills group) :1 (computer games control) randomization strategy. Participants were assessed with a comprehensive battery consisting of well-validated measures of cognition, social cognition, self-efficacy, and functional outcomes before, during, and after treatment. Assessments were conducted by an administrator blind to group assignment. Treatment consisted of 12 weeks of compensatory cognitive training groups (Twamley et al., 2012), 20-40 hours of computerized drill-and-practice cognitive exercises (Kurtz et al., 2007; 2015), or 20-40 hours of computer games depending upon group assignment.

Results: To date 24 participants with schizophrenia-spectrum-illness meeting all inclusion/exclusion criteria have been enrolled in the study. Analysis of data collected to date in the 8 participants who have completed treatment, revealed a trend towards improvement in working memory as measured by the Digit Span Backwards test, when data from both the drill-and-practice and strategy-based forms of CR were combined. Preliminary results from the Digit Span Backward Test revealed a pre-treatment mean raw score of 6.00 vs. a post-treatment mean raw score of 7.33 in the two CR-treated groups (Hedge's $g=.48$). Data from approximately 15 participants on cognitive, social cognitive, attitudinal and functioning measures before and after treatment will be available for presentation in April.

Discussion: These preliminary findings suggest that both forms of CR, drill-and-practice and compensatory training, improve working memory skills at a trend level relative to scores at baseline. As our sample size increases we will evaluate the relative efficacy of these two empirically-supported cognitive interventions across a broader array of outcome measures and as compared to a computerized games control condition.

F78. A SYSTEMATIC REVIEW AND META-ANALYSIS OF TRANSCRANIAL MAGNETIC STIMULATION IN TREATING POSITIVE AND NEGATIVE SYMPTOMS OF SCHIZOPHRENIA: PRELIMINARY RESULTS

Konstantinos Pallis^{*1}, Anahita Fazel Dehkordi¹, Charles Laidi², Philippe Huguelet¹, Stefan Kaiser¹, Indrit Bègue¹

¹University Hospitals of Geneva, ²INSERM U955, Institut Mondor de la Recherche Biomédicale (IRMB), Univ. Paris Est Créteil, Equipe 15 Neuropsychiatrie Translationnelle La Fondation Fondamental, Créteil, France NeuroSpin, Neuroimaging Platform, CEA, UNIACT Lab, PsyBrain Team,

Background: Transcranial magnetic stimulation (TMS) has emerged as a promising therapeutic approach for addressing symptoms in individuals with schizophrenia. Preliminary results indicate encouraging outcomes, but the evidence suggests nuanced efficacy across different symptom categories. This systematic review and meta-analysis explore the effectiveness of TMS in alleviating positive and negative symptoms associated with schizophrenia. Our study aims to comprehensively understand the patterns of TMS effectiveness, considering the distinct challenges posed by each symptom domain. We sought to identify factors contributing to variations in outcomes and contribute to a better understanding of TMS as a potential intervention for schizophrenia.

Methods: We systematically searched Pubmed, EMBASE, Web of Science, and PsycINFO for double-blind, randomized sham-controlled trials (RCTs) of TMS in patients with schizophrenia. We specifically included trials where the symptom of interest was a primary outcome. To quantify the impact of TMS relative to sham, the standardized mean difference (SMD, using Cohen's d) along with 95% confidence intervals (95%CI) were calculated. An inverse variance random effects model was utilized to aggregate data across the selected studies. Additionally, subgroup analyses were carried out to assess the effects of different stimulation locations and protocols.

Results: We performed a meta-analysis on 3'111 participants across the spectrum of schizophrenia symptoms. Regarding NS (N = 1654, 39 studies) analysis revealed an overall positive effect size (SMD = 2.02, confidence intervals [1.32; 2.7191], p LESS THAN 0.0001), indicating a substantial impact of TMS vs. sham, regardless of the stimulation protocol. However, the high heterogeneity ($I^2 = 92.9\%$) suggests notable variability in effect sizes across studies. Regarding positive symptoms (N = 859, 21 studies) we found a positive but statistically not significant trend in the overall effect size (SMD = 0.2735, confidence intervals [-0.06, 0.61] with high heterogeneity among the studies ($I^2 = 97.5\%$)).

Discussion: Our study highlights the potential efficacy of TMS in mitigating negative symptoms of schizophrenia, evident from the significant overall effect size observed. The next step involves detailed subgroup analysis to understand how different stimulation protocols and other factors contribute to this effect. The absence of statistical significance in the improvement of positive symptoms, coupled with substantial heterogeneity across studies, emphasizes the need for continued research in this domain. These findings collectively aim to inform future research and shape intervention strategies that are more effectively customized to meet the varied requirements of individuals with schizophrenia.

F79. A RANDOMIZED CONTROLLED CLINICAL STUDY OF HIGH-DEFINITION TRANSCRANIAL DIRECT CURRENT STIMULATION (HD-TDCS) TO IMPROVE COGNITIVE FUNCTION IN PATIENTS WITH SCHIZOPHRENIA

Xiangyang Zhang*¹

¹*Institute of Psychology, Chinese Academy of Sciences*

Background: Cognitive impairments serve as a critical component among schizophrenic symptoms and effective pharmacologic treatments for this dysfunction have lacked consideration. Transcranial direct current stimulation (tDCS) appears to be a potential clinical add-on treatment to improve clinical symptoms and cognitive functions in schizophrenic patients. The present study aimed to investigate the clinical efficacy of high-definition tDCSv(HD-tDCS) in improving the cognitive function in patients with schizophrenia.

Methods: We recruited 46 schizophrenic patients and allocated them randomly to the HD-tDCS real/sham stimulation group. Patients were treated with 20 sessions (once a day, five times a week) of 1.5 mA stimulation of the left dorsolateral prefrontal cortex (DLPFC) using the HD-tDCS technique. Cognitive functioning was measured using the Repetitive Battery of Neuropsychological Status (RBANS) with clinical symptoms measured by the Positive and Negative Symptom Scale (PANSS).

Results: Compared to the sham stimulation group, the real stimulation group demonstrated a significantly greater improvement on clinical symptoms and cognitive function. In real stimulation groups, patients receiving twenty sessions showed better improvement in cognitive function than those receiving ten sessions, indicating that the efficacy of twenty sessions was significantly better than that of ten sessions.

Discussion: Our results showed that HD-tDCS had significant efficacy in the treatment of cognitive impairment in schizophrenia patients, in which such phenomenon was better in long sessions than in short sessions. Our study presented a great practical significance to provide more treatment options for the clinical intervention of schizophrenia, particularly emphasizing concerns on patients' cognitive function.

F80. TREATMENT WITH EVENAMIDE FOR 1 YEAR IN TRS PATIENTS NOT BENEFITTING TO CURRENT ANTIPSYCHOTICS IS ASSOCIATED WITH SUSTAINED, CLINICALLY IMPORTANT BENEFIT: RESULTS FROM A PROSPECTIVE, PILOT, 1 YEAR, RANDOMIZED, OPEN-LABEL TRIAL

Ravi Anand*¹, Alessio Turolla², Giovanni Chinellato³, Francesca Sansi², Rodolfo Giuliani², Richard Hartman⁴

¹*Anand Pharma Consulting*, ²*Newron Pharmaceuticals SpA*, ³*Newron Pharmaceuticals*, ⁴*NeurWrite LLC*

Background: Treatment resistant schizophrenia (TRS) leads to reduced life-expectancy, frequent hospitalizations, indigent status, and increasing costs for families and society (Kennedy et al., 2014). Many strategies have been pursued for its management like the off-label prescription of more than one antipsychotic (AP) despite the absence of benefit (Galling et al., 2017), and the usage of clozapine (Kane et al., 1988) that, although exceptionally efficacious, is vastly underutilized due to its safety concerns (agranulocytosis, myocarditis, sedation). Evenamide, a selective inhibitor of voltage-gated sodium channels, devoid of biological activity at GREATER THAN 130 CNS targets, normalizes glutamate release without affecting its basal levels. Preclinical experiments have indicated that it is likely to benefit patients responding inadequately or resistant to AP. Evenamide was evaluated as monotherapy or add-on to APs in animal models in which pre-pulse inhibition was impaired using amphetamine, scopolamine, phencyclidine, MK-801, ketamine, or sleep deprivation. It

demonstrated efficacy across a broad spectrum of experiments, including models of mania, depression, impulse control loss, and obsessive-compulsive behavior (Anand et al., 2018).

Methods: This 1 year, randomized, open-label, rater-blinded international study (study 014/015) aims to assess safety, tolerability, and efficacy of evenamide added on to AP orally at three fixed doses (7.5, 15 and 30 mg bid) in patients with documented TRS. After an initial treatment period of 6 weeks, patients had the opportunity to continue for up to 1-year.

Selection criteria for the study require patients to meet standardized criteria for TRS: non-response to two APs, baseline PANSS total score 70-90 with predominant positive symptoms, at least two moderate core symptoms and functional deficits. Efficacy data (PANSS, CGI-S/C, and LOF) were collected regularly every 10/12 weeks and were analyzed using paired t-test for changes from baseline to endpoint and descriptively for each dose group and for the responder analyses. Safety was assessed at all visits throughout the 1-year period.

Results: Scheduled review of safety data by an ISMB did not detect any pattern of motor or CNS symptoms, weight gain, sexual dysfunction or laboratory/EKG abnormalities, indicating the good tolerability of evenamide at all doses in addition to low incidence of ADOs (1.9%). Furthermore, the attrition rate was extremely low (~25% at 1-year) in contrast to published TRS studies (Homman et al., 2021). After 1 year of treatment, the overall improvement in symptoms from baseline was -20% (PANSS total), with a clinically important benefit in the positive subscale (-26%). ~45% of the patients were considered at least “much improved” on the CGI-C, and the severity of disease improved by more than 1 point on average, with 30% of the patients improving by 2 categories or more on the CGI-S. Furthermore, the benefit seen in all efficacy scales (including functioning), is sustained and long-lasting, as seen in the first cohort (Aanand et al., 2023), with the largest improvement in the 15 and 30 mg bid dose groups. Validated and final, 1-year, efficacy and safety results, available by the time of the Congress, will be presented demonstrating remarkable efficacy of evenamide at 1-year.

Discussion: This is the first international 1-year trial of evenamide add-on to any AP (except clozapine) in patients with TRS. Encouraging results of this study have expedited the conduct of a potentially pivotal, phase 3, randomized, double-blind, placebo-controlled, 1-year, international study to demonstrate the profound, multi-domain, long-lasting efficacy of the combination of evenamide and AP. These data demonstrate the unique benefits of glutamate modulation when added to APs.

F81. INVESTIGATING ASSOCIATIONS BETWEEN ANTIPSYCHOTIC DOSAGE, MOVEMENT DISORDERS, BODY MASS INDEX, AND WAIST CIRCUMFERENCE IN PATIENTS AFTER A FIRST EPISODE OF PSYCHOSIS

Yinzhaio Liu^{*1}, Dr. P. Roberto Bakker², Dr. Sanne Kooops¹, Prof. Dr. Iris Sommer¹

¹University of Groningen, University Medical Center Groningen, ²Arkin, Institute for Mental Health, Amsterdam,; Maastricht University Medical Center, School for Mental Health and Neuroscience

Background: Side effects of antipsychotic medication (APS) include movement disorders and metabolic syndrome. It is unclear how antipsychotic dose and dose reduction/discontinuation are related to these side effects. The present study aims to investigate the associations between antipsychotics dose and movement disorders, body mass index (BMI), and waist circumference, at 6 months and 12 months follow-up.

Methods: Patients in remission after a first-episode psychosis (FEP) were selected from the single-blind randomized controlled trial: Handling Antipsychotic Medication: Long-term

Evaluation of Targeted Treatment (HAMLETT). 267 were followed for 6 months, from whom 225 patients were followed for 12 months. Of them, approximately 30% of patients used aripiprazole, 40% of patients used olanzapine, and the last 30% of patients used various APS at the baseline. Over the course of 6 and 12 months, 63.67% and 52% of patients gradually reduced/discontinued their APS doses respectively, to a variable extend. For some, after an initial dose reduction, the previous dose needed to be reinstalled upon worsening of psychotic symptoms. Movement disorders including parkinsonism, dyskinesia, dystonia and akathisia were assessed with St. Hans Rating Scale (SHRS), and Barnes Akathisia Rating Scale. Olanzapine equivalent doses (OLZE) were used for standardizing doses of antipsychotics. Data were analyzed using a mixed-effects model, adjusting for sex, age, psychotic symptoms, treatment duration, adjunctive antipsychotic, SSRI/SNRI, lithium, anticonvulsants, benzodiazepine, glucose-lowering medication, antihypertensive medication, drinking coffee, alcohol, and smoking status.

Results: For the APS with the movement disorders risk, the mixed effects model yielded significant coefficients linking parkinsonism to OLZE over both the 6- and 12-month follow-up ($B=0.158$, $p < 0.001$ and $B=0.120$, $p=0.013$, respectively), meaning that 1mg of OLZE increment was associated with increases of 0.158 and 0.120 points on the SHRS total parkinsonism scores over 6 and 12 months. There was also a significant association between decreased parkinsonism and OLZE reduction/discontinuation across 12 months ($B=-2.720$, $p=0.007$). No significant associations between other domains of movement disorders and OLZE were found. Besides, 1mg of aripiprazole dose was significantly related to a 0.121 increase in parkinsonism ($B = 0.121$, $p=0.033$) across 6 months, but not for 12 months. No other significant relationship was found between aripiprazole doses or dose reduction/discontinuation and other domains of movement disorders. For the change in metabolic measures across 6 and 12 months, the mixed effects model did not show significant associations between OLZE of APS with the risk of weight gain and either BMI or waist circumference. Olanzapine doses were not associated with BMI and waist circumference change across 6 and 12 months either. However, olanzapine dose reduction/discontinuation was significantly associated with BMI decreasing over 12 months ($B = -3.348$, $p=0.0493$).

Discussion: For APS with the movement disorder risk, parkinsonism was associated with OLZE at 6- and 12-month follow-up, and with OLZE reduction/discontinuation at 12 months. Olanzapine dose reduction/discontinuation was associated with BMI decreases after 12 months. No significant association with the other movement disorders or metabolic measures and OLZE nor OLZE reduction/discontinuation was observed. This shows that a dose reduction in maintenance treatment is associated with reduced movement disorders at a scale, and a reduced risk for weight gain in olanzapine of 6 to 12 months follow-up.

F82. COGNITIVE BEHAVIORAL GROUP TREATMENT FOR LOW SELF-ESTEEM IN PSYCHOSIS: A PROOF OF CONCEPT STUDY

Elise van der Stouwe^{*1}, Chris Geraets¹, Mirjam Rutgers¹, Wim Veling¹

¹*University Medical Center Groningen*

Background: Patients with a psychotic disorder often suffer from low self-esteem, which has been related to higher suicidal risk, poor quality of life and, the maintenance of psychotic and depression symptoms. However, intervention studies are scarce and reported interventions

concern individual therapies provided by highly educated psychologists. Both the individual setting and the required qualifications of the therapist may contribute to a low level of availability of an intervention. Therefore, we aimed to investigate the efficacy of an easily accessible psychological group treatment targeting self-esteem in patients with a psychotic disorder.

Methods: Thirty patients with a psychotic disorder were included in this pilot study. All participants received nine weekly group sessions of 90 minutes. The therapy was offered in groups of six to eight patients and was provided by a psychiatry nurse and a graduate psychologist. To assess self-esteem the Rosenberg Self-esteem Scale and the Self-Esteem Rating Scale were used, to measure depression symptoms the Beck Depression Inventory-II was administered. Questionnaires were completed at baseline and post-treatment.

Results: Twenty-seven patients (90%) completed treatment. At post-treatment, self-esteem was significantly increased, and depression symptoms were significantly decreased compared to baseline.

Discussion: This pilot study demonstrates the feasibility and treatment potential of a self-esteem group treatment provided by a psychiatry nurse and graduate psychologist in a patient population that receives little psychological treatment. Results suggest that this easily accessible intervention may be effective in improving self-esteem and reducing depression symptoms.

F83. COMPUTATIONALLY DISSOCIABLE ABNORMALITIES IN SEMANTIC REPRESENTATION AND SEMANTIC RETRIEVAL IN SCHIZOPHRENIA AND FORMAL THOUGHT DISORDER

Isaac Fradkin^{*1}, Rani Moran², Beth Jefferies³, Rick Adams⁴, Raymond Dolan⁴

¹Max Planck UCL Centre for Computational Psychiatry and Ageing Research, ²Queen Mary University of London, ³University of York, ⁴University College London

Background: Abnormalities in language and semantic cognition are suggested as biomarkers for schizophrenia. Such abnormalities are particularly evident in patients with Formal Thought Disorder (FTD) - diagnosed based on atypicality in discourse. However, the precise components of semantic cognition that go awry in schizophrenia, including those distinguishing patients who have FTD from patients without FTD, have yet to be specified. We combine computational modeling with neural decoding of semantic representation to disaggregate core abnormalities in semantic structure from abnormal retrieval and executive dysfunction, and detail how they interact in schizophrenia and FTD.

Methods: Thirty-one patients with schizophrenia and thirty-one matched controls completed a word association task during MEG. Patients varied in the degree of FTD symptoms, assessed using the thought and language disorder scale (TALD). We characterized abnormalities in semantic structure by modeling the subjective strength of participants' associations and by mapping semantically meaningful spaces to participants' neural representations of cues (using representation similarity analysis). These measures were then used to characterize participants' personalized associative structures, allowing us to investigate the retrieval and control processes operating on these structures by modeling free association as a controlled accumulation of internal evidence.

Results: As expected, patients produced more atypical associations (Odds ratio [OR] Credible Interval; CI = [1.11, 1.36]), and association atypicality was positively correlated with FTD scores among patients (OR = [1.001, 1.71]). A stark dissociation emerged with respect to participants' subjective ratings of the strength of their associations, which were decreased in

patients (CI=[-0.14,-0.01]) but showed a non-significant, positive correlation with FTD (CI = [-0.02, 0.09]). A computational analysis of the personalized associative structures underlying these behavioral findings suggested that patients' semantic structures are characterized by weakened connectivity (CI = [-0.03, -0.006]). However, this weakening is not found in patients with notable FTD, whose semantic structures are, instead, characterized by more atypical connections (CI = [0.04, 0.26]). Neural representation similarity analysis provided further support for these abnormalities in semantic structures (Cohen's d = [-1.49, -0.40]). Finally, consistent with the idea that atypical associations in FTD can be exclusively explained by abnormal semantic structure, only diagnosis (Adjusted R^2 = 0.24) but not FTD symptoms (Adjusted R^2 = 0.02) predicted abnormal retrieval and control processes, as indicated by a computational analysis of retrieval dynamics.

Discussion: Mechanisms of FTD can be partially dissociated from those explaining general semantic cognition abnormalities in schizophrenia. Whereas patients exhibit more noisy semantic structure and retrieval, FTD was exclusively explained by abnormalities in semantic structure. The formation of an abnormal semantic structure in FTD may reflect a compensatory response to a fundamental loss of precision in structure and retrieval.

F84. RECONSIDERING EVIDENCE FOR PSYCHEDELIC-INDUCED PSYCHOSIS: A SYSTEMATIC REVIEW AND META-ANALYSIS OF HUMAN STUDIES

Michel Sabe^{*1}, Natacha Perez¹, Adi Sulstratova¹, Akram Elrhaoussi², Alban Glangetas¹, Marco De Pieri¹, Luc Mallet³, Logos Curtis¹, Helene Richard-Lepouriel⁴, Katrin Preller⁵, Louise Penzenstadler⁶, Federico Seragnoli⁶, Gabriel Thorens⁶, Daniele Zullino⁶, Kerem Boge⁷, Stefan Leucht⁸, Marco Solmi⁹, Stefan Kaiser¹, Matthias Kirschner¹

¹University Hospitals of Geneva, ²University of Geneva, ³Univ Paris-Est Créteil, DMU IMPACT, Hôpitaux Universitaires Henri Mondor - Albert Chenevier, Assistance Publique-Hôpitaux de Paris, ⁴Mood Disorder Unit, Psychiatric Specialties Service, Geneva University Hospital, ⁵Neuroscience, and Psychology Yale University, Psychiatric University Hospital Zurich, ⁶University Hospitals of Geneva, ⁷Campus Benjamin Franklin, Charité - Universitätsmedizin Berlin; and Freie Universität Berlin; and Humboldt-Universität zu Berlin; and Berlin Institute of Health, Germany, ⁸School of Medicine, Technical University of Munich, ⁹University of Ottawa,

Background: Patients with schizophrenia are currently contraindicated for psychedelic-assisted therapy due to concerns about the potential for psychedelic-induced acute or persistent psychotic symptoms. However, meta-analytic evidence of the precise risk for psychedelic-induced de novo and exacerbation of psychotic symptoms in pre-existing psychotic disorders remains scarce.

Methods: We conducted a systematic review and meta-analysis to examine the prevalence of psychedelic-induced psychosis in the general population and the exacerbation of psychotic symptoms in schizophrenia following our protocol (CRD42023399591). Classical psychedelics were considered: LSD, psilocybin, peyote, DMT, salvia, MDMA, and ecstasy. Embase, PubMed, PsyARTICLES, and PsynFO, and different trial registries were searched from inception until July 2023. Results were limited to human studies. The prevalence of psychedelic-induced psychosis and its variance was computed using a random effects meta-analysis model. Risk of Bias in Non-randomized Studies-of Interventions, Cochrane risk-of-bias, and AMSTAR-2 tools were used to assess the quality of studies.

Results: We retained 113 publications published from 1947 to date: 14 systematic reviews, 21 reviews, 25 randomized-controlled trials (RCT), 8 case-control studies, 26 non-randomized controlled trials (NRCT), and 18 cohort types of studies. Most articles studied LSD. Nine studies were included in our meta-analysis. The prevalence of psychedelics-induced psychosis found in population studies was 0.002% (95%; CI 0- 0.006) in absence of heterogeneity ($I^2=0\%$) ($N=123800$; $n=2$); 0.2.% (95%; CI 0.1- 0.3)($I^2=0\%$) in NRCT including healthy individuals ($N=6535$; $n=6$); 0.6% (95% CI 0.2-1.8)($I^2=0\%$) in RCT including healthy population and patients with depression ($N=563$; $n=3$); 0.4% (95%; CI 0.1-2.8)($I^2=0\%$) for healthy population and patients with depression in RCTs ($N=563$; $n=3$); 3.8%(95%; CI 1.6-8.9)($I^2=0\%$) for NRCT including patients with schizophrenia ($N=133$; $n=2$); and 13.1% (95%; CI 9.4-17.9) ($I^2=24\%$) for conversion from psychedelics-induced psychosis to schizophrenia ($N= 353$; $n=3$). Sensitivity analyses confirmed the main findings.

Discussion: Prevalence for psychedelic-induced psychosis is low in all populations and slightly raised when including patients with schizophrenia. Dose-finding trials for patients with schizophrenia who benefit from maintenance treatment and exhibit treatment-resistant or residual depressive and negative symptoms should be considered.

F85. LINKING CEREBELLUM AND CEREBELLAR PROCESSES TO PSYCHOSIS PHENOTYPES

Alexandra Moussa-Tooks^{*1}, Jonathan Tsay², Jinyuan Liu³, Kristan Armstrong³, Baxter Rogers⁴, Richard Ivry², Neil Woodward³, Stephan Heckers³

¹Indiana University Bloomington, ²University of California Berkeley, ³Vanderbilt University Medical Center, ⁴Vanderbilt University Institute of Imaging Sciences

Background: Motor disturbance, including psychomotor slowing, has been identified as a key feature of psychotic disorders, with motor signs observed in upwards of 66% of unmedicated, first-episode patients, and present even before formal onset of the disorder. While recent work has linked cerebellum to sensorimotor processing deficits, the brain-behavior-symptom relationships have been difficult to establish. This may be due in part to a muddling of distinct processes in our current tasks, inhibiting our ability to capture disturbances in the various subprocesses and their relationships to brain and symptoms. A more complete understanding becomes exceedingly important as the field continues to develop and refine novel mechanistic approaches for treatment, including TMS-based interventions.

Methods: To address these gaps, we first (Study One) present findings from a sample of 339 psychosis patients (242 schizophrenia-spectrum, 97 bipolar with psychotic features) and 217 controls where we evaluated the relationship between cerebellar grey matter volume in the Yeo sensorimotor network and processing speed (assessed via the Screen for Cognitive Impairment in Psychiatry [SCIP]). We tested the role of these variables in predicting psychomotor disturbance (mannerisms and posturing, retardation, excitement of the Positive and Negative Syndrome Scale [PANSS]) using a mediation analysis for an a priori model in the psychosis group: predictor=cerebellar sensorimotor volume; mediator=processing speed; outcome=psychomotor disturbance. Since tasks of “processing speed” incorporate various psychological processes, we secondarily (Study Two) present a new line of work leveraging a computerized motor learning task that has not yet been utilized in the psychiatry literature. Participants ($N=10$) completed a brief computerized motor learning task that allows us to capture directly measured and computationally modeled latent constructs (motor speed, planning time, learning rate, motor system noise). During the task, participants make reaching movements to a target with and without an angular visual perturbation to their reach. Change,

or lack thereof, across metrics are characterized and relationships with cerebellar subregions and psychosis symptom features were assessed. Cerebellar volumes were calculated using optimized processing through the Spatially Unbiased Infratentorial (SUIT) toolbox. Statistical analyses were performed in R. As appropriate, models included total intracranial volume, age, sex, chlorpromazine equivalents as covariates.

Results: In study one, as expected, sensorimotor cerebellar volume was positively associated with processing speed in the whole sample ($t=3.428$, p LESS THAN 0.001, $d=0.30$). Effects were present in both the control sample ($t=2.345$, $p=0.020$, $d=0.32$) and the psychosis sample ($t=2.188$, $p=0.029$, $d=0.24$). Within the psychosis group, no significant direct effect (cerebellar volume $\square$ psychomotor disturbance) was observed in this mediation model ($\beta=-0.035$, $p=0.59$, $d=0.06$). Rather, the indirect path (average combined effect: $\beta=-0.043$, $p=0.014$) showed a significant partial mediation by processing speed, with a small effect of cerebellum on processing speed ($\beta=0.172$, $p=0.029$, $d=0.24$) and medium effect of processing speed on psychomotor disturbance ($\beta=-0.254$, p LESS THAN 0.001, $d=0.60$). In study two, we observed no differences between groups in any metrics of motor speed (initiation or execution of the reach). Psychosis participants did exhibit higher modeled motor noise ($d=0.6$). Moreover, implicit adaptation was positively correlated with cerebellar volume in the psychosis group ($d=0.54$).

Discussion: The current findings suggest a critical role of cerebellar circuitry in sensorimotor aberration in psychosis (processing speed) and the presentation of related psychomotor phenotypes within psychosis. Our follow-up study begins to provide evidence that the slowing observed may not be due to mechanical limitations of the motor system, but noise present in the motor system and an inability to update internal motor models, driven by cerebellum. We plan to continue this work, increasing our sample and tracking symptoms and task performance longitudinally so that we may more effectively linking these brain-behavior relationships to symptoms in psychosis. Future research may also determine the magnitude of these relationships within subtypes of psychosis (e.g., disorganized behavior or catatonia) as well as the specificity to motor, versus non-motor (e.g., cognitive, social), cerebellar functions and cerebellar connectivity with cerebrum.

F86. DEVELOPMENT OF A POPULATION PHARMACOKINETIC MODEL TO DESCRIBE THE PHARMACOKINETICS OF ARIPIRAZOLE 2-MONTH READY-TO-USE, A NOVEL LONG-ACTING INJECTABLE FORMULATION OF ARIPIRAZOLE FOR ADMINISTRATION ONCE EVERY 2 MONTHS

Yanlin Wang¹, Matthew Harlin*¹, Frank Larsen², Xiaofeng Wang¹, Wansu Park³, Benjamin Rich⁴, Jogarao V. Gobburu⁵, Arash Raoufinia¹

¹Otsuka Pharmaceutical Development and Commercialization, Inc. (OPDC), ²H. Lundbeck A/S, ³Alnylam Pharmaceuticals, ⁴InnoMx Inc., ⁵University of Maryland

Background: Compared with oral antipsychotics, long-acting injectable (LAI) antipsychotic formulations are associated with greater treatment adherence and a reduced risk of hospitalization or relapse. Aripiprazole 2-month ready-to-use (Ari 2MRTU) 960 mg is a novel LAI formulation of aripiprazole monohydrate for gluteal intramuscular administration once every 2 months. Ari 2MRTU 960 will offer an extended dosing interval versus aripiprazole once-monthly 400 mg (AOM 400). As part of the development of Ari 2MRTU 960, population pharmacokinetic (popPK) modelling was undertaken to characterize the pharmacokinetics (PK) of this formulation. The final popPK model is described here.

Methods: A previously developed and validated popPK model for characterizing aripiprazole plasma concentrations following administration of oral or AOM 400 (gluteal or deltoid intramuscular injection) formulations was expanded to include the novel Ari 2MRTU formulation. Overall, 8,899 aripiprazole PK samples from 1,191 adults (schizophrenia, schizoaffective disorder, or bipolar I disorder [BP-I], n=1,139; healthy individuals, n=52) from ten Phase 1 and 3 trials were included in the final combined analysis dataset; of these, 240 patients with schizophrenia or BP-I received Ari 2MRTU across three trials. All fixed-effects parameters from the prior model remained fixed throughout the model development, as did random-effects parameters for the first-order absorption rate constant of the oral and AOM routes, apart from CL/F and Vc/F, which were re-estimated. Covariate effects from the original model were retained, with additional potential effects related to the absorption and relative bioavailability of the Ari 2MRTU formulation formally tested using a modified stepwise approach. Data were analyzed using non-linear mixed effects modeling software (NONMEM v7.4.2).

Results: A 3-compartment model with linear elimination and different absorption models for each formulation best described the data. Absorption of the Ari 2MRTU formulation was modeled by a parallel zero-order and lagged first-order process that accounted for an identified double peak in plasma concentrations of aripiprazole post-administration of Ari 2MRTU. All disposition parameters were shared between the formulations except Vc/F (oral and AOM formulations, 93.4 L; Ari 2MRTU formulation, 2035 L); the different Vc/F value for the Ari 2MRTU formulation was attributed to the terminal half-life being absorption driven. Sex was a significant covariate on the absorption of the Ari 2MRTU formulation (90.7% higher absorption rate constant and 56.0% lower fraction of first-order absorption in males versus females); however, simulated C_{avg,ss} values were identical in both sexes, indicating no clinically relevant effect. As expected, simulated aripiprazole concentrations were higher in poor versus extensive metabolizers of CYP2D6; the effect of CYP2D6 metabolizer status was thus retained as a covariate from the prior model.

Discussion: The final popPK model was considered fit for purpose, adequately describing aripiprazole PK following administration of Ari 2MRTU 960. The model also established estimates for key popPK parameters and identified sources of variability in drug exposure. The model will be used to perform simulations to support dosing of Ari 2MRTU 960 across multiple realistic clinical scenarios.

F87. IDENTIFYING SCHIZOPHRENIA SPECTRUM DISORDERS FROM HEALTHY CONTROLS USING ACOUSTIC FEATURES

Elif Kizilay¹, Berat Arslan¹, Emre Bora^{*1}

¹*Dokuz Eylül University, School of Medicine*

Background: In the diagnosis and assessment of schizophrenia spectrum disorders (SSD), speech plays a crucial role as it reflects formal thought disorder. Acoustic characteristics of speech, such as rate, pauses, articulation, duration of speech, pitch, and tone, can serve as important indicators of formal thought disorder as well as negative symptoms present in patients with SSD. In this study, we aimed to analyze acoustic features from speech recordings obtained from patients with SSD and healthy controls (HC) using the extended Geneva Acoustic Minimalistic Parameter Set (eGeMAPS) and to differentiate patients from HC using these features with a machine learning approach.

Methods: Speech samples were obtained from 41 Turkish-speaking patients with SSD and 36 HC during The Discourse in Psychosis Speech Bank Protocol, a semi-structured interview on

different topics, including free conversational speech, personal narrative, health narrative, picture descriptions, storyboard, dream reports, and reading-recall task sections. Speech pre-processing was carried out using PRAAT, resulting in only speech segments of participants. Acoustic features were acquired through the use of OpenSMILE, utilizing the eGeMAPS parameter set, yielding a grand sum of 88 parameters. A random forest classifier with ten-fold cross-validation method was performed using 88 acoustic parameters to assess the role of these acoustic features in identifying SSD from HC. The receiver operator curve (ROC) and area under the curve (AUC) are obtained after the random forest classification.

Results: The random forest classifier using 10-fold cross-validation with 300 n-estimators achieved a mean accuracy of 73.9% with an AUC of 0.77 in classifying patients with SSD and HC. Seventeen significant acoustic parameters were identified. Two of these were temporal and are described as increased variation of voiced segment length per second and increased average unvoiced segment length ($p = 0.035$ and 0.036 , respectively), suggesting fragmented speech segments and extended pauses in patients with SSD. Patients diagnosed with SSD exhibited a higher average spectral slope in the voiced section ($p=0.029$), and a reduced average spectral slope in the unvoiced section ($p=0.045$). Additionally, individuals diagnosed with SSD had higher mean F1 bandwidth and frequency ($p= 0.026$ and $p= 0.006$, respectively). Furthermore, within the SSD group, there was a decrease in the mean relative energy of the first, second and third formants' center frequency to the energy of the spectral peak at pitch (F0) ($p= 0.003$, $p= 0.016$ and 0.016 , respectively) while the variations of these features increased ($p=0.002$, $p= 0.015$ and $p= 0.016$, respectively), suggesting differences in intonation attributes and voice quality compared to HC. Patients with SSD exhibited lower mean jitter ($p=0.018$) and reduced mean shimmer ($p=0.029$), indicating diminished voice quality. Additionally, the mean Hammarberg index of the unvoiced segment and variation in loudness were found to be higher in SSD ($p= 0.044$ and $p= 0.038$, respectively). Moreover, the decreased loudness peaks per second feature was highly significant (p LESS THAN .001).

Discussion: In this study, we found the acoustic analysis of speech had an accuracy of 73.9% in identifying within a small sample of Turkish-speaking patients with SSD from HC. Furthermore, our analysis revealed a highly significant decrease in loudness peaks per second, suggesting that this aspect of speech may serve as a crucial indicator for distinguishing SSD from HC among Turkish individuals. Our analysis showed that acoustic features of speech can be a potential biomarker in SSD.

F88. INSIGHTS ON THE ROLE OF E/I BALANCE IN NETWORK DYNAMICS UNDERLYING REMISSION FROM PSYCHOTIC EPISODE: INTERPRETING PHENOMENOLOGICAL MODELS

Ludovica Mana^{*1}, Manel Vila-Vidal¹, Gustavo Deco¹

¹*Universitat Pompeu Fabra*

Background: In Mana et al. 2023, we investigated the functional-structural interplay underlying remission and relapse following a first psychotic episode, by means of a phenomenological whole-brain model applied to fMRI and DTI data of 128 healthy controls and 88 early psychosis patients. We investigate the interplay between global and local dynamics, shedding light on a potential compensatory mechanism involved in clinical remission. Intriguingly, in fact, we observe opposite alterations in functional connectivity (FC) between remitting and non-remitting patients compared to controls. We provide evidence suggesting that these alterations may arise due to the loss of heterogeneity in regional stability, a crucial property for filtering out irrelevant stimuli and preventing excessive network

synchronization while maintaining functional flexibility by relaxing structural constraints. Consequently, we propose that this could represent a compensatory response to the reduced structural conductivity observed in patients. However, the biological mechanisms underlying this phenomena cannot be understood by such a phenomenological model.

Methods: The current work therefore aims to deepen our understanding and interpretation of these findings employing a more biophysically constrained model based on Wilson-Cowan equations. Specifically, we explored the hypothesis that an excitatory/inhibitory (E/I) imbalance underlies this compensatory mechanism. Dysregulation of this balance is in fact considered to be crucially implicated in psychotic disorders, and glutamate and GABA levels have been found to vary in individuals at high genetic risk and in patients at different stages of psychosis (Gonzalez-Burgos and Lewis 2012; Liu et al. 2021). To test our hypothesis, we utilized a biophysically constrained model based on the Wilson-Cowan equations. Through a detailed characterization of model properties and a direct comparison with properties of the Stuart Landau model, we explored the impact of E/I modulation on network synchronization and stimulus processing.

Results: The findings of our model simulations revealed that alterations in E/I balance influenced both local and global network properties, mirroring the effects of changes in the bifurcation parameter as observed in previous analyses. E/I balance regulates the local behaviour of nodes, affecting their stability, their level of activation and the frequency and amplitude of oscillations. Moreover, we show that local E/I is influenced by global coupling of structural connectivity and that in turn local values of E/I modulate nodes' synchronization, thereby affecting functional global dynamics. In particular, lower values of E/I in critical nodes allow for the emergence of complex patterns of functional connectivity and modulate the response to incoming stimuli preventing excessive network synchronization. Disinhibition arising from increased local values of E/I in such nodes could therefore represent a possible mechanism to explain the functional over synchronization observed in patients remitting from a first psychotic episode. These results are consistent with recent literature suggesting that hyperactivity may be recruited as compensation for connectivity deficiencies in psychotic disorders.

Discussion: While future studies will be needed to provide definitive proof for these hypotheses, the current study serves as an initial exploration of the possible network dynamics underlying remission from psychotic episode and suggest a crucial role of E/I balance.

F89. COGNITIVE CONTROL IN EARLY PSYCHOSIS: COMPARING OBSERVED AND MODELED PERFORMANCE OF THE TRANSLATIONAL ORIENTATION PATTERN EXPECTANCY TASK (TOPX)

Jessica Arend*¹, Zoe Liu¹, Olivia Calvin¹, Kaylee Enevold¹, Sadrisha Pandit¹, Anita Kwashie², Caroline Demro¹, Angus MacDonald, III¹

¹University of Minnesota, ²Icahn School of Medicine at Mount Sinai,

Background: The translational orientation pattern expectancy (TOPX) task is an AX-expectancy task variant (also related to AX-CPT and DPX) designed to investigate proactive and reactive cognitive control in individuals with early psychosis and healthy controls. Participants must identify a predominant target sequence (known as AX) of gabor stimuli among more rare, non-target sequences (AY, BX, and BY). BX trials require greater proactive control, whereas AY trials require greater reactive control.

Methods: 121 participants (60 controls, 61 patients; M = 25.5 years old, 55% female, 71% white) completed TOPX as part of a larger ongoing neuroimaging study. We examined

accuracy and response time (RT) by trial type across groups. d' -context and d' -expectancy were calculated to assess use of proactive and reactive control, respectively. We hypothesized that patients would demonstrate lower d' -context (BX/proactive control sensitivity), as well as higher RTs, compared to controls.

Results: Significant effects of trial type were found for accuracy ($F(3,484) = 34.36$, $p < .001$) and response time ($F(3, 484) = 152.9$, $p < .001$). Group effects were present for accuracy ($F(4, 484) = 7.973$, $p = .005$), such that patients had lower accuracy on BX and AY trials compared to controls. Interaction effects were not observed. However, patients demonstrated lower d' -context than controls ($t(155.84) = -18.733$, $p < .001$) as well as lower d' -expectancy ($t(161.65) = -17.144$, $p < .001$). These results held constant at a one-month follow-up visit.

Discussion: Preliminary analyses suggest a partial replication of established cognitive control patterns, largely in support of our hypotheses. Data collection is ongoing as is data analysis, including hierarchical drift diffusion modeling (hDDM). hDDM is a singular analysis that integrates accuracy and reaction times to model within-subject variability. Previous literature shows that people with psychosis have slower drift rates (the rate at which evidence is accumulated to make a decision) and longer non-decision times (response delay) than controls. We will present these data, seeking to replicate previous findings in our early psychosis sample.

F90. A NORMATIVE MODELING APPROACH TO INVESTIGATE ALTERATIONS IN BRAIN ACTIVITY DURING WORKING MEMORY IN SCHIZOPHRENIA

Gabriele De Agazio^{*1}, Thomas Wolfers², Francesco Massari³, Roberta Passiatore¹, Giuseppe Stolfi¹, Giuseppe Blasi³, Leonardo Fazio¹, Teresa Papolizio⁴, Antonio Rampino³, Alessandro Bertolino³, Giulio Pergola⁵, Pierluigi Selvaggi¹

¹University of Bari "Aldo Moro", ²University of Tübingen, ³University of Bari "Aldo Moro", Bari, Italy; ³U.O.C. Psichiatria Universitaria, A.O.U. Consorziale Policlinico di Bari, ⁴IRCCS Casa Sollievo Della Sofferenza, ⁵University of Bari "Aldo Moro", Lieber Institute for Brain Development

Background: Working Memory (WM) impairments are a consolidated finding in Schizophrenia (SCZ) at the level of cognitive performance and related brain activity. Functional Magnetic Resonance Imaging (fMRI) studies found that the patients with SCZ show a shift of the physiological inverted-U-shape response of the Dorsolateral Prefrontal Cortex during WM tasks, associated with inefficient task performance. Case-control studies in psychiatry, however, tend to introduce an artificial symmetry between groups, often assuming variance homogeneity within groups. Instead, ample heterogeneity characterizes SCZ at the level of risk factors, neurobiology, phenomenology, and treatment response. Normative Modeling (NM) addresses heterogeneity by estimating features as functions of a set of covariates, returning "deviations", i.e., the difference between real and estimated feature values. Applications of NM on brain structural metrics have shown that deviations are frequent in patients with SCZ, but highly heterogeneous, occurring largely in non-overlapping regions. Here, we aimed to study WM inefficiency in SCZ via NM for the first time. We hypothesized that SCZ patients would show a pattern of extreme deviations in the WM network when compared to healthy controls (HC). While we did expect a degree of heterogeneity in the deviation distribution, we also hypothesized that SCZ patients would show deviations in brain activity to occur more frequently in the Cognitive Control Network (CCN).

Methods: A sample of 923 subjects (791 HC, 132 SCZ; 483 M, 440 F; aged 14 - 63 years, with a mean age of 28 ± 7.9 years) with fMRI data during the 2-Back task WM, no excessive head motion and task performance above 25% was used to estimate and test WM NM. For each subject, we estimated functional connectivity networks using the Neuromark Independent Component Analysis parcellation. Forty-nine networks were used as features for NM estimation, after removing cerebellar networks. Age, sex, scanner, performance at the 2-Back task and reaction times were used as covariates. NMs were estimated independently for each network using Bayesian Linear Regression and 10-fold cross-validation. We then applied the resulting coefficients to our clinical cohort to calculate the deviation of each subject in each component from the estimated NM, expressed as Z-scores (Zs). Positive Zs indicate increased activity, while negative Zs indicate decreased activity. We defined “extreme deviations” (XZ) as Zs GREATER THAN $|1.96|$. We used permutation-based t-tests to compare XZs and mean Zs between HC and SCZ.

Results: Patients with SCZ had globally more positive XZs than HCs (pFDR = 0.02). The highest rates of overlapping XZs in SCZ were observed in the middle cingulate cortex and in the middle frontal gyrus (MiFG), with an overlapping rate of 7.5% in both regions. Patients also showed significantly more positive XZs than HCs in the whole CCN (pFDR = 0.014). No significant difference between groups was found on negative XZs. We observed significantly increased mean positive deviations in CCN regions such as the inferior frontal gyrus (pFDR = 0.02) and the MiFG (pFDR = 0.04) in SCZ. No significant difference between groups was found on mean negative deviations.

Discussion: Our preliminary findings suggest that the NM framework can parse heterogeneity in SCZ at the functional level using a working memory task. Our results suggest an equal or greater degree of overlap of functional deviations from the norm as compared to NM studies using structural metrics. Further studies with larger sample sizes will help validate these insights and explore fMRI abnormalities in SCZ at the level of individual.

F91. NATURAL LANGUAGE PROCESSING TO DETECT MENTAL STATE EFFECTS OF KETAMINE IN DEPRESSION

Farida Zaher^{*1}, Nicolas Garel², Stephane Richard--Devantoy², Alban Voppel³, Lena Palaniyappan²

¹McGill University, ²Douglas Mental Health University Institute, ³McGill University, Department of Psychiatry

Background: In current psychological practices, mental states are mostly detected through self-reports. This means that individuals only receive help when they actively pursue it and that means we have no objective way of assessing internal mental state changes. In cases of psychosis, this can lead to significant health and economic consequences, because a relapse is only detected when mental states and symptoms become overt. Natural Language Processing (NLP) is a technique that aims to assess the mental states of individuals through text and spoken word. NLP data can be collected from sources such as social media and clinical interviews to examine markers in speech to provide an objective way to identify subtle changes in mental states. Ketamine is a well-established treatment for depression in unipolar and bipolar disorder and is regarded as a model for symptoms of psychosis. Ketamine has been shown to induce difficulties in abstract thinking and speech disturbances, including lack of spontaneity and flow of conversation, as well as formal thought disorder. NLP is highly sensitive to psychedelic states and has the ability to partially predict individual therapeutic outcomes and collect information important for early diagnosis. We propose to use NLP to detect ketamine speech

markers to test: (1) whether ketamine therapy can reduce depression-related features of language, to further studies establishing NLP speech markers as an objective marker of mental states; and (2) the validity of ketamine use as a model of psychosis.

Methods: Speech samples will be collected from 20 patients with depression undergoing ketamine treatment at the Douglas Institute's Ketamine Clinic. A speech sample consisting of story-reading and recall, a picture description task, and a short semi-structured interview will be administered during the baseline and final treatment sessions, before and after ketamine administration, for a total of 4 recordings. The recorded speech will then be transcribed and preprocessed to extract acoustic (pauses in speech, pitch), semantic (word choices), and syntactic (complexity of expressed ideas) markers of speech. Sentiment analysis will also be carried out on the semi-structured interview, to assess the frequency of various mental state clusters (positive and negative emotional tones).

Results: Preliminary results to be determined

Discussion: To date, no study has examined the potential effect of ketamine on objective speech-based markers. This study will help advance the development of objective markers of mental states, further the applications of NLP which can eventually be used to detect relapse before it occurs, test the efficacy of treatment through language analysis, reliably diagnose mental illness, and even contribute to early diagnosis. This study will contribute to future studies examining the linguistic features of treatment-resistant depression in individuals undergoing ketamine treatment and will determine if regular speech recording can help in therapeutic monitoring for depression and psychosis.

F92. COMPLEX SEIZURE DISORDER SYMPTOMS MANIFESTING IN TREATMENT-RESISTANT SCHIZOPHRENIA SPECTRUM DISORDERS IN YOUNG ADULTS WITH PRIOR CANNABIS USE: A CLINICAL OVERVIEW

Sophia Walker^{*1}, Katharine Cutts Dougherty¹, Howard Weiner¹, Suma Srishaila¹, David Rowe¹, Lisa Mann¹, Rocco Marotta²

¹*Silver Hill Hospital*, ²*Silver Hill Hospital, Yale University*

Background: In the last decade, a notable surge in admissions of young adults to our private psychiatric hospital has revealed an intriguing trend. A significant cohort of these individuals, predominantly comprising college students or recent graduates, presents with severe psychiatric symptoms meeting the criteria for Schizophrenia Spectrum Disorder. These cases share a common history of cannabis use, alongside a substantial portion having received treatment for Attention-Deficit/Hyperactivity Disorder and other attentional spectrum disorders, employing stimulants and other medications during their academic tenure. Surprisingly, formal mental status assessments unveil intact cognitive faculties, often demonstrating a high intellectual aptitude, with some individuals functioning at advanced levels, such as completing graduate school. Paradoxically, upon establishing trust, these patients divulge idiosyncratic convictions of embodying special beings, assuming roles like messiahs or even deities.

Methods: Regrettably, conventional treatments, including second-generation antipsychotics and varied medication combinations, have yielded poor responses, necessitating referral to our team specializing in treatment-resistance. As part of the preliminary evaluation, these individuals underwent a comprehensive twenty-question Complex Partial Seizure Checklist (Krusz, 1987), exhibiting response patterns consistent with cases of partial complex seizure disorder, akin to temporal lobe epilepsy, outlined in Lishman's seminal work, "Organic Psychiatry" (2009), which stressed that diagnosis of epilepsy is clinical.

Results: The present case series posits several factors contributing to the recent surge in such cases, including prolonged exposure to high-potency cannabis from an early age, concurrent usage of psychostimulants, cultural and societal influences from platforms like social media, and the potential impact of COVID-19 infection on delicate limbic and frontal brain structures. The analysis and treatment outcomes of eight cases will be synthesized herein. All cases demonstrated exposure to marijuana and nearly all had exposure to psychostimulants. All cases had intact intelligence, ability to abstract, limited negative symptoms, positive symptoms marked by paranoia, grandiosity, and philosophical and existential preoccupations. Furthermore, presentations were marked by sleep impairment, including nightmares, marked episodes of mood instability, bizarre sensory experiences, loss of time, and lack of overt sexual activity despite sexual preoccupation. Notably, all patients sought benzodiazepines, claiming they were beneficial to them, along with cannabis and psychostimulant use, leading to classification as substance induced psychosis. Scores on the twenty-point scale described above were greater than 11 out of 20.

Discussion: Noteworthy in our observations is the efficacy of Clozapine as an intervention; however, its usage is impeded by patients' intolerance towards associated side effects. We concede that such presentations are consistent with schizophrenia; however, the clinical insights gained from these cases sheds light on the complex interplay between numerous environmental factors, seizure-like symptoms, and treatment-resistant manifestations of Schizophrenia Spectrum Disorders. The increased density of cases more recently is intriguing and requires a nuanced approach in their diagnosis and management.

F93. IDENTIFYING CASES OF MENSTRUAL PSYCHOSIS USING ELECTRONIC HEALTH RECORDS

Thomas Reilly^{*1}, Edward Chesney², Amelia Jewell², Philip McGuire³, Ian Brockington⁴

¹*Institute of Psychiatry, King's College*, ²*Institute of Psychiatry, Psychology and Neuroscience, King's College London*, ³*University of Oxford*, ⁴*University of Birmingham*

Background: Menstrual psychosis has been described by numerous case reports. It has been defined as: (i) episodes of psychosis, mania, catatonia or confusion, (ii) with acute onset, (iii) in synchrony with the menstrual cycle, (iv) showing complete recovery within two weeks. However, case reports rely on clinicians to identify, accurately report, and then publish a summary. This is prone to bias and may be unrepresentative of the underlying patient population. The Clinical Record Interactive Search was used to identify patients from Case Register of South London and Maudsley NHS Foundation Trust with menstrual psychosis.

Methods: Keywords were used to search electronic records of patients within this large mental health trust, for example, 'premenstrual', 'menstrual', 'catamenial', 'menses', 'menarche') adjacent to ('psychosis', 'psychotic', 'mania', 'manic', 'catatonia', 'catatonic'). Next, a search of cases diagnosed with a psychotic disorder was performed, using the search terms 'premenstrual', 'menstrual', 'catamenial', 'menses', 'menarche'. Clinical records, including emergency assessments, progress notes, ward rounds, clinic letters, and discharge summaries were reviewed. Cases were included if they met criteria for menstrual psychosis. Patients who had menstrual exacerbation of a chronic psychotic disorder (without full recovery between episodes) were excluded. Demographic and diagnostic information were extracted from the clinical records.

Results: The initial search returned 472 patient records. Of these, 364 were immediately excluded: 55 had no link with the menstrual cycle, 283 had no evidence of psychotic symptoms, 25 were irrelevant records. Of the 108 records in which a patient, family member or clinician

reported a link between symptoms and the cycle, 68 were exacerbation of an underlying chronic illness, four were likely premenstrual dysphoric disorder or premenstrual syndrome, two did not have enough information, and 34 met criteria for menstrual psychosis. In 16 cases, the clinical team explicitly documented a diagnosis of menstrual psychosis, though none were published in the literature as case reports. The most common diagnosis of cases was schizophrenia spectrum disorder (48.5%), followed by bipolar disorder (27.3%). This was similar to patients with menstrual exacerbation, 68.1% of whom were diagnosed with schizophrenia and 20.8% with bipolar disorder. The modal age of onset of menstrual psychosis was 14, median 17 (interquartile range 14-25.3), while the modal age of onset for patients with a diagnosis of menstrual exacerbation was 16, median 21 (interquartile range 17-27.3). There was a borderline difference in age of onset between groups (Wilcoxon rank sum test with continuity correction $p=0.05$).

Discussion: This study is the first to identify cases of menstrual psychosis using searches of electronic health records from a single mental health trust. This identified 34 cases which met pre-specified criteria, with a larger number of patients identified who had menstrual exacerbation of an underlying disorder. In approximately half of the cases, the treating clinicians recognised the diagnosis of menstrual psychosis, though notably none of these cases were published as case reports. This suggests the published literature is a gross underestimation of the true incidence of this disorder. Some features are consistent with previously published cases. Peak onset was in early adolescence, slightly earlier than the illness onset of patients with menstrual exacerbation. In contrast with the published cases, the most common ICD-10 diagnosis was schizophrenia spectrum disorders.

F94. THE PLEASURE EXPECTANCIES SCALE (PLEX): EXAMINING THE RELIABILITY AND VALIDITY OF A SELF-REPORT MEASURE OF LOW EXPECTANCIES FOR PLEASURE IN SCHIZOPHRENIA

Sarah Saperia^{*1}, Alex Prosserman², Konstantine Zakzanis³, Margaret Hahn⁴, Mahavir Agarwal⁴, George Foussias⁴

¹*Centre for Addiction and Mental Health, University of Toronto Scarborough*, ²*Centre for Addiction and Mental Health*, ³*University of Toronto Scarborough*, ⁴*Centre for Addiction and Mental Health, University of Toronto*

Background: According to the cognitive model, negative symptoms are conceptualized as maladaptive compensatory responses to dysfunctional beliefs, expectancies, and appraisals. Implicated within this model are low expectancies for pleasure, which refer to a set of unhelpful beliefs characterized by low levels of anticipated enjoyment and generally negative expectations for experiences of pleasure. While this hypothesized belief system derives from a growing body of research suggesting that motivational and hedonic deficits in schizophrenia are reflective of reductions in anticipatory pleasure, there is concern that existing measures may actually be tapping into one's disposition towards experiencing pleasure in-the-moment while anticipating future events, as opposed to the beliefs and expectancies one holds regarding their likelihood and/or capacity to experience pleasure. To this end, the goal of the current study is to test the reliability and validity of a new brief measure, titled the Pleasure Expectancies Scale (PLEX), evaluating low expectancies for pleasure in schizophrenia.

Methods: Seventy nine participants with schizophrenia-spectrum disorder have been recruited to date. After excluding invalid responders, the sample consisted of 68 participants. All participants were administered the 8-item PLEX, along with a battery of other self-report and observer-rated measures. Cronbach's alpha was calculated to evaluate the scale's internal

consistency. Convergent validity was assessed using the anticipatory subscale of the Temporal Experience of Pleasure Scale (TEPS), as well as the future anticipation subscale of the Savoring Beliefs Inventory (SBI), while discriminant validity was examined using the positive symptom and excitement subscales of the Brief Psychiatric Rating Scale (BPRS). To confirm the relationship hypothesized by the cognitive model, bivariate correlations were conducted between the PLEX, the negative symptom subscale of the BPRS, as well as the Motivation and Pleasure Scale – Self-Report (MAP-SR). Finally, a hierarchical multiple regression analysis was run to test the predictive value of the PLEX on the MAP-SR, above and beyond the effects of the TEPS and SBI anticipatory subscales.

Results: The reliability of the scale was acceptable at $\alpha = 0.76$. Convergent validity was demonstrated, with significant inverse correlations between low expectancies for pleasure on the PLEX with the anticipatory pleasure subscales of the TEPS ($r = -0.37$, $p = 0.002$) and SBI ($r = -0.42$, $p < 0.001$). Discriminant validity was also demonstrated, as indicated by the non-significant correlations between the PLEX and the BPRS positive symptom subscale ($r = 0.13$, $p = 0.28$) and excitement/mania subscale ($r = 0.04$, $p = 0.77$). Significant correlations also emerged between the PLEX and BPRS negative symptom subscale ($r = 0.33$, $p = 0.006$) and MAP-SR ($r = 0.45$, $p < 0.001$). The results of the hierarchical multiple regression analysis revealed that the PLEX significantly contributed an additional 10% of the variance in MAP-SR scores after accounting for the TEPS and SBI anticipatory subscales, with the final model significantly accounting for 24% of the variance ($F(3,66) = 6.67$, $p < 0.001$), and with only the PLEX emerging as a significant predictor ($\beta = 0.36$, $p = 0.006$).

Discussion: Preliminary results suggest that the PLEX is a promising new brief self-report measure of low expectancies for pleasure, with good reliability and validity. Importantly, the PLEX overcomes the issues with existing measures of anticipatory pleasure by more explicitly tapping into beliefs and expectancies about pleasure, and contributes unique variance to self-reported motivational and pleasure deficits beyond that accounted for by these other measures.

F95. AN OBSERVATIONAL STUDY USING THE RADIOLIGAND [11C]UCB-J FOR IMAGING SYNAPTIC DENSITY IN PATIENTS WITH A PSYCHOTIC DISORDER AND THEIR HEALTHY SIBLINGS

Monique van der Weijden-Germann^{*1}, Erik De Vries², Chris W. J. van der Weijden³, Sanne Brederoo⁴, Carl M. Sellgren⁵, Iris E.C. Sommer⁶

¹University of Groningen, University Medical Center Groningen (UMCG), ²Department of Nuclear Medicine and Molecular Imaging, University of Groningen, University Medical Center Groningen, Groningen, the Netherlands, ³Department of Radiology and Department of Nuclear Medicine and Molecular Imaging, University of Groningen, University Medical Center Groningen (UMCG), Groningen, The Netherlands, ⁴University Center of Psychiatry, University Medical Center Groningen (UMCG), Groningen, The Netherlands, ⁵Department of Physiology and Pharmacology, Karolinska Institutet, Stockholm, Sweden, ⁶Department of Psychiatry, University of Groningen, University Medical Center Groningen (UMCG), Groningen, The Netherlands

Background: The majority of patients with schizophrenia (SCZ) suffer from global disabling cognitive symptoms affecting multiple cognitive domains. Recent studies assessing the pathophysiology underlying cognitive deficits in SCZ highlight the crucial role of a genetically overexpressed complement compound C4 which leads to excessive complement-mediated

microglial synaptic pruning. Such a faulty programmed pruning process may further result in a decrease of synaptic density, and ultimately leads to impaired cognitive functioning. Whereas a recent [11C]UCB-J PET-study confirmed the consequential loss of synaptic density in patients with SCZ, the effect of the genetic predisposition for SCZ on unaffected relatives remains unclear. In an attempt to disentangle genetic vulnerability from secondary disease and medication related effects, the current investigation assessed synaptic density using [11C]UCB-J PET-scans and cognitive functioning in SCZ patients, their healthy siblings, and healthy controls.

Methods: The present mono-center, cross-sectional observational study enrolled N = 75 participants aged between 26 – 65 years. Patients were diagnosed with schizophrenia, schizoaffective disorder, or a schizophreniform disorder. All participants underwent cognitive testing, an [11C]UCB-J PET-scan, and an T1w-MRI-scan for anatomical reference. PET-images were corrected for motion, co-registered with T1w-images, and segmented. Non-displaceable binding potential (BPND) images were estimated using the Simplified Reference Tissue Model 2 (SRTM2) with the centrum semiovale as a reference region. Per group, regional and whole cortex mean BPND were computed and an ANCOVA with years of education as covariate was used to compare the whole cortex mean BPND between the groups.

Results: Albeit sex ($p = 0.147$) and age ($p = 0.138$) did not significantly differ between the groups, the healthy sibling group significantly differed from the SCZ group in terms of years of education. That is, healthy siblings (15.24 ± 1.3) had significantly higher number of years of education ($p = 0.017$) compared to SCZ patients (13.6 ± 3.3). The whole cortex BPND turned out to be significantly lower in patients with SCZ (2.90 ± 1.42) compared to their healthy siblings (3.08 ± 1.52 , $p = 0.012$) and compared to healthy controls (3.26 ± 1.60 , $p < 0.001$). Strikingly, healthy siblings were found to have a significantly lower whole cortex BPND as compared to healthy controls ($p < 0.001$). Furthermore, the right putamen, left nucleus accumbens, and the right posterior cingulate cortex showed the highest BPND across all groups.

Discussion: The current investigation provides a first in-vivo assessments of synaptic density in patients with psychotic disorders and their unaffected siblings. Our results demonstrate a significantly decreased synaptic density in patients with SCZ as well as in their healthy siblings as compared to healthy controls, which further supports the notion of a genetic vulnerability for SCZ which leads to aberrant complement-mediated microglial synaptic pruning. This renders the pruning machinery as a potential target for early treatment and prevention strategies. Based on the peak of excessive pruning in late adolescence and early adulthood, interventions aimed at preventing over-pruning may prove most beneficial early on in adolescent individuals who are at high risk to develop SCZ. As a crucial next step, future analyses of the present study will provide more insight into whether the loss of synapses may be related to decreased cognitive functioning in SCZ and their healthy siblings.

F96. THE LONGITUDINAL STRUCTURE OF NEGATIVE SYMPTOMS IN TREATMENT RESISTANT SCHIZOPHRENIA

Noham Wolpe^{*1}, Aya Vituri¹, Peter Jones², Moni Shahar¹, Emilio Fernandez-Egea²

¹Tel Aviv University, ²University of Cambridge

Background: The negative symptoms of schizophrenia are strong prognostic factors but remain poorly understood and treated. Five negative symptom domains are frequently clustered into the motivation and pleasure (MAP) and emotional expression (EE) ‘dimensions’, but whether this structure remains stable and behaves as a single entity or not remains unclear.

Methods: We examined a cohort of 153 patients taking clozapine for treatment-resistant schizophrenia in a regional mental health clinic. Patients were assessed longitudinally over a mean period of 45 months using validated scales for positive, negative and mood symptoms. Network analyses were performed to identify symptom ‘communities’ and their stability over time. The influence of common causes of secondary negative symptoms as well as centrality measures were also examined.

Results: Across patients at baseline, two distinct communities matching the clinical domains of MAP and EE were found. These communities remained highly stable and independent over time. The communities remained stable when considering psychosis, depression, and sedation severity, and these causes of secondary negative symptoms were clustered into the MAP community. Centrality measures also remained stable over time, with similar centrality measures across symptoms.

Discussion: Our results suggest that MAP and EE are independent domains that remain highly stable over time in chronic schizophrenia patients treated with clozapine. Common causes of secondary negative symptoms mapped onto the MAP domain. Our results emphasise the need for clinical trials to address either MAP or EE, and that treating causes of secondary negative symptoms may improve MAP.

F97. PROSODIC CUES ARE LINKED TO PECULIAR SUBJECTIVE EXPERIENCES IN SCHIZOPHRENIA: A COMBINED ACOUSTIC AND PHENOMENOLOGICAL ANALYSIS

Valeria Lucarini^{*1}, Martine Grice², Jalal Al-Tamimi³, Francesco Rasmi⁴, Stefano Amorosi⁴, Nikolas Fascendini⁴, Carlo Marchesi⁴, Linda Scoriels⁵, Matteo Tonna⁴, Marie-Odile Krebs¹

¹*Université Paris Cité, Institute of Psychiatry and Neuroscience of Paris (IPNP), INSERM U1266*, ²*IfL-Phonetics, University of Cologne, Cologne, Germany*, ³*LLF, CNRS – UMR 7110*, ⁴*University of Parma*, ⁵*Université Paris Cité - Laboratoire de Psychologie du développement et de l'éducation de l'enfant*

Background: Automated linguistic analysis in patients with schizophrenia is an extremely rapidly evolving research field. Peculiarities in patients’ speech have been identified at various levels, including prosody, also referred to as tone of voice. Although there is evidence of different prosodic patterns between patients and healthy controls, results are contradictory, analyses are often limited to few cues, and the association with psychopathological dimensions has been poorly investigated. Moreover, the relationship with experiential anomalies, considered by the phenomenological tradition to be at the core of schizophrenia but still scarcely assessed in clinical and research contexts, has never been explored.

Methods: We enrolled 58 participants, all native Italian speakers (29 healthy controls – HC; 29 patients with schizophrenia – SCZ) at the University Hospital of Parma. We obtained high-quality dual channel audio files from recorded interviews between each participant and a clinician. Praat software was used to extract an extensive range of acoustic features from 4 prosodic domains (temporal profile, intonation range, intonation variability, voice quality). Patients underwent a thorough psychopathological exploration with the Positive and Negative Syndrome Scale for Schizophrenia (PANSS), the Examination of Anomalous Self Experience scale (EASE) and the Autism Rating Scale (ARS). (Protocol approved by the AVEN, Emilia-Romagna region ethics committee, 05/05/2021 code:1235/2020/SPER/AUSLPRLANG_20.)

Results: SCZ and HC significantly differed in temporal profile and intonation variability (e.g. speech rate $t = 2.72$, $p < .01$; total nuclei duration $t = 3.32$, $p < .01$; total internuclei duration $t = 4.59$, $p < .001$; total pause duration $U = 169$, $p < .001$; glissando $t = 2.51$, $p < .01$; intrasyllabic trajectory $t = 2.39$, $p < .05$). We did not find differences in intonation range and voice quality patterns. Prosodic patterns were correlated with negative (e.g. pitch range and PANSS negative score $\rho = -0.599$, $p < .001$) and disorganization dimensions (e.g. pitch range and PANSS disorganization score $\rho = -0.510$, $p < .001$, F0 mean and PANSS disorganization score $\rho = -0.421$, $p < .001$) but not with positive symptoms. Moreover, we found significant associations with the EASE and ARS scores, especially with stream of consciousness, ipseity and attunement anomalies (e.g. speech rate and EASE total score $\rho = -0.460$, $p < .01$, total internuclei duration and EASE total score $\rho = -0.486$, $p < .001$).

Discussion: We showed for the first time that Italian-speaking patients with schizophrenia display significant differences from healthy controls in a number of prosodic patterns, prosodic cues being associated with negative and disorganization symptoms. Also, for the first time, we showed significant associations in the relationship between prosody and subjective experiential anomalies. Our results suggest that communication features are deeply intertwined with core symptoms and subtle deep subjective peculiar experiences in schizophrenia. This underscores the need for research projects on speech analyses in psychiatric conditions that are strongly interdisciplinary in both design and conduct, using appropriate linguistic techniques and including accurate psychopathological evaluations.

F98. A SYSTEMATIC REVIEW OF NON-VERBAL CORRELATES ASSOCIATED WITH PARANOID IDEATION

Ron Haarms^{*1}, Hannah Jongsma¹, Chris Geraets¹, Wim Veling¹

¹UMCG

Background: Diagnostic instruments that help classify psychotic disorders, such as paranoid ideations, are heavily reliant on language-based assessments (e.g. interviews or questionnaires). During the florid stage of the illness healthcare professionals rely on their clinical experience for a diagnosis. However, interviews and self-report questionnaires strongly rely on patients' memory, current mental state, self-understanding, and insight. Ideally, auxiliary methods in the form of observations of non-verbal behaviours could provide supplemental evidence for the diagnosis. In order to be able to develop novel non-verbal diagnostic tools that are valid, knowledge about non-verbal correlates and their association with paranoid delusions is needed. The aim of the paper is to create an overview concerning all non-verbal correlates associated with paranoid delusions and to critically review them.

Methods: The systematic literature review followed the PRISMA guidelines and the protocol was registered with PROSPERO (CRD42022288001). Articles were included if they concerned qualitative or quantitative research in people with clinical or subclinical levels of paranoia. Assessed non-verbal correlates were measured using a non-verbal method in a standardised way, thereby excluding (self-report) questionnaires and interviews. Screening was done in duplicate and data was extracted using a standardised format.

Results: The search strategy yielded 4286 potentially eligible titles, from which 21 studies were selected to fit with inclusion criteria. The included studies considered the following non-verbal correlate themes: visual perception ($n=5$), spatial behaviour ($n=7$), physiology and distress ($n=4$), information processing ($n=5$), and other ($n=5$), some studies covered multiple

themes. Patients with paranoid delusions exhibited significant differences in visual perception compared to controls, specifically in ambiguous social scenes. Overall, the evidence suggests that paranoia influences social approach and avoidance behaviours, impacting both proxemics and responses to emotional stimuli (spatial behaviour). However, findings on physiological measures and information processing were mixed.

Discussion: The current evidence emphasizes the multifaceted nature of paranoia, shedding light on its diverse manifestations across various non-verbal domains. These outcomes underscore the potential of a diagnostic framework that assesses behavioural dimensions. Further research is needed, amongst others, to inquire the applicability of non-verbal approaches.

F99. TUNING TO THE VOICE: DISTINGUISHING SUBTYPES OF AUDITORY VERBAL HALLUCINATIONS TO GUIDE TAILORED TREATMENT

Sanne Brederoo*¹

¹*University Medical Center Groningen*

Background: With a lifetime prevalence of around 10%, the experience of auditory verbal hallucinations (AVH) is quite common. For about one third of the people who hear AVH, these cause suffering to the extent that they seek treatment for it. A wide array of psychological therapies exists aimed at decreasing the occurrence and resulting distress of voice-hearing, each through different methods. Examples are cognitive behavioural therapy (CBT)-based therapies (e.g., CBT, Acceptance and Commitment Therapy), and ‘dialoguing’ therapies (e.g., Voice Dialogue and Avatar Therapy). Unfortunately, these one-size-fits-all treatment approaches have not proven sufficiently effective in countering the often-debilitating effects of AVH, as evidenced by their small-to-modest effect sizes. As a result, some voice-hearers enter lengthy treatment trajectories from which they do not profit, causing further distress and damaging their confidence in mental health care. However, arguably each of these therapies in fact does have its own merit, but they are not yet effective to their full potential because they are not prescribed for the type of voices that they best target.

The core shared feature of all AVH is that they are linguistic in nature. Intriguingly, linguistic differences are also what sets AVH apart from each other, but in current clinical practice there is no appreciation of this fact. In a recent study, a data-driven approach showed that linguistic characteristics can be used to distinguish different ‘voice-types’ that align with clinical impressions. Some AVH are ‘compact’ –they are short utterances with little grammatical complexity, sometimes consisting of short commands or swear words. Other AVH are ‘expanded’ –they are longer and more complex utterances, and resemble the way we speak to each other. Not only do these results suggest the existence of different voice-types, they may also explain previous discrepant findings regarding underlying working mechanisms of voice-hearing. Some research posits that AVH originate in the right cerebral hemisphere –which is nondominant for language. This finding aligns with the linguistic presentation of ‘compact’ AVH, as language that the non-dominant right hemisphere can produce is very simple in nature. However, more ‘expanded’ AVH arguably do not originate from the right-hemisphere, as this hemisphere is incapable of such complex language. Different voice-types likely have different neural origins, but, importantly, they also presumably call for different types of treatment. As a case in point, a person who hears short and repetitive utterances may not profit from a therapy based on the principle of engaging in dialogue with the voice in the way that a voice-hearer

with ‘expanded’ AVH will: offering Voice Dialogue or Avatar therapy to a ‘compact’-voice-hearer will likely result in suboptimal treatment. The key to improvement may lie in providing the treatment that is tailored to the type of AVH people hear. The presented study aims to distinguish and characterize different voice-types, examine differential neural working mechanism of voice-types, and evaluate the role of voice-type in treatment effectiveness.

Methods: A sample of $n = 146$ voice-hearers will be recruited. Verbatim repetitions of the AVH will be collected and transcribed, and then subjected to a data-driven clustering analyses based on linguistic features. The assessed linguistic features include pronouns, time references, content, and structure measures, function word classes, and content word classes. In addition, voice-related measures will be collected using the PSYRATS-AHRS and the Revised Beliefs About Voices Questionnaire. Lateralization of cortical language areas will be measured using functional near-infrared spectroscopy (fNIRS) during a dichotic listening task. Finally, voice-hearers will receive their psychological therapy as planned, and a pre- and post-assessment (10 weeks) will be done to evaluate treatment effectiveness using the Voices Impact Scale.

Results: The results are hypothesized to show at least two different voice-types based on the linguistic analyses. A ‘compact’ voice-type is expected to be associated with more right-hemisphere involvement. Dialoguing therapies are expected to be more effective for ‘expanded’ than for ‘compact’ voice-types.

Discussion: The outcomes of the study are expected to yield strong added value for both clinical practice and fundamental research.

F100. A NETWORK ANALYSIS OF PSYCHOSIS SYMPTOMS AND POST-TRAUMATIC SEQUELAE AMONG THERAPY-SEEKING INDIVIDUALS PRESENTING WITH COMORBID PSYCHOSIS AND POST-TRAUMATIC STRESS DISORDER

Rachel Frost¹, Ciaran O'Driscoll², Emmanuelle Peters^{*1}, Amy Hardy¹, STAR (Study of Trauma And Recovery) Research group³

¹*Institute of Psychiatry, Psychology and Neuroscience, King's College London*, ²*University College London*, ³*London, Manchester, Newcastle, Oxford and Sussex*

Background: Post-traumatic sequelae are theorized to contribute to the development and maintenance of psychosis symptoms. There is limited research evaluating the relationship between psychosis symptoms and multiple post-traumatic sequelae simultaneously. Specifically, there has been little investigation of the relative contribution of core post-traumatic stress disorder (PTSD) symptoms (re-experiencing, hyperarousal and avoidance) and those reflective of complex PTSD, operationalized as ‘disturbances of self-disorganization’ (DSO) in ICD-11 (negative self-concept, relationship difficulties, and affective dysregulation). This study employed network analysis to examine interactions between psychosis, core post-traumatic stress, and complex post-traumatic symptoms. It was predicted that trauma-related beliefs would have the greatest predictability in the network, based on previous evidence suggesting they have a stronger role in psychosis relative to other post-traumatic sequelae. Accordingly, it was also hypothesised that the association between voices and trauma-related beliefs would be greater than the association between voices and re-experiencing.

Methods: The study utilized baseline data from a randomized controlled trial evaluating an integrated Trauma-Focused Cognitive Behaviour Therapy for Psychosis, the Study of Trauma and Recovery (STAR trial). The sample comprised 305 individuals meeting criteria for ICD-10 schizophrenia-spectrum disorder (F20-29) and DSM-V PTSD and presenting with

distressing hallucinations and/or delusions. A network was estimated comprising psychosis symptoms (delusions and voices), using the frequency factor items (Woodward et al, 2014) of the Psychosis Symptom Rating Scales (PSYRATs; Haddock et al, 1999); core post-traumatic stress and DSO symptoms, assessed using the International Trauma Questionnaire (ITQ; Cloitre et al, 2018); trauma-related beliefs (negative cognitions about the self and world, and self-blame), assessed using the Post-Traumatic Cognitions Inventory (PTCI-9; Wells et al, 2019).

Results: The hypotheses were not supported. All symptoms had similar predictability scores so it was not possible to discriminate symptom centrality. There was no evidence for conditionally dependent relations between re-experiencing and voices, nor between trauma-related beliefs and voices, suggesting no difference between these associations. However, delusions had a positive direct connection with self-blame whilst voices had positive direct connections with affective dysregulation (including numbing) and avoidance (including internal suppression). Further analysis demonstrated that affective dysregulation predicted hallucinations whilst self-blame predicted delusions.

Discussion: Unlike previous findings, there was no evidence of trauma-related beliefs being of greater centrality in the network, relative to other symptoms; nor was there indication of trauma-related beliefs being linked to voices. Variation in symptom presentation within the sample may hinder accurate representation in networks; identifying subgroups with similar symptom profiles may improve reliability. Notably, there were no direct associations between the ‘core’ re-experiencing symptoms of PTSD and psychosis symptoms either. However, self-blame, a type of trauma-related belief, and affective dysregulation, may be key mechanisms influencing the maintenance of delusions and voices, respectively. The findings may have implications for psychological interventions, as targeting specific post-traumatic stress sequelae could reduce psychosis symptoms, but further research is required to test this hypothesis.

F101. SUBJECTIVE DISTURBANCES OF IMAGINATION IN SCHIZOPHRENIA-SPECTRUM DISORDERS: RECENT EMPIRICAL INVESTIGATIONS

Andreas Rasmussen*¹

¹*Mental Health Center Amager*

Background: Patients often report distressing or functional impairing imaginative experiences such as vivid intrusive images, aggressive fantasies or extensive daydreaming. In 20th century psychiatry, various aberrations of imagination were discussed in the context of schizophrenia. Thus, Bleuler included this domain under the concept of autism defined as a detachment from reality linked with a predominance of the inner life. Jaspers discussed the so-called pseudo-hallucination as an intermediate phenomenon between imagination and hallucination. And, within neurocognitive research, aberrations of imaginative processes have been proposed to underlie development of delusions and hallucinations, most recently articulated under the notion of source monitoring deficits. However, none of these approaches have explored the subjective (experiential) character of imagination in schizophrenia. Psychopathology lacks concepts for this domain, and the rich variety of these complaints is only partly captured by notions such as obsession and rumination.

Methods: An overview of recent empirical research addressing subjective disturbances of imagination in schizophrenia-spectrum disorders.

Results: Phenomenological-qualitative studies of imagination and fantasy life in patients with schizophrenia-spectrum disorders have recently articulated several phenomena that appear to

have received little attention in the previous literature. These include a characteristic spatialization of mental imagery and fantasy experience. Thus, imagery is described as temporally stable with a highly articulated spatial character and autonomous development. Furthermore, patients report a variety of subtle and transient subjective disturbances of the tacit discrimination of fantasy life from other modalities such as memory or an insecurity of such discrimination. These psychopathological concepts have received more systematic support in a recent empirical study that found that these subjective disturbances of imagination aggregate selectively in patients with schizophrenia-spectrum disorders compared to other mental disorders or healthy controls. Moreover, they are retrospectively reported to have an early onset, several years before clinical contact, and to be involved in patients' account of the formation of delusions and hallucinations. A semi-structured interview, the Examination of Anomalous Fantasy and Imagination (EAFI), addressing these disturbances has been developed. This instrument has been found to have good-excellent reliability and internal consistency. Finally, it has been argued that subjective disturbances of imagination reflect the same disorder of subjectivity as disorders of basic self.

Discussion: These notions addressing subjective disturbances of imagination facilitate an awareness of the lived experience of patients with a schizophrenia-spectrum disorder, crucial to clinical work. Moreover, these disturbances have a potential clinical relevance for differential diagnosis and early detection. Future studies should address their temporal trajectory and possible longitudinal associations with self-disorders and other schizophrenia-spectrum psychopathology.

F102. SCHIZOPHRENIA: WHEN NO DIFFERENCES MAKE THE DIFFERENCE

Simona Garobbio^{*1}, Dario Gordillo¹, Maya Roinishvili², Eka Chkonia³, Andreas Brand¹, Michael H Herzog¹

¹*École Polytechnique Fédérale de Lausanne (EPFL)*, ²*Beritashvili Centre of Experimental Biomedicine, Free University of Tbilisi*, ³*Free University of Tbilisi, Tbilisi State Medical University*

Background: The common practice of only publishing significant results often leads to the impression that patients with schizophrenia have deteriorated performance in the majority of paradigms. Identifying intact functions is, therefore, not only important to avoid stigmatization of the patients but also to obtain a clear-cut picture of what is and what is not impaired in the disease.

Methods: We run a battery of tests targeting many aspects of visual information processing to investigate what is and what is not impaired in schizophrenia, and in addition we report some previous results from our group. We tested tasks that require high attention and for which accuracy was measured, as well as tasks addressing the subjectivity of perception and for which bias rather than sensitivity was determined.

Results: In the attention-demanding tasks, schizophrenia patients showed intact performance in two out of three tasks (i.e., in contextual modulation and complex motion processing, but not in visual backward masking). In tasks targeting the phenomenology of schizophrenia, patients showed intact performance in four studies: bodily self-representation during changes in body ownership induced by prolonged multisensory stimulation, perception of illusions, impulsivity as tested by a delay-discounting task, and an occlusion task where participants indicated if a dot traveling from left to right describing a concave-up curved trajectory would

reappear above or below a tick-mark after occlusion. Differences between patients and controls were found in two subjective tasks: ambiguous figures and free viewing.

Discussion: Our findings indicate that there is no general impaired mechanism in schizophrenia, as patients showed both intact and deteriorated visual processing. Although patients with schizophrenia are often thought to perceive the world very differently than controls, such as strongly fragmented in time and space, we show that this is not always the case. It is important for a holistic understanding of schizophrenia to publish null results, i.e., studies where patients are not impaired and hence there are no significant group differences. Understanding the intact mechanisms will help understanding the abnormal ones.

F103. VALIDATION OF SELF-REPORT ITEMS TO ASSESS SELF AND REALITY EXPERIENCES IN PSYCHOSIS

Dan-Andes Bekkering-Bauer*¹, Marieke (Gerdina) Pijnenborg¹, Jasper Feyaerts², Lisette Van der Meer¹

¹University of Groningen, ²Ghent University

Background: Psychosis poses a substantial societal burden, prompting the identification of individuals at ultra-high risk (UHR) for psychosis. However, UHR criteria are grounded in a third-person approach which limits the capturing of nuanced subjective experiential alterations reported by individuals with lived experiences of psychosis. Advocating for a paradigm shift, phenomenological researchers emphasize the active meaning-making process and experiential dimensions of self and reality in psychosis. Self and reality related experiences can be assessed with self-report instruments, such as the Examination of Anomalous Self Experience (EASE) which translates anomalous self and reality experiences into a semi-structured interview. However, the EASE does not allow for the assessment of temporal patterns and changes over time. Therefore, our research aims to systematically explore and document anomalous self and reality experiences reported by individuals at ultra-high risk and those with lived experiences of psychosis. Based on the resulting data, we will develop and validate self-report assessments of anomalous experiences, and elucidate necessary adaptations for deployment in experience sampling methods (ESM) to enable the capture of moment-to-moment fluctuations in anomalous self and reality experiences in a future study.

Methods: This qualitative exploratory study addresses four research questions concerning anomalous self and reality experiences. An interview guide will be developed through discussions with experience-experts from December 2023 to February 2024. Qualitative semi-structured interviews in February and March 2024 will explore self and reality experiences in 10 individuals (UHR and first-episode psychosis), employing thematic analysis with inductive and deductive coding schemes. The identified themes will inform the development of self-report items which will be validated for use in an experience-sampling study.

Results: We will present a set of validated items that can be used to assess self-disturbances in psychotic disorders.

Discussion: Study outcomes will be helpful in enhancing our understanding of the daily self and reality related experiences of individuals with psychosis. These items will be used in future studies, to assess the interplay between these experiences over time and the association between these items and transition to psychosis.

F104. EFFECT OF AEROBIC EXERCISE INTENSITY COMBINED WITH SOCIAL COGNITIVE SKILLS TRAINING ON SOCIAL COGNITION AMONG SCHIZOPHRENIA PATIENTS

Lya Ehrenfeld*¹, Avraham Munitz¹, Yuri Rassovsky²

¹Bar-Ilan University, ²UCLA/Bar-Ilan University

Background: Patients with schizophrenia typically display a wide range of cognitive impairments, including both deficits in social and non-social cognition. While both social and non-social cognitive impairments are associated with poor community functioning, social cognition is more closely related to daily functioning than non-social cognition in schizophrenia. Therefore, interventions designed to improve social cognitive functioning may have important impact on the clinical and functional outcome of these individuals. To this end, a social cognitive skills training (SCST) program for patients with schizophrenia. While showing promising results, individual heterogeneity remains. Aerobic exercise (AE) was suggested as an augment to SCST since it previously showed a positive effect on social cognition. Thus, here we will evaluate the augmenting effect of AE on SCST in patients with schizophrenia.

Methods: Schizophrenia patients were recruited from major psychiatric hospitals and other local community care facilities. Subjects were randomly assigned to one of two conditions: (1) moderate-intensity continuous training (MICT) + SCST, and (2) low-intensity stretching exercise control condition (SE) + SCST. Participants exercised in small groups (4-6 participants), followed by SCST administered in the same group. The intervention was 2 days per week, for a total of 12 weeks. Assessments include the Penn Emotion Recognition Task (ER-40), Hinting Task and The Intentional Bias Task (IBT) and were administered at baseline, at midpoint after 6 weeks, and at completion of 12 weeks of training.

Results: A two-way repeated measures ANOVA was performed for each of the social cognition assessments (ER-40, Hinting Task and IBT). In each model, the within-subjects factor was time (pre vs. post) and the between-subjects factor was condition (MICT vs. SE). While there were no significant effects, each model showed a non-significant trend towards greater improvement in the MICT group.

Discussion: Preliminary results suggest a trend towards a greater improvement in social cognition following the intervention in the MICT group compared to the SE group. Whether this trend becomes statistically significant will be seen upon further data collection. Altogether, this research has the potential to provide a deeper insight into social cognitive remediations for patients with schizophrenia.

F105. SENSE OF ABERRANT SALIENCE AND DELUSIONALITY IN CLINICAL AND NON-CLINICAL POPULATIONS: A SYSTEMATIC REVIEW

Chen Zhu*¹, Suzanne So²

¹Shenzhen University, ²The Chinese University of Hong Kong

Background: Anomalous experience has been theoretically proposed and empirically shown as a relevant factor in the development of delusions. A change of perceived meaning in one's lived experience is commonly reported at the early stage of delusional. Namely, what used to be normal and unremarkable starts to have unusual significance and novelty, and vice versa. Despite the fact that this sense of aberrant salience itself is not a psychotic symptom, it has

been reported to be aggregated in patients with schizophrenia and people high in psychosis proneness. A sense of aberrant salience also tends to be positively associated with the presence of delusions and delusion-like experiences. Its reduction tends to be positively correlated with the likelihood of change in delusions. Of note, such salience is not about hedonic pleasure. While some researchers have proposed that a sense of aberrant salience might be a potential prodromal marker for the development of psychosis, the relationship between a sense of aberrant salience and the severity of delusions remains unclear. Therefore, the current systematic review aimed to collate the empirical evidence on aberrant salience and delusions in clinical and non-clinical samples.

Methods: The systematic review was prepared according to the PRISMA protocol (Liberati et al., 2009; Moher et al., 2009). The inclusion criteria for studies were: measuring and reporting an association between the sense of aberrant salience and delusionality; empirical research; published in peer-reviewed journals; with English text available. Case studies and qualitative studies were excluded. Studies were also excluded if there was insufficient information to compute the effect sizes from their reports and upon request. The inclusion criteria for participants were: adult (aged 18 years or above); with delusions or delusion-like experiences. Clinical participants must be diagnosed with schizophrenia-spectrum and other psychotic disorders. Database search was conducted in November 2018 in PubMed, PsycINFO (1806 -), PsycARTICLES, and Scopus (1823 -) using “aberrant salience AND delusion*”. No limit was applied for the year of application. For all included articles, study characters, participant characters, measures of delusionality, measures of the sense of aberrant salience and effect sizes in Pearson’s r were extracted. The risk of bias was evaluated for each included study.

Results: Out of 451 records, twelve fulfilled the inclusion criteria. Common measures for the sense of aberrant salience included the Aberrant Salience Inventory (Cicero et al., 2010), the Salience Attribution Test (Roiser et al., 2009), the Experience of Aberrant Novelty and Salience (Reininghaus et al., 2016), and the Implicit Salience Paradigm (Katthagen et al. 2016). Overall, the included studies showed an acceptable level of risk of bias. Among six empirical studies that data were available ($N = 2172$), eight effect sizes were extracted (range of Pearson’s $r = 0.45 \sim 0.62$, all ps LESS THAN .05). Patients with higher delusions tended to report a higher sense of aberrant salience. All patients but three in the current review were under antipsychotic treatments at the time of the assessments. However, they still tended to present a sense of aberrant salience.

Discussion: The degree of delusionality and sense of aberrant salience tended to be positively associated in both clinical and non-clinical samples. Considering that most studies focused on the prodromal or early stage of psychosis, the relationship between a sense of aberrant salience and chronic patients awaits further research. There is also limited research on the effect of subtypes of delusional themes and antipsychotics.

F106. USING NATURAL LANGUAGE PROCESSING FOR IDENTIFICATION OF NEGATIVE SYMPTOMS IN SCHIZOPHRENIA FROM ELECTRONIC HEALTH RECORDS DATA IN THE UNITED STATES

Pin Xiang^{*1}, Mona Nili¹, James K Nelson², Carrie W Mills², Cory Pack², Randall Thompson², Joe Vasey², Joseph Parks³

¹Boehringer Ingelheim, ²Veradigm Health, ³National Council for Mental Wellbeing

Background: Schizophrenia is a chronic and debilitating condition characterized by a combination of positive and negative symptoms and cognitive impairment. Negative symptoms (NS) significantly contribute to long-term disability and the diminished functional capacity of

affected individuals. The NS domain includes five main components: blunted affect, avolition, asociality, and anhedonia. The objective of this study is to use natural language processing (NLP) to identify NS in the unstructured electronic health records (EHR) of patients with schizophrenia and to describe their characteristics.

Methods: This retrospective cohort study used patient records from the Veradigm Network EHR database spanning from January 1, 2016, to February 28, 2023. The EHR data used were sourced from ambulatory (outpatient) medical facilities throughout the United States. Adult patients (≥ 18 years) with a minimum of two schizophrenia diagnoses and at least 12 months of EHR activity prior to the first schizophrenia diagnosis (index date) were included. All unstructured texts from patient records during the study period were processed for review. A list of key terms for NS was created in collaboration with medical informatics specialists and clinical experts. For the NLP component of the study, Python scripts converted clinical notes into plain text, and Python NLP libraries segmented this text into sentences to extract context around keywords related to NS. Keywords were evaluated for false-positives using regular expressions and rule-based techniques. Patient characteristics were assessed in the 12 months preceding the index date.

Results: This study included 79,326 schizophrenia patients, with 14,992 (18.9%) having documented evidence of NS. Among those with 50 or more notes available, 41.5% had documented evidence of NS, in contrast to only 2.3% for those with 1-5 notes. Avolition was identified most often (44.0%), followed by blunted affect (41.9%), alogia (25.0%), anhedonia (22.0%), and asociality (5.4%). The most common key terms found included “poor hygiene” for avolition, “flat affect” for blunted affect, “poverty of speech” for alogia, “apathetic” and “loss of interest” for anhedonia, and “withdrawn” and “poor eye contact” for asociality. Patients with documented evidence of NS were slightly younger (49.3 vs. 51.0 years, $p < .01$) compared to those without NS and had slightly higher rates of anxiety (18.7% vs. 15.7%, $p < .01$), depression (19.0% vs. 17.3%, $p < .01$), and substance use disorder (17.7% vs. 15.4%, $p < .01$).

Discussion: This study successfully employed NLP to identify NS from an unstructured EHR database, overcoming the limitations of traditional structured databases. These results highlight the importance of advanced data analytics in psychiatric research, offering new insights into the characteristics of NS in schizophrenia. This study detected overall lower rates of documented evidence of NS. This raises the question of whether the presumed missed information using the NLP approach is due to shortcomings in the usual clinical exam for NS, the number of available notes, or the NLP methodology itself. The pattern of most predominant type of specific negative symptom reported in this study is different than several other studies that reported that decreased emotional expression is more uncommon compared to reduced social motivation. Additionally, this study reported slightly higher rates of other mental disorders in patients with documented evidence of NS. This study informs the need for future treatment strategies and healthcare policies for improving management of NS among patients with schizophrenia.

F107. THE SPATIAL LOCATION OF AUDITORY VERBAL HALLUCINATIONS IN PATIENTS WITH SCHIZOPHRENIA: SELF-REPORT AND CLINICIAN-RATING COMPARISON

In Won Chung^{*1}, Hee Yeon Jung², Se Hyun Kim³, Seong Hoon Jeong⁴, Kyuyoung Lee⁵, Yong Sik Kim⁶

¹Yong-In Mental Hospital, ²SMG-SNU Boramae Medical Center, Seoul National University College of Medicine, Seoul, Republic of Korea, ³Seoul National University College of Medicine, ⁴DaeJeon Eulji University School of Medicine, ⁵Nowon Eulji University Hospital, ⁶NoWon Eulji University School of Medicine, Seoul, Korea

Background: The spatial location of auditory verbal hallucinations (AVHs), whether they come from inside the head (internal) or outside (external), has been thought to be one of the cardinal features that defines the phenomenology of AVHs and is associated with the severity of psychopathology in psychotic disorders.

Methods: We categorized subgroups of patients with schizophrenia according to the spatial location of AVHs as assessed by clinician-rated Psychotic Symptom Rating Scale-Auditory Hallucinations (PSYRATS-AH) and self-report Hamilton Schizophrenia Voice Questionnaire (HPSVQ) assessed on the same day. We compared the distribution of patients between groups categorized by internal, bilateral, and external spatial location according to the two scales, and explored the severity and linearity of scores by spatial location for each group of patients reclassified according to each scale. The main inclusion criterion was a score of 3 or higher on the PANSS-P3 item of hallucinations.

Results: The mean age of the 85 patients was 33.51 ± 9.75 years, and the mean duration of illness and AVH experience was 9.89 ± 6.72 and 9.23 ± 6.85 years, respectively. The patient distributions of 15 (17.6%), 44 (51.8%), and 26 (30.6%) by PSYRATS-AH and 23 (27.1%), 22 (25.9%), and 40 (47.1%) by HPSVQ, respectively, showed a significant difference and the agreement of patient distribution in groups of spatial location between the two scales was somewhat lower. The total scores and emotional component scores in three categorized groups were statistically significantly different and showed clear monotonic increase with increasingly outward localization (internal LESS THAN both LESS THAN external).

Discussion: The different patient distributions and low agreement on spatial locations between two scales are likely due to the different response wording and the ambiguity in the definition of spatial location across scales. Patients with external AVHs had more severe scores on the total and emotional component scores, suggesting greater concern about external AVHs.

F108. VALIDATION OF EPICOG-SCH SCREENING BATTERY IN FIRST EPISODE PSYCHOSIS: COHORT STUDY TO FOLLOW UP COGNITION AND FUNCTIONALITY

Rosa Ayesa-Arriola^{*1}, JULIO Bobes², M PAZ García-Portilla², Rebeca Magdalena-Herrero¹, Angel Yorca-Ruiz³, Manuel De Gracia Blanco⁴, Gemma Escartin Martin G⁵, Víctor Ortíz-García de la Foz¹, Jolanda Ruiz⁶, Silvia Zaragoza Domingo⁷

¹Valdecilla Biomedical Research Institute IDIVAL Research Group on Mental Illness, Marqués de Valdecilla University Hospital, University of Cantabria, ²CIBERSAM UNIVERSITY OF OVIEDO, ³Valdecilla Biomedical Research Institute IDIVAL Research Group on Mental Illness, Marqués de Valdecilla University Hospital, University of Cantabria,, ⁴Faculty of Psychology, University of Girona, Girona, Spain, ⁵Parc Sanitari Sant Joan De Déu, Barcelona, Spain, ⁶Faculty of Psychology, University of Barcelona, Barcelona, Spain, ⁷Neuropsychological Research Organization s.l (Neuropsychro), Barcelona, Spain

Background: Objective the Epidemiological Study of Cognitive Impairment in Schizophrenia (EPICOG-SCH) is a brief battery to screen for cognitive impact of schizophrenia in outpatient settings. The EPICOG-SCH includes well-known subtests available worldwide that cover key cognitive domains demonstrated to be related to a variety of functional outcomes: Letter-

Number-Sequencing-LNS, Category Fluency Test-CFT, Logical-Memory Immediate Recall-LM, and Digit-Symbol-Coding-DSC. A composite score is derived from the battery, which is based on algorithms modelled to predict patient's functionality in daily life. Functional composite scores (FWCS) showed adequate discriminant capacity in identifying patients with up to moderate disability levels with fair discriminant accuracy, areas under the curve (AUC) $\square$ 0.70, p $\square$ 0.0001 from a receiver-operating characteristic (ROC) method. A FWCS cut-off $\geq$ 96 provided the best balance between sensitivity (0.74) and specificity (0.62). We want to confirm the constancy and utility of this method in the context of first episode schizophrenia and at discharge during a follow up period.

Methods: Participants and Methods Data for the present investigation were obtained from the epidemiological and three-year longitudinal intervention program of first-episode psychosis (PAFIP) conducted at the outpatient clinic and the inpatient unit at the University Hospital Marques de Valdecilla, Spain. The cohort is composed by 167 patients with a diagnose of Schizophrenia and 160 healthy controls recruited between February 2001 to February 2014. For all analyses, a subset of measures was selected corresponding to the EPICOG-SCH domains as Letter-Number-Sequencing-LNS, Category Fluency Test-CFT Animals, Digit-Symbol-Coding-DSC and for Verbal Memory it was selected the Rey Auditory Verbal Learning Test (RAVLT) in substitution of Logical Memory not available in the cohort. Functional outcomes were measured by the Disability Assessment Scale (DAS) and the General Assessment for Function (GAF) scales. Functional measurements were conducted regarding premorbid, baseline set at clinical stabilization and 1, 3 year follow-up, and cognitive assessments where conducted at baseline and 1, 3 years of follow up.

Results: All patients included at baseline and a total of 122 patients and 114 Controls completed the study with a 3-year follow up were included in the analysis. We present descriptive of cognitive results by subtests and as composite scores. EPICOG-SCH composite scores were validated using Baseline results. Consistency across evaluations is also tested. A regression analysis including the different EPICOG-SCH subtests at baseline as predictors of functionality at the different time points to explore the best predictive algorithms at 1 and 3 years of patient's functionality in daily life following a first-episode. Results on predictive capacity of baseline cognition of functionality will be compared with previous results, and an additional analysis of functional impact is planned by gender and age ranges.

Discussion: Conclusions The EPICOG-SCH brief battery is administered in less than 20 minutes, proved to be a useful first to screen for the cognitive impact of schizophrenia and second to ascertain the associated functionality in daily life, validated in a cross-sectional cohort and from this study its validity at 1 and 3 years predictive capacity is described. This research work will validate the composite scores for a context of use of first-episodes schizophrenia and follow up. To date it has not been described an efficient and straightforward way for clinicians working with schizophrenia to transfer quantitative information about patient cognitive profile into real life. The EPICOG-SCH modelled FWCS global composite score provides valuable information to clinicians which can facilitate disease management, drawing a roadmap for cognitive rehabilitation, and planning of supportive resources from the community and health care system. Future research is needed to ascertain the utility of this new battery to monitor drug adjustments for outpatients and its corresponding impact on patient functionality. In addition, additional validation work and calibration of the algorithm in different world geographical regions is needed. This will provide a more accurate result reflecting variations on cultural attitudes towards patients suffering from severe mental health disorders in the community.

F109. ASSESSING EARLY-STAGE SCHIZOPHRENIA BASED ON PARALINGUISTIC ANALYSIS OF SPEECH - SYSTEMATIC REVIEW AND CASE STUDY

Julianna Olah^{*1}, Kelly Diederer¹, Thomas Spencer¹, Nicholas Cummins¹

¹*King's College London*

Background: Automated analysis of paralinguistic parameters of speech, combined with contemporary machine learning approaches could aid crucial early interventions in schizophrenia and bipolar disorder. However, the literature has not been synthesised on the efficacy of paralinguistic approaches and reported findings have not been replicated.

Methods: In this study, we first systematically reviewed the literature on paralinguistic analyses and machine learning approaches in schizophrenia. We observed that studies typically applied feature engineering and shallow learning approaches without a reproducible code base. Studies tend to report inflated accuracies (GREATER THAN 0.90) when discriminating between the speech of individuals with a full-blown disorder against the speech of healthy controls, a use-case we argue has limited clinical relevance. We then applied conventional modelling approaches and one deep learning approach (Sch-net) on the task of identifying individuals at elevated risk of developing schizophrenia. Finally, to evaluate the potential of clinical application we also tested the bias of the model for gender, age, education and ethnicity.

Results: 34 papers met our inclusion criteria. Studies that aimed to discriminate healthy control from schizophrenia could achieve high performance (highest accuracy reported was 97%), similar to papers that aimed to discriminate schizophrenia from bipolar disorder (highest AUC = 0.92). Papers on discriminating healthy control from bipolar disorder reported good performance (highest AUC = 0.8). When papers aimed to discriminate between more than 2 conditions, performance dropped to 69-77% accuracy. Studies that aimed to discriminate between different states of the same disorder reported moderate to good performance (highest performance was UAR = 0.79 with three classes and 86% accuracy with 2 -classes). Papers both applied conventional machine learning approaches and DNN-s with no clear trend in better performance in any specific algorithm type. Also, patterns of limitations appeared that might hinder the progress of the field. These include the lack of external validation, publicly available code bases and datasets, standardization of measurements, performance metrics and speech elicitation tasks and the limited considerations of applicability and early detection. The Sch-net model achieved a more moderate accuracy (0.70) for identifying individuals at elevated risk of developing schizophrenia tasks while shallow machine learning approaches reached excellent accuracy (0.879). All models were moderately biased toward reaching higher accuracy on white, female and educated individuals.

Discussion: Our work highlighted the lack of data and reproducible code in the field and how it can lead to unreliable results. Increasing reproducibility and publicly available databases could be a potential solution to overcome the vulnerability for biases and provide sufficient training data to experiment with more scalable deep learning approaches in the field to eventually complement human expertise in early mental health care.

F110. CHANGING CITIES IN ORDER TO PROMOTE RECOVERY IN PATIENTS WITH PSYCHOSIS

Philippe Conus*¹, Lilit Abrahamyan Empson¹, Ola Söderström², Marc Wintz¹, Aurora Ruggeri²

¹Lausanne University Hospital, ²Neuchâtel University

Background: The movement of deinstitutionalization has led to a reduction in the duration of hospitalization and the development of community treatment. However, this shift was not always accompanied by a necessary intervention at the population level to facilitate the integration of patients in the community. Patients therefore live in the city but nevertheless feel excluded and have no access to work and leisure activities.

Methods: We conducted video-elicitation interviews of urban walks and ethnographic observations in a community care centre in the city of Lausanne and identified factors that constitute excess of stress for patients in the city. Through a large survey, we also compared first episode psychosis and university students regarding their patterns of use of the city and perception of stress and respite in the urban environment

Results: After a first episode of psychosis, young patients avoid city centers and have no access to many of the positive aspects of the urban environment. Patients identify various domains where adaptations of the environment would facilitate their access to the enrichment cities have to offer.

Discussion: After a first episode of psychosis, patients avoid cities and are deprived of social integrations. Based on these interviews, we currently develop, in collaboration with patients, professionals and the city authorities, a set of interventions that should promote social integration of patients and facilitate their access to the city.

F111. IMPACT OF REFERRAL OUTCOME OF CLINICAL HIGH RISK OF PSYCHOSIS SUBJECTS TO EARLY INTERVENTION SERVICES IN SWITZERLAND: PRELIMINARY DATA FROM THE PSY YOUNG MULTICENTRIC STUDY

Caroline Conchon*¹, Elodie Sprungli-Toffel², Luis Alameda², Martine Cleusix², Logos Curtis³, Anne Edan⁴, Nathalie Nanzer⁴, Ana Liso-Navarro⁵, Remy Barbe⁶, Marco Armando⁷, Kerstin von Plessen⁷, Davina Genoud⁷, Barbara Bailey⁸, Philippe Stertz⁸, Evelyn Herbrecht⁸, Christian Huber⁸, Stefan Borgwardt⁹, Christina Andreou⁹, Philippe Conus¹⁰

¹General Psychiatry Service, Lausanne University Hospital and University of Lausanne,

²Service of General Psychiatry, Lausanne University Hospital and the University of Lausanne,

³Geneva University Hospitals, ⁴Child and Adolescent Psychiatric Service, Geneva University Hospitals, ⁵Medical Pedagogical Office, State of Geneva, ⁶Child and Adolescent Psychiatric Service, Geneva University Hospitals, and ⁷Medical Pedagogical Office, State of Geneva,

⁸Service of Child and Adolescent Psychiatry, Lausanne University Hospital and the University of Lausanne, ⁹University of Basel Psychiatric Hospital, ¹⁰University of Lübeck, ¹⁰Service of General Psychiatry, Centre Hospitalier Universitaire Vaudois (CHUV) and University of Lausanne (UNIL),

Background: Psychotic disorders are one of the main causes of chronic disability in young people. Subclinical symptoms ('clinical high risk for psychosis' (CHR-P)), precede the first psychotic episode by several years in the majority of patients, however, while only about a third of these patients develop full-blown psychosis, most of the CHR-P suffer from psychiatric comorbidities and have unfavourable functional outcomes. Unfortunately, a very small proportion of FEP patients have benefited from treatment in CHR-P early intervention services

(EIS), which shows the deficient pathways to care of this population. The PsyYoung project aims to improve the detection of CHR-P patients by increasing access to specialist care and reducing the pathway to care. The objectives and assumptions of the project are: (i) Increase the flow and speed of treatment by improving pathways to care; (ii) aim to reduce unnecessary referrals; (iii) improve clinical and functional outcomes and quality of life, aim for reduction in the Duration of Untreated Psychosis (DUP).

Methods: The PsyYoung project is a multicentric study involving 6 psychiatric units in three cantons (Basel, Vaud and Geneva)). The project uses a stepped-care model, that proposes an intervention which consist of the application of a standardised pathway to care model for access to EIS, harmonising the assessment batteries and practises across centers, implementing activities to increase the awareness in the general public as well as teaching and network activities targeting professionals in the education and healthcare sector. This intervention aims, among other things, to optimize detection of CHR-P by improving pathways to care, and to reduce unnecessary psychiatric treatments in patient before and during the CHR-P phase. Data are collected over a period of 2 years and 8 months, wIncluding a pre- and post-implementation phase. Each site collects its own data. Inclusion criteria: patients aged between 15 and 35 referred to an early intervention center. Changes before and after the implementation will be measured at several levels ((at service, patient, referring professionals and center levels). In the current report we will present the percentage of referred patients with a CHR-P status and those without CHR-P (ie. CHR-N), before and after the implementation.

Results: We focus on the preliminary results for the treatment and early intervention in one psychosis program (TIPP, one of the 6 centers, based in Lausanne) between March 2021 and August 2023. Before implementation, the number of CHR-P patients was 52.8% for TIPP. After implementation the number dropped to 47.2%. The number of patients with a CHR-N status was 59.2% before implementation and 40.8% after the implementation.

Discussion: These preliminary results showed a decreased percentage of CHR-N referred to TIPP suggesting that stakeholders are better informed about the CHR paradigm and also more familiar with pre-test tools proposed by PsyYoung. Updated results will be presented in SIRS 2024.

F112. ABNORMAL INTER-HEMISPHERIC EFFECTIVE CONNECTIVITY FROM LEFT TO RIGHT AUDITORY REGIONS DURING MISMATCH NEGATIVITY (MMN) TASKS IN PSYCHOSIS

Christian Valt*¹, Francisco José López Caballero², Angelantonio Tavella¹, Brian Coffman², Dylan Seebold², Pierluigi Selvaggi¹, Antonio Rampino¹, Mario Altamura³, Giuseppe Barrasso⁴, Antonello Bellomo³, Filippo Iovine⁴, Alessandro Saponaro⁵, Domenico Semisa⁶, Alessandro Bertolino¹, Giulio Pergola¹, Dean Salisbury²

¹University of Bari 'Aldo Moro', ²University of Pittsburgh School of Medicine, ³University of Foggia, ⁴ASL Barletta-Andria-Trani, ⁵ASL Brindisi, ⁶ASL Bari

Background: Psychosis is currently thought to result from functional dysconnectivity between cortical processing areas that prevents effective communication between brain regions. Accordingly, the abnormal auditory Mismatch Negativity (MMN) observed in psychosis may result from impaired communication between brain regions, even at the perceptual stages of stimulus processing. MMN studies investigating functional or effective connectivity in schizophrenia and psychotic disorders have yielded mixed results regarding the dysfunctional connectivity processes underlying blunted MMN amplitude. The variability in these results

may be due to the limited spatial resolution of electroencephalography (EEG) signals, which affects the precision of source reconstruction of neurophysiological scalp potentials for accurate analysis of connectivity between brain regions. Leveraging the superior spatial resolution of magnetoencephalography (MEG), the present MMN study investigated effective connectivity within and between auditory regions in patients with psychosis.

Methods: Analyses were performed on two different magnetic MMN (MMNm) datasets: one on duration and pitch MMNm in individuals with a first episode of psychosis (FEP, N = 35) and matched neurotypical controls (NC, N = 34); another on duration MMNm in a cohort with various diagnoses within the psychosis spectrum (N = 82) and matched NC (N = 91). We applied spectral Granger causality to MEG source-reconstructed signals to compute effective connectivity within (LL, RR) and between (LR, RL) the left and the right primary auditory cortex in two time windows after stimulus onset (50-150ms and 150-250ms). The Granger value difference between deviant and standard stimuli was considered as an index of MMNm effective connectivity. This index was first contrasted between patients and controls to detect possible group differences. It was then correlated with event-related field (ERF) amplitudes to determine the relationship between effective connectivity and MMNm peak amplitude.

Results: The first experiment showed lower MMNm effective connectivity in the theta frequency band from left hemisphere to right hemisphere auditory regions in FEP compared to NC, $F(1,64) = 4.26$, $p = .043$, especially for duration deviant stimuli, $t(65) = 3.05$, $p = .003$. Interestingly, this directional connectivity also showed the strongest correlation with MMNm peak amplitude for duration deviant stimuli, $r = .66$, $p \text{ LESS THAN } .001$. The evidence for abnormal connectivity from left to right auditory regions was replicated in the second experiment. Again, compared to controls, patients with psychosis or at clinical high risk for psychosis showed lower connectivity from left to right auditory regions, $t(170) = 2.78$, $p = .006$. The correlation between mMMN peak amplitude and effective connectivity was not replicated in this sample.

Discussion: These two experiments suggest that blunted MMNm in psychosis may reflect a deficit in inter-hemispheric communication from the left to the right auditory regions. We interpret these results as evidence for a possible directional “disconnection” in individuals with psychosis. In addition, it appears that the strength of this interhemispheric connectivity may significantly influence the magnitude of the MMNm response to duration-deviant stimuli, although further evidence is needed to substantiate this finding.

F113. PRELIMINARY DATA ON MEDICATION INTAKE IN SWISS INDIVIDUALS REFERRED TO EARLY INTERVENTION SERVICES FOR SUSPICION OF CLINICAL HIGH RISK FOR PSYCHOSIS

Elodie Sprüngli-Toffel*¹, Caroline Conchon¹, Luis Alameda¹, Philippe Golay², Martine Cleusix¹, Logos Curtis³, Anne Edan⁴, Nathalie Nanzer⁴, Ana Liso Navarro⁵, Remy Barbe⁶, Marco Armando⁷, Kerstin von Plessen⁷, Davina Genoud⁸, Barbara Bailey⁹, Philippe Sterzer⁹, Evelyn Herbrecht⁹, Christian Huber⁹, Stefan Borgwardt¹⁰, Christina Andreou¹⁰, Philippe Conus²

¹General Psychiatry Service, Lausanne University Hospital and University of Lausanne,

²Service of General Psychiatry, Centre Hospitalier Universitaire Vaudois (CHUV) and University of Lausanne (UNIL), ³Young Adult Psychiatry Unit, Geneva University Hospitals,

⁴Child and Adolescent Psychiatric Service, Geneva University Hospitals, ⁵Medical Pedagogical Office, ² State of Geneva, Geneva, Switzerland, ⁶Child and Adolescent

Psychiatric Service, Geneva University Hospitals, Geneva, Switzerland and Medical Pedagogical Office, 2 State of Geneva, 7Service of Child and Adolescent Psychiatry, Lausanne University Hospital and the University of Lausanne, 8Division of Child and Adolescent, Lausanne Hospital (CHUV), 9University of Basel Psychiatric Hospital, , 10University of Lübeck,

Background: Psychotic disorders are one of the main causes of chronic disability in young people. Attenuated symptoms ('clinical high risk for psychosis' (CHR-P)), precede the first psychotic episode (FEP) by several years in the majority of patients. While only about a third of these patients develop full-blown psychosis, most of the CHR-P suffer from psychiatric comorbidities and have unfavorable functional outcomes. Unfortunately, a very small proportion of FEP patients have benefited from treatment in a CHR-P early intervention service (EIS), which shows the deficient pathways to care of this population. The PsyYoung project is a multicentric study in Switzerland that uses a stepped-wedge design to implement an intervention in Swiss EIS, in order to optimize early detection and intervention in psychosis. Through this intervention, the project wants, among other things, to reduce unnecessary psychiatric treatments in in patient before and during the CHR-P phase. The aim of this study is to assess the impact of the project intervention specifically regarding medication intake in Swiss individuals referred to early intervention services for an evaluation of CHR-P.

Methods: 576 patients aged 15-35 years have been referred to EIS for suspicion of psychosis of the six PsyYoung units. Data is collected at service level and at 4 timepoints (baseline, 4, 6 and 12 months follow-up) over a year to inform about referrals trends. The project is still in the data collection phase, so the current report examines preliminary data on medication intake in individuals referred to EIS for suspicion of CHR-P.

Results: Descriptive analysis showed 576 referrals to a PsyYoung unit between March 2021 and March 2023, of which 505 had completed data for analysis (25% CHR-P, 36.2%FEP and 37.8% CHR-N). 23.6% CHR-P patients were referred from hospitals, 29.6% of CHR-P were already on antipsychotics at referral. Pearson correlations analyses showed that the number of CHR-P patients on antipsychotic medication before referral in EIS significantly decreased over time (before and after the implementation of the PsyYoung strategy) ($r=-.192$, $p=.032$). Updated results will be presented in April 2024.

Discussion: These preliminary results suggest that the PsyYoung strategy is associated with a decrease in the number of referrals for suspicion of CHR-P who take antipsychotic medication, which is important, given the lack of evidence that antipsychotic need to be prescribe for this population. The project also gives the opportunities of a transcantonal and inter-services collaboration regarding early detection and intervention on psychosis.

F114. DOES METACOGNITIVE TRAINING (MCT) IMPROVE NEUROCOGNITIVE PERFORMANCE IN PSYCHOSIS? A SYSTEMATIC REVIEW AND META-ANALYSIS

Clayton Jeffrey^{*1}, Danielle Penney², Genevieve Sauve³, Daniel Mendelson⁴, Steffen Moritz⁵, Martin Lepage¹

¹McGill University, Douglas Mental Health University Institute, ²Douglas Mental Health University Institute and L'Université du Québec à Montréal, ³Douglas Mental Health University Institute, Université du Québec À Montréal, ⁴McGill University, ⁵University Medical Center Hamburg

Background: Previous research has elucidated that metacognitive training (MCT) offers benefits for addressing hallmark deficits and symptoms in schizophrenia spectrum disorders. These benefits include reductions in positive symptoms such as delusions and cognitive biases, improvements in social cognition, and an overall increase in functioning. However, results from individual studies diverge regarding the relationship between MCT and neurocognition, with some showing a positive effect and others none whatsoever. A comprehensive understanding of the nature of this relationship would significantly contribute to the existing literature and provide valuable insights to clinicians regarding the potential added value of MCT as a cognitive capacity enhancing intervention for psychosis. Therefore, this systematic review and meta-analysis aim to determine the efficacy of MCT in improving neurocognitive performance (including speed of processing, attention/vigilance, working memory, verbal learning and memory, visual learning and memory, reasoning, and problem-solving) when compared against control conditions.

Methods: This systematic review and meta-analysis summarizes the existing literature considering the relationship between MCT and neurocognitive performance. Across eleven electronic databases, 1355 sources were identified, and 14 studies were included in this review. Measures of estimated effect sizes were calculated with Hedge's g , moderator analyses used Cochrane's Q statistic and significance tests to measure group differences according to control conditions including treatment as usual (TAU) and active (ACT) control interventions.

Results: Twelve studies, 11 RCT's and 1 non-RCT, were included in the main meta-analyses, consisting of 673 participants ($n_{MCT} = 345$, $n_{control} = 328$). When comparing MCT against control interventions, minimal nonsignificant differences in estimated effect sizes were observed across all six neurocognitive domains when evaluating pre-post, post-follow-up, and pre-follow-up changes in neurocognition ($g \leq 0.1$, p GREATER THAN 0.05). Likewise, moderator analyses demonstrated that no significant differences were demonstrated between TAU or ACT control condition for any of the timepoint comparisons (p GREATER THAN 0.05). Two additional studies were included in a narrative review, corroborating these findings.

Discussion: These results suggest that when compared against both passive and active control conditions, MCT does not pose a statistically meaningful difference compared to control interventions across the six neurocognitive domains assessed. This relationship was demonstrated when evaluating immediate effects (pre-post), maintenance effects (post-follow-up), and sustained effects (pre-follow-up). These findings indicate that general practice/learning effects are likely the main contributor that leads to improvement in neurocognitive performance, and not a difference of intervention allocation when considering MCT. Despite some initial positive findings, improvement of neurocognitive was never an explicit aim of MCT, however these findings help establish the specificity of its effects.

F115. DEVELOPING AND TESTING THE CLINICAL HIGH RISK FOR PSYCHOSIS SERVICES - FIDELITY SCALE (CHRPS-FS)

Mark Savill¹, Lindsay M. Banks¹, Briana Sepulveda¹, Valerie L. Tryon¹, Kathleen E. Nye¹, Christopher Blay², Michelle Carlson², Adrian F. Asbun¹, Sabrina Ereshefsky¹, Kristin LaCross², Stephanie L. Hayes¹, Tara A. Niendam¹, Donald Addington³

¹University of California Davis, ²University of California San Francisco, ³University of Calgary

Background: Fidelity scales measure the adequacy of implementation of an evidence-based practice. They are necessary to inform early stages of model development for promising

practices, support program-level quality improvement, and can facilitate research aimed at identifying, measuring, and improving the components and effectiveness of interventions.

To record what components of care early psychosis (EP) programs deliver to their clients with psychosis, numerous fidelity scales have been developed and validated. However, no tool to date has been validated to assess the specific components of care that are delivered to individuals at clinical high-risk for psychosis (CHRP), despite many EP programs also providing care for individuals with CHRP. This is problematic, as while many shared features of care exist, some treatment recommendations for CHRP do deviate from best-practice care for EP. We detail the steps taken to develop, refine, and validate the Clinical High Risk for Psychosis Services – Fidelity Scale (CHRPS-FS) tool within the EPI-CAL EP learning healthcare network.

Methods: We used a three-step development, measurement, and validation process to develop the CHRPS-FS. First, the items and rating criteria were developed following a review of the literature, focusing on identifying common and contrasting components with the First Episode for Psychosis – Fidelity Scale (FEPS-FS). Next, we explored the face validity of the tool through a Delphi consensus process with clinical and academic experts in the field of CHRP care. Items were amended based on participant feedback and sent out for additional review until consensus was achieved across GREATER THAN 80% of all items and ratings. While the Delphi study was ongoing, we tested and refined measurement practices through piloting the tool in 11 EPI-CAL EP clinics that served individuals experiencing CHRP.

Results: The review identified two components of CHRP care distinct from those detailed in the FEPS-FS. Six FEPS-FS items were removed as they were not considered relevant to CHRP care. In the piloting of the tool, the median CHRPS-FS rating scored across the eight participating clinics was 4.03 (IQR 3.72 – 4.16). The median percentage of items rated at good-to-high fidelity was 68.8% (IQR 65.6 – 78.1). In the Delphi study, 17 clinical and academic experts based in seven different counties participated. Both expert groups achieved a consensus of GREATER THAN 80% within two rounds, with feedback leading to some changes in item wording, and in the addition of an item measuring the stepped care approach. In the final version of the CHRPS-FS, six items of the FEPS-FS 1.1 were removed, three items unique to the CHRPS-FS were added, and for three items the item description remained the same, but their rating criteria were modified.

Discussion: The newly developed CHRPS-FS was found to be feasible to implement in both community and university settings, could be conducted in conjunction with a FEPS-FS assessment and alone, and was able to detect variability in service delivery between programs. Additionally, the scale component and rating criteria was found to have face validity amongst both academic and clinical experts in the field.

The CHRPS-FS could support researchers, providers, and policy makers to assess what components of care are being provided to individuals with CHRP and at what standard, within and across EP programs. This could be critical to supporting a formal validation of the team-based approach to CHRP care, could support the subsequent development of clinical practice guidelines, and could facilitate the benchmarking of CHRP care necessary for improving CHRP care standards worldwide.

F116. PATTERNS OF PRIMARY CARE USE PRIOR TO A FIRST DIAGNOSIS OF PSYCHOTIC DISORDER: A 2-YEAR RETROSPECTIVE COHORT STUDY

Paula Suárez-Pinilla*¹, Nazareth Sánchez-Gallego², Oscar Vallina-Fernández³, Alicia Ruiz-Toca⁴, Javier Vazquez-Bourgon⁵, Rocio Perez-Iglesias⁶

¹University Hospital Maqués de Valdecilla, ²University Hospital Marqués de Valdecilla, ³Hospital Comarcal Sierrallana, ⁴Hospital Comarcal de ⁵University Hospital Marqués de Valdecilla, Institute of Biomedical Research Valdecilla (IDIVAL), CIBERSAM, ⁶University Hospital Marques de Valdecilla

Background: Many patients experience early symptom before the diagnosis of a first episode of psychosis (FEP), suggesting that there may be help-seeking prior to diagnosis. A longer duration of untreated psychosis (DUP) is usually related to worse clinical and functional prognosis. General Practitioners (GPs) may play a role in detecting those subjects, as are often the first point of contact. This study examined patterns of Primary Care use preceding a diagnosis of psychotic disorder.

Methods: We reviewed health administrative records of Primary Care of 35 patients included in the Early Intervention (EI) Clinical Program for Psychosis (ITP-Can-Santander) in Spain during 2020. Patients are consecutively treated in a real-world setting EI program. Inclusion criteria were: aged from 17 to 65, and being affected by a drug-naïve FEP (affective or non-affective). Exclusion criteria were: suffering from a severe neurological disease or traumatic brain injury, severe intellectual disability or/and psychosis directly induced by illicit substances. For this study, we investigated patterns of primary care use in the 2 years prior to first diagnosis of psychosis.

Results: Mean age at diagnosis was 36.6 years, and 57% were females. Mean DUP was 9.02 months. Patients were referred to ITP-Can-Santander through different pathways: 22 from Emergencies (63%), 5 from Primary Care (14.3%), 7 from Specialist Care (20%), and 1 from other departments (2.7%). Out of 35 patients, 28 (80%) contacted with GP during the previous 2 years. Overall, 147 consultations in Primary Care were accounted, with a mean of 5.25 consultations per patient. More than 40% of FEP patients (n=15) asking for mental health related signs and symptoms, being anxiety and social problems the most frequently recorded before psychotic diagnosis. Among patients who asked about physical problems (n=13; 34%), the most common patterns of attention were diseases of the digestive system and musculoskeletal pain. However, the DUP was virtually the same for subjects that did and did not contact with GP, for those referred to the program thorough Primary Care vs other pathways, and for those who did and did not contact for mental health related symptoms. A higher sample size is needed to clarify patterns of Primary Care use prior to FEP diagnosis.

Discussion: During 2 years before the diagnosis of FEP, 8 out of 10 patients consulted their GP, and half of them sought help for mental health-related problems. Improving GP knowledge in identifying patterns of prodromal symptoms may alter to those developing psychosis, facilitating earlier referral to specialist care. Initiatives to support GPs in their role detecting FEP are warranted.

F117. A BETTER UNDERSTANDING OF GAMING DISORDER AND PROBLEM GAMBLING AMONG PEOPLE WITH FIRST-EPISODE PSYCHOSIS: A NEW PATH TOWARDS RECOVERY

Maxime Huot-Lavoie*¹, Olivier Corbeil², Laurent Béchard³, Sébastien Brodeur¹, Charles Desmeules¹, Chantale Thériault⁴, Colombe Claveau⁵, Anne-Marie Essiambre⁴, Michel Dorval⁶, Magali Dufour⁷, Amal Abdel-Baki⁸, Isabelle Giroux⁹, Yasser Khazaal¹⁰, Marie-France Demers¹¹, Marc-André Roy¹²

¹Université Laval Faculty of Medicine, ²Faculty of Pharmacy, Université Laval, ³Pharmacy Faculty, Laval University, ⁴CERVO Brain Research Centre, ⁵Psychology School, Laval University, ⁶Faculty of Pharmacy, Laval University, ⁷UQAM, ⁸Centre hospitalier de l'Université de Montréal, ⁹School of psychology, Laval University, ¹⁰Université de Lausanne, ¹¹Faculté de pharmacie de l'Université Laval, Institut Universitaire en Santé Mentale de Québec, Centre de Recherche de l'Institut Universitaire en Santé Mentale de Québec, ¹²Faculté de médecine de l'Université Laval, Institut Universitaire en Santé Mentale de Québec, Centre de Recherche de l'Institut Universitaire en Santé Mentale de Québec

Background: Treatment approaches for psychotic disorders are shifting to prioritize overall patients' recovery beyond symptom control and emphasizing early intervention for first-episode psychosis (FEP). Despite these changes, comorbid conditions, such as gambling disorder (GD) and problem gambling (PG), still remain neglected and understudied. The first studies on GD and PG in young adults with FEP, conducted by our team, revealed an increased prevalence of these comorbidities compared to the general population and a significant impact on patients' recovery. Building upon this, we obtained research grants to further explore the consequences and correlates of those behavioral addictions in FEP patients.

Methods: A prospective multicenter cohort study is being conducted in two clinics for FEP in Quebec, Canada. This study should include over 600 adults aged 18 to 35, with a diagnosis of FEP (either affective or non-affective), followed for an average period of 36 months. These patients will undergo a systematic screening for GD and PG at admission and every 6 months, which will allow to: 1) quantify the prevalence of these 2 comorbidities among people with FEP and, 2) identify potential risk factors for developing problematic behaviors. Additionally, qualitative interviews will be performed with a sample of individuals with GD and PG to describe motivations underlying video gaming and gambling behaviors, their consequences on patients' lives and the efficiency of available treatment modalities for these conditions.

Results: The findings of this study will lay the groundwork for the development of tailored approaches for enhancing screening, prevention, and treatment of GD and PG adapted to the FEP population. The results will be disseminated through various channels, including a FEP-dedicated website, scientific publications, continuous education programs, and engagement with the media. Being part of an internationally recognized care model enhances the global reach of our findings. A robust network of partnerships, including mental health institutes, caregiver/patient associations, and professional organizations, supports widespread dissemination.

Discussion: FEP is often associated with problematic gambling and video gaming habits, acknowledged as a potential source of concern by the World Health Organization. However, limited data exist regarding both GD and PG in individuals with FEP. This study will help filling this gap by providing essential insights to better support the recovery of young individuals dealing with FEP.

F118. BECAUSE COGNITION EMERGES FROM CULTURE: ETHICAL NEED FOR A TRANSCULTURAL NEUROPSYCHOLOGY AND TREATMENT OPTIMIZATION IN THE PSYCHIATRY OF FIRST EPISODE PSYCHOSIS

Amelie Pavard^{*1}, Alexia Cuisniak², Nicolas FRANCK³, Tasneem Pichori⁴, Julien Plasse², Frederic Haesebaert⁵

¹CH Le Vinatier, Lyon, ²CH Le Vinatier, Lyon (France), ³University of Lyon, Vinatier Hospital, ⁴Abt Brain, Lyon (France), ⁵PSYR2 Team, INSERM U1028, CNRS UMR5292, Lyon

Neuroscience Research Center, Université Claude Bernard Lyon 1, Lyon, France, Lyon, France.

Background: The risk of developing a first episode psychosis (FEP) increases with the experience of migration (Brandt et al., 2019), often due to traumatic events and living conditions in the host country. In our early intervention services nearly 30% of users were born in a non-western country, thus increasing the amount of users in intercultural situations.

As good cognitive functioning plays a decisive role functional recovery in FEP (Lam, 2018), neuropsychological assessment is highly recommended in early intervention settings, to offer recovery and user oriented care. The anticholinergic burden of treatment (ACB) and the cultural considerations (Casaletto and Keaton, 2017) are among the most important factors influencing the interpretation of neuropsychological assessment. Indeed, cognition is a dynamic process (Barsalou, 2008): based on our experiences, we produce inferences to understand our environment, and respond accordingly. Our ways of interacting and reasoning are therefore modulated by cultural determinants. Nevertheless, neuropsychological tests are constructed according to a Western problem-solving logic, including measures of efficiency and speed. Therefore, they are not very suitable for intercultural evaluation. Elsewhere, if ACB is well-known, only moderate concordance was found among anticholinergic scales (Naples et al., 2015) and a very few studies examine the load associated to the treatment dosage. This study aims to assess the impact of both cultural and medication factors on the neuropsychological evaluation of young people with early psychosis.

Methods: We invited FEP users (half of whom were Westerners) to perform executive and attentional assesment, either through classic neuropsychological testing (TMT, Stroop, D2-R), or with Mindpulse©, a new assessment battery using culturally shared stimuli (Suarez et al., 2021). The ACB of their treatment was calculated according to Crideco anticholinergic scale (Ramos et al., 2022), an updated of ACB scale (Salahudeen et al., 2015), and cumulated with a score of low, median, or high antipsychotic defined daily dosage, as we called “total ACB”.

Results: 12 users were recruited. Non-Western group has a higher score at EPICES scale of precarity. Results show a significant test*group interaction, where the non-Western group reaction time was longer for usual neuropsychological test (TMT-B) than the occidental group, but not with Mindpulse flexibility clue (p LESS THAN .05). As total ACB shows no difference between the two cultural groups, total ACB score was correlated with error number (p = .01) and total score in Stroop inhibition test (p = .08), on executive speed (p = .08), and on flexibility clue (Mindpulse, p = .006). Data will be hence by further recruitment in the early 2024.

Discussion: These results highlight the importance of considering both the anticholinergic load and treatment dosage when assessing cognitive impacts in individuals with FEP. Given that cognition plays a crucial role in achieving improved clinical recovery and social functioning (Lam, 2018), early intervention care should incorporate treatment optimization strategies to enhance the cognitive and social functional outcomes. This study shows that classical neuropsychological tests such as TMT are not suitable in intercultural evaluation. Mindpulse© battery seems more appropriate in the executive and attentional assessment for intercultural groups. As migration serves as both a contributor to disengagement from care and a risk factor for psychotic transition, one of the imminent challenges in psychiatry and neuropsychology is the development of intercultural assessments.

F119. COMPUTATIONAL SPEECH AND LANGUAGE FEATURES FOR WITHIN- AND BETWEEN-SUBJECT SYMPTOM CHARACTERIZATION IN FIRST-EPIISODE PSYCHOSIS

Michael Spilka*¹, Anthony Yeung², Mengdan Xu¹, Bertina Jebanesan³, Wishah Khan³, Sarah Ahmed³, William Simpson¹, Jessica Robin¹, Farooq Naeem⁴

¹Winterlight Labs, ²University of British Columbia; Centre for Addiction and Mental Health, ³Centre for Addiction and Mental Health, , ⁴University of Toronto, Centre for Addiction and Mental Health

Background: Alterations in speech and language are evident in psychotic disorders, reflecting core positive, negative, and cognitive symptoms. Speech assessment and analysis using computerized approaches have the potential to enhance clinical care by providing objective and easy-to-deploy symptom screening and monitoring. Digital speech assessment may be particularly useful in first-episode populations, where monitoring symptom exacerbations and predicting relapse is crucial for timely intervention. However, it is unclear whether similar speech and language characteristics are sensitive to symptom severity differences between vs. within individuals, knowledge of which will help determine the most relevant speech-based markers for symptom screening and monitoring. In the current study, we compared between-subject and within-subject associations between speech and symptom severity in a longitudinal study of first-episode psychosis.

Methods: 43 first-episode psychosis outpatient participants underwent clinical assessments (Brief Psychiatric Rating Scale [BPRS], Scale for the Assessment of Negative Symptoms [SANS]) and completed speech tasks from the Winterlight assessment app (journaling, picture description, paragraph reading) at baseline, and at 3-, 6-, 9-, and 12-month follow-up. Participant speech and language were characterized using 74 core acoustic and linguistic features extracted from signal analysis and natural language processing of speech task recordings and transcripts. Associations between speech features and symptom severity (BPRS Total, BPRS Positive, SANS Total) were examined with linear mixed-effects models controlling for demographic characteristics (age and gender), with between-subject effects estimated using participants' subject-level mean across visits, and within-subject effects estimated using participants' visit-specific deviations from their subject-level mean.

Results: 23 unique features were significantly associated with symptom severity differences between participants, with most associations for negative symptoms (14 features), followed by overall symptoms (9 features) and positive symptoms (5 features). In contrast, 15 features were associated with symptom severity changes within participants, with the greatest number of associations with overall (10 features) and positive (9 features) symptoms, followed by negative symptoms (4 features). Both the between- and within-subject results included several linguistic feature categories, while acoustic features were only significantly associated with symptom severity between subjects. Only one feature was consistently associated with symptom severity both between- and within-subjects: greater speech graph connectivity during the journaling task was associated with greater positive symptom severity.

Discussion: Computational speech features are sensitive to symptom severity in first-episode psychosis. Although similar feature categories generally show associations with symptom severity both between and within subjects, there was little overlap in specific features, suggesting different features may be appropriate for patient screening vs. monitoring applications.

F120. SELF-STIGMA AND STIGMA RESISTANCE AFTER A FIRST EPISODE OF SCHIZOPHRENIA: CLINICAL, COGNITIVE, AND FUNCTIONAL CORRELATES AND CHANGE OVER TIME

Thanh Le*¹, Ruth Firmin², Joseph Ventura³, Kenneth Subotnik³, Keith Nuechterlein³

¹University of California, Los Angeles, School of Medicine, ²McLean Hospital/Harvard Medical School, ³University of California, Los Angeles, Department of Psychiatry and Behavioral Sciences

Background: Individuals with mental disorders experience considerable public stigma, which can lead to self-stigma, or applying and internalizing these negative beliefs and stereotypes to oneself. Most research on self-stigma has focused on individuals with multi-episode schizophrenia. Little is known about self-stigma in first-episode schizophrenia (FES), particularly regarding clinical, cognitive, and functional correlates. Moreover, there have been very few investigations on whether stigma changes over time in the context of comprehensive treatment. Of note, stigma resistance is an active process of using one's skills and experiences to challenge stereotypes at the personal level, which is then used to help peers with mental illness and advocate at the public level. This study investigated the: 1) positive and negative symptoms, cognitive, and role and social functioning correlates of self-stigma stigma and stigma resistance in individuals with first-episode schizophrenia, and 2) changes in self-stigma and stigma resistance over a 6-month comprehensive early intervention.

Methods: Ninety-two participants with FES from the UCLA Aftercare Research Program were enrolled in a 6-month comprehensive early intervention program that included medication management, weekly case management and individual supportive therapy, and psychoeducation focused on recovery and life skills. Participants were also enrolled in a 6-month RCT comparing cognitive training plus healthy living training versus cognitive training plus physical exercise. They were administered baseline measures of positive symptoms (SAPS), negative symptoms (SANS), cognition (MATRICS Consensus Cognitive Battery), and functioning (Role Functioning Scale), as well as baseline and 6-month measures of self-stigma (Internalized Stigma of Mental Illness Scale) and stigma resistance (Stigma Resistance Scale; SRS). Paired sample t-tests were used to examine changes between baseline and 6 months for the two self-stigma variables. Pearson correlations were used to investigate the baseline correlates of the self-stigma variables.

Results: Higher baseline self-stigma was associated with greater baseline severity of positive symptoms ($r = .27$, $p < .05$) and anhedonia ($r = .26$, $p < .05$), and approached significance with poorer social cognition ($r = -.19$, $p = .08$). Higher baseline stigma resistance was associated with lower severity of negative symptoms ($r = -.23$, $p < .05$), particularly anhedonia ($r = -.29$, $p < .01$), and greater social functioning with peers ($r = .23$, $p < .05$). These significant associations appear to be largely driven by Personal Identity (finding meaning in life outside their mental illness), Peer Stigma Resistance (use of one's experience to help others with stigma), and Public Stigma Resistance (ways people challenge public stigma) subscales of the SRS. Self-stigma did not significantly change over the 6-month intervention period, $t = .92$, $p = .36$. However, stigma resistance (SRS total score) increased at 6 months compared to baseline values, $t = 2.07$, $p < .05$, Cohen's $d = .27$). This significant gain over time was largely driven by increases in the Personal Cognition (cognitive strategies used to challenge negative mental illness thoughts) and Peer Stigma Resistance subscales of the SRS.

Discussion: These findings provide key information about the correlates of self-stigma of mental illness in FES, which may lead to a better understanding of self-stigma mechanisms to inform treatment development. Stigma resistance also improved over time during comprehensive intervention services. However, the modest effect size observed suggests a need for a more tailored focus on resisting stigma in the early illness stages.

F121. ASSOCIATION BETWEEN EXPOSOME SCORE FOR SCHIZOPHRENIA AND GENERAL FUNCTIONING IN REMITTED FIRST-EPISODE PSYCHOSIS: EARLY RESULTS FROM THE HAMLETT STUDY

Sterre Kamphuis^{*1}, Marieke Begemann², P. Roberto Bakker³, Sinan Guloksuz¹

¹Maastricht University Medical Centre, ²University Medical Center Groningen, ³Arkin, UMCG

Background: Psychosis spectrum disorder is known for its wide range of clinical representations, varying from complete remission to a chronic course with significant functional impairment. Evidence suggests that environmental exposures might be contributing to this variety, not only by increasing the risk for psychosis but also by influencing the course of illness. Recent studies have shown a negative association between general functioning and the exposome score for schizophrenia (ES-SCZ), a weighted score of cumulative environmental liability for schizophrenia, in patients with psychotic disorders. This replication study aims to validate and extend these findings in patients with remitted first-episode psychosis (FEP) and lays the groundwork for further longitudinal investigation of the influence of environmental exposures on psychosis liability and long-term outcomes.

Methods: Data were obtained from the baseline assessments of the ongoing HAMLETT study (Begemann et al., 2020). This multicenter pragmatic single-blind RCT investigates the effects of continuation versus dose-reduction/discontinuation of antipsychotic medication after remission of FEP on functioning, psychotic symptom severity, and health-related quality of life. In total 346 patients were randomised, who were 3–6 months in remission of their first psychotic episode (defined as a score of 3 or below on the positive scale of the PANSS (Positive and Negative Symptom Scale)). The ES-SCZ was calculated based on formerly validated estimates and included data derived from questionnaires on childhood adversity, cannabis use, hearing impairment, and bullying. Childhood adversity was assessed using the Dutch Childhood Trauma Questionnaire Short Form (CTQ-SF). The Global Assessment of Functioning (GAF, range 0-100) was used to measure general functioning. Multiple regression analyses were conducted to examine the association between GAF and ES-SCZ.

Results: Data from 123 patients were available for this analysis, including 83 men and 40 women. In this subsample, the mean age was 28.5 (SD=8.6, range: 17-54) years, mean GAF was 64.04 (SD=11.47), and mean ES-SCZ was 4.3 (SD=1.3) at baseline. The mean time between remission after FEP and enrolment in the study was 139.4 (SD=51.5) days. The ES-SCZ was significantly negatively associated with GAF ($B=-1.929$, $p=0.015$), after adjusting for age and sex. The model accounted for a small proportion of the variance in GAF (Multiple R-squared: 0.065) and was statistically significant in predicting GAF from the combined aforementioned set of predictors ($F(3,119)=2.759$, $p=0.045$).

Discussion: These preliminary results suggest that ES-SCZ shows a significant and independent association with general functioning, with age and sex as covariates. These findings confirm the previously identified negative link between ES-SCZ and functioning, this time in remitted FEP patients. More data on the previously mentioned variables are currently being collected and will allow for further investigation of the association between general functioning and ES-SCZ, whilst adjusting for other environmental factors and important clinical factors in a larger sample with repeated assessments for longitudinal analyses. We anticipate that increasing data points and the number of participants from the ongoing HAMLETT study will strengthen the model. Taken together, the use of ES-SCZ for clinical

purposes might facilitate clinical characterization and subsequently tailor clinical interventions to individual needs.

F122. COGNITIVE RESERVE AND PANSS SYMPTOMATOLOGY IN FIRST EPISODES OF SCHIZOPHRENIA

Mabel Rodriguez^{*1}, Karolina Knížková¹, Barbora Keřková¹, Aneta Siroňová¹, Aleš Hrubý¹, Monika Večeřová¹, Filip Spaniel¹

¹*National Institute of Mental Health*

Background: Heterogeneity in schizophrenia is not yet fully explored. The concept of cognitive reserve (CR) becomes increasingly important in relation to the expression of the disease. As cognitive reserve we understand the individual's ability to optimize their cognitive activity by using alternative neural networks. The relationship between CR and symptomatology has been studied in general terms. The results of the few studies indicate a correlation between CR and negative symptoms. In our study we analyzed in detail the relationship between CR and symptomatology measured with the Positive and Negative Symptom Scale (PANSS)

Methods: We assessed demographic (sex, age, education) and symptoms (PANSS) variables in a sample of 137 stable patients (46 females, aged 25.93 ± 6.47) diagnosed with either schizophrenia F20.XX(N = 77) or acute and transient psychotic disorder with schizophrenia symptoms F23.1, F23.2(N = 60), ICD-10. CR was operationalized by a composite score based on three proxy measures reflecting lifetime cognitive experiences: education, premorbid IQ, and socioeconomic status. Three different approaches were used to assess symptomatology: 1) the positive, negative, general and total symptomatology 2) the five-factor model with positive symptoms, negative symptoms, disorganization, excited, and depressed as variables 3) PANSS Negative sub-factors2: diminished expression and amotivation. To analyze the relationship between CR and PANSS symptoms, we used a Pearson's correlation. In the case of a significant relationship, the results were further explored with a multivariate multiple regression analysis

Results: 1) A significant negative relationship was found between CR and the PANSS negative symptom scale: $r = -0.28$, $p < 0.01$, 95% CI (-0.42;-0.11). No other significant relationships were observed for the other PANSS scales. Specifically, the relationship between CR and the PANSS positive symptom scale was: $r = -0.04$, $p = 0.65$, 95% CI (-0.21; 0.13); for the PANSS general symptom scale: $r = -0.094$, $p = 0.28$, 95% CI (-0.26;0.075); for the overall PANSS scale: $r = -0.17$, $p = 0.05$, 95% CI (-0.33;-0.001)

2) A significant negative relationship was observed between CR and PANSS five-factor model negative symptom scale, $r = -0.23$, $p < 0.01$ (95%CI -0.38; -0.063); Furthermore, a significant negative relationship was found between CR and PANSS excited symptom scale $r = -0.26$, $p < 0.01$, 95%CI(-0.41; -0.10). However, a significant association was not observed between CR and PANSS positive scale, $r = -0.06$, $p = 0.49$, 95%CI(-0.23; 0.11); PANSS disorganized scale $r = 0.01$, $p = 0.93$, 95%CI (-0.16; 0.17); PANSS depressed scale, $r = 0.09$, $p = 0.28$, 95%CI(-0.087; 0.26).

3) For the PANSS negative sub-factors, the diminished expression scale was mildly negatively correlated with CR, $r = -0.2$, $p < 0.05$, 95%CI (-0.36; -0.03). However, a significant association was not observed between CR and amotivation scale $r = -0.16$, $p = 0.063$, 95%CI (-0.32;0.01) The results of linear regression analysis supported CR as significant predictor of PANSS diminished expression scale $F(1, 135) = 5.62$, $p < 0.05$,

indicating that higher levels of CR were associated with lower scores on the PANSS diminished expression scale. However, the model accounted for a small amount of variance in PANSS diminished expression scores ($R^2 = 0.04$, adjusted $R^2 = 0.03$) Multivariate multiple regression analysis was utilized to examine the relationship between CR and both the PANSS negative symptom scale and the PANSS excited symptom scale, considering them as the dependent variables. Multiple multivariate regression analysis revealed that CR is a significant predictor for both PANSS negative symptom scale and PANSS excited symptom scale ($V = 0.09$; $F(2, 134) = 6.23$, $p < 0.01$). The model explained a small proportion of variance in both PANSS negative symptom scale ($R^2 = 0.05$, adjusted $R^2 = 0.045$) and PANSS excited symptom scale ($R^2 = 0.07$, adjusted $R^2 = 0.063$)

Discussion: Although CR is a significant predictor for PANSS negative symptom and excited symptom factors, in both cases it explains a small proportion of the variance. CR is like "a mini puzzle piece" in the level of the expression of symptomatology

F123. SUCCESSFUL PATIENT RECRUITMENT IN PSYCHIATRIC RESEARCH PROJECTS BRIDGING THE GAP BETWEEN RESEARCH AND CLINIC

Marianne Melau^{*1}, Lone Baandrup¹, Mette Ødegaard², Rikke Hilker¹

¹*Mental Health Services in the Capital Region Denmark, Copenhagen University Hospital,*

²*Mental Health Centre Glostrup, Mental Health Services of the Capital Region*

Background: Clinical research serves as a fundamental pillar for the development of novel and enhanced treatment interventions for patients with mental illness. Successful recruitment is vital for any research study. In the Capital Region of Denmark, the proportion of patients recruited to psychiatric research projects amounted to only 3% in 2022 and locally 6% in Mental Health Center Copenhagen. Difficulties in recruitment are common and annual project terminations due to insufficient recruitment is not unusual. This recruitment improvement intervention aims to enhance collaboration between research projects, patients within the target population, and the clinical setting to augment recruitment to research projects. The goal is to enhance the proportion of patients recruited to 20 % of the patient target population in an outpatient clinic for first-episode psychosis (OPUS team).

Methods: In the OPUS team, we aim to intervene at three levels: 1. Organizational; Facilitate collaboration between research and clinical practice by regular intersections to exchange knowledge bidirectionally and involve clinical experts in the early state of protocol drafting. In addition, shared positions for clinicians are recommended. 2. Clinical; Promote research projects through various channels by inviting researchers to present lectures for both patients and staff and provide easy overview of current research projects. 3. Individually; Involving patients and staff directly in the research process by performing interviews to gain more insight into barriers and how to improve.

Results: Data from semi-structured interviews with patients, researchers and clinical staff will be presented alongside data on recruitment success from clinical research projects recruiting from OPUS. We expect an increasing awareness of the importance of patient recruitment for clinical research and a resulting increase in patients referred to and included in clinical research projects.

Discussion: Which recruitment strategies seemed particularly effective? Which strategies can surmount obstacles, and how are their sustainability and maintenance assured?

F124. IS DURATION OF UNTREATED PSYCHOSIS ASSOCIATED WITH COGNITION AFTER FIVE-YEARS OF AN EARLY ONSET OF PSYCHOSIS?

Inmaculada Baeza*¹, Patricia Camprodon-Boadas², Gisela Sugranyes³, Daniel Ilzarbe⁴, Adriana Fortea⁵, María Moya⁶, Yamila Tosetti⁷, Josefina Castro-Fornieles⁸, Elena De la Serna⁹

¹Hospital Clinic de Barcelona, ²Fundació de Recerca Clínic Barcelona-Institut d'Investigacions Biomèdiques August Pi i Sunyer (IDIBAPS), CIBERSAM, ³Instituto de Investigaciones Biomédicas de Barcelona, CSIC-IDIBAPS-CIBERSAM, ⁴Institute of Neuroscience, Hospital Clinic de Barcelona, ⁵Hospital Clinic / Fundació Clínic per la la Recerca Biomèdica (FCRB) / Universitat de Barcelona, ⁶FCRB-IDIBAPS, ⁷Institut Clínic de Neurociències, Hospital Clínic Universitari, Fundació Clínic per a la Recerca Biomèdica, ⁸Hospital Clinic de Barcelona. Centro de Investigación Biomédica en Red de Salud Mental, CIBERSAM, ⁹Centro De Investigación Biomédica En Red De Salud Mental, CIBERSAM

Background: Early-onset psychoses (EOP LESS THAN 18 years of age) are more severe disorders than those with adult-onset (AOP), and age at onset results in specific patterns of cognitive interference, being in EOP worse at first months after the first-episode of psychosis (de la Serna et al, 2023). Also, duration of untreated psychosis (DUP) is longer in EOP than AOP (Baeza et al, 2023). Meta-analyses have not shown a relationship between DUP and cognition, but they included almost only studies with AOP samples (Allot et al, 2018; Bora et al, 2018). The objective of this study is to assess in a sample of adolescents who had an EOP the possible relationship between DUP and cognition after 5-years of evolution, and compare cognition domains in patients with long and short DUP.

Methods: This is a 5-year prospective longitudinal study of patients who had a first episode of psychosis before 18 years of age. A sample of healthy controls (HCs) were also included. At baseline as well as 5-year assessment both a clinical and cognitive evaluation was conducted including intelligence, verbal memory, working memory, attention and executive functions.

Results: Thirty-four patients with an EOP and 31 HC were included with both assessments. At baseline, no differences were found in age between patients and HC (15.8 ± 1.8 vs. 15.3 ± 1.4 years, respectively, $t=1.301$, $p=0.197$) and sex (70 vs 60.8% males, $\chi^2=0.835$, $p=0.386$). Both at baseline and at 5-year follow-up, patients performed significantly worse than HC in all the cognitive domains. From 34 EOP patients at baseline, 23 (67.6%) were diagnosed with schizophrenia and 11 (32.4%) with bipolar disorder at 5-year assessment. Mean DUP for patients with schizophrenia was 60.2 ± 59.4 days and for bipolar disorder: 35.9 ± 30.8 days, without reaching statistically significant differences ($t=1.065$, $p=0.300$). When we divided the sample between those with longer DUP (mean+ 1 SD) for each diagnosis, 25% of the sample had a long DUP (mean of 112.2 ± 66.8 days) vs the others (33.7 ± 24.5 days). No differences in total PANSS or any of the PANSS subscales at 5-year follow-up were shown in both groups. Comparing cognitive domains at 5-year assessment, patients with longer DUP performed worse in the executive function domain ($t=2.460$, $p=0.024$) than the other EOP patients, without significant differences in the other domains.

Discussion: Executive functions are more impaired in EOP patients with longer DUP at 5-years of follow-up, suggesting a possible neurotoxic role of untreated psychosis in younger patients. It's important to study the impact of DUP in long-term cognition in EOP patients to analyze its consequences and try to detect and treat the psychotic symptoms as soon as possible.

This study has been funded by Fundación Alicia Koplowitz, Instituto de Salud Carlos III (ISCIII) through the project PI20/00654 and co-funded by the European Union.

F125. INTEGRATION OF CLINICAL AND EEG PREDICTORS USING MACHINE LEARNING

Livia Dominicus^{*1}, Melissa Zandstra¹, Josephine Franse¹, Wim Otte¹, Arjan Hillebrand², Simone De Graaf¹, Karen S. Ambrosen³, Birte Glenthøj⁴, Andrew Zalesky⁵, Floor Scheepers⁶, Cornelis Stam⁷, Bob Oranje⁸, Bjorn Ebdrup⁹, Edwin van Dellen¹

¹UMC Utrecht, ²Amsterdam UMC, ³Center for Neuropsychiatric Schizophrenia Research (CNSR) and Center for Clinical Intervention and Neuropsychiatric Schizophrenia Research (CINS), ⁴Center for Neuropsychiatric Schizophrenia Research, CNSR, and Center for Clinical Intervention and Neuropsychiatric Schizophrenia Research, Mental Health Centre Glostrup, University of Copenhagen, ⁵The University of Melbourne, Melbourne Neuropsychiatry Centre, ⁶University Medical Center Utrecht, Utrecht, ⁷VU University Medical Center, ⁸Center for Neuropsychiatric Schizophrenia research, ⁹University of Copenhagen

Background: Prompt diagnosis and intervention are crucial for first episode psychosis (FEP) outcomes, but predicting response to antipsychotics in FEP remains a challenge. We tested (1) the performance of a prediction model with clinical features and (2) if a prediction model of combined clinical and EEG characteristics outperforms clinical models for treatment response.

Methods: Our study incorporated EEG data from 70 antipsychotic-naïve FEP patients for the clinical model and 45 for the combined model. The clinical model was tested and validated in two separated datasets (N=70 and N=45). Clinical attributes included Positive and Negative Symptom Scale (PANSS) items and sociodemographic details. From the resting state EEG data we derived relative power, functional connectivity, and network organization metrics. Treatment response was assessed via changes in PANSS positive subscale scores from baseline to a 4-6 week follow-up. We applied machine learning algorithms for the prediction of treatment response using a random forest regression model.

Results: The clinical models elucidated a 12-32% variance in symptom reduction. Integrating EEG markers showed 34% variance in symptom reduction, but did not significantly improve the clinical model. High hallucination symptom scores and a more hierarchical organization of alpha band networks (Tree hierarchy) were associated with Δ PANSS+ reduction.

Discussion: We found that both clinical and combined clinical-EEG models can be used for the prediction of treatment response in patient with a first psychotic episode. However, there is no significant difference between the clinical model and the combined model, suggesting that in practice, one can work solely with the clinical model.

F126. CANNABIS WITHDRAWAL ASSOCIATED PSYCHOSIS: CASE SERIES AND SYSTEMATIC REVIEW

Edward Chesney^{*1}, Thomas Reilly², Fraser Scott³, Ikram Slimani¹, Ananya Sarma¹, Daisy Kornblum³, Dominic Oliver², Philip McGuire²

¹Institute of Psychiatry, Psychology and Neuroscience, King's College London, ²University of Oxford, ³South London and Maudsley NHS Foundation Trust

Background: Cessation of heavy cannabis use can cause a withdrawal syndrome which is characterised by irritability, anxiety, insomnia, reduced appetite, restlessness and physical symptoms such as abdominal pain, headache and sweating. Recent reports have described cases

in which cannabis withdrawal has been associated with the acute onset of psychosis. Our objective was to identify cases of psychosis associated with cannabis withdrawal.

Methods: We searched a large electronic database of psychiatric healthcare records in South London using the Clinical Record Interactive Search system. We reviewed entries (n=1,058) which had terms related to both psychosis and cannabis withdrawal. A case was included if two psychiatrists agreed that the patient had an episode of psychosis which was ‘probably’ or ‘definitely’ associated with cannabis withdrawal. All demographic and clinical data were either extracted or reviewed by a psychiatrist. Psychotic symptoms were assessed using the OPCRIT criteria. We also completed a systematic review of previously published case reports, case series and other studies.

Results: In the health record study, we identified 69 cases in which cannabis withdrawal was associated with the onset of acute psychosis. Forty-eight cases involved a first presentation of psychosis while 21 were relapses in people with an existing psychotic disorder. Almost all cases were daily cannabis users who stopped using cannabis abruptly, and many reported severe sleep disturbance before the emergence of psychotic symptoms. Psychosis emerged within 1 week of cessation in 48 (69.6%) of cases, with the highest incidence at four days post-cessation. The symptoms with the highest prevalence were persecutory delusions (76.8%), poor appetite (71.0%), initial insomnia (69.6%), loss of insight (68.1%), and agitated activity (66.7%). A sleep disturbance of any type was identified in 62 (89.9%) of participants. Cases who continued to use cannabis after the acute episode had a much higher risk of subsequent relapse than those who did not (Odds ratio = 14.7 [95% CI: 4.3 to 60.0]; $\chi^2 = 21.1$, $p < 0.00001$). Terms describing cannabis withdrawal or the cannabis withdrawal syndrome were only written in the clinical records in a minority of cases (24; 34.8%). The systematic review identified a total of 28 cases from 16 studies. The demographic and clinical features of these cases were similar to those identified from the health record search, with a high proportion of male patients, frequent histories of heavy cannabis use followed by abrupt withdrawal, and many cases with a history of insomnia prior to psychosis onset.

Discussion: These studies comprise the largest set of cases of cannabis withdrawal associated psychosis collected to date (n=97). They suggest that the cannabis withdrawal syndrome may precipitate the onset of psychosis more often than has been recognised previously. It is important that clinicians are aware that psychotic symptoms can emerge after the cessation of cannabis use, as well as following cannabis use.

F127. CHILDHOOD TRAUMA AND TREATMENT RESISTANCE IN FIRST-EPISODE PSYCHOSIS: INVESTIGATING THE ROLE OF PREMORBID ADJUSTMENT AND DURATION OF UNTREATED PSYCHOSIS

Kristin Wold*¹, Akiah Ottesen², Camilla Bärthel Flaaten³, Trine Vik Lagerberg⁴, Kristin Lie Romm⁵, Carmen Simonsen⁶, Line Widing¹, Gina Åsbø¹, Ingrid Melle⁷

¹NORMENT, Oslo University Hospital and Institute of Clinical Medicine, University of Oslo, ²Norwegian Centre for Violence and Traumatic Stress Studies, ³NORMENT Centre for Research on Mental Disorders, University of Oslo and Oslo University Hospital, ⁴NORMENT, Oslo University Hospital and Institute of Clinical Medicine, University of Oslo, ⁵Early Intervention in Psychosis Advisory Unit for South East Norway, Oslo University Hospital, ⁶NORMENT, Division of Mental Health and Addiction, Oslo University Hospital and Institute of Clinical Medicine, University of Oslo, ⁷Early Intervention in Psychosis Advisory Unit for

South East Norway, Oslo University Hospital, ⁷NORMENT, Division of Mental Health and Addiction, Oslo University Hospital and Institute of Clinical medicine, University of Oslo,

Background: Early identification of treatment non-response in first-episode psychosis (FEP) is essential for outcomes, but the impact of childhood trauma (CT) is not thoroughly investigated. How the interplay between CT and other pre-treatment variables affects outcome is also not comprehensively examined. We use an adaptation of recent consensus criteria to identify FEP without early clinical recovery (no-ECR), an indicator of early treatment resistance, to investigate the relationship between CT and potential treatment resistance at one-year follow-up.

Methods: 141 participants recruited in their first year of treatment for a schizophrenia-spectrum disorder participated in this prospective one-year follow-up study. We investigated clinical status, childhood trauma (CT), premorbid adjustment (PA), and duration of untreated psychosis (DUP) at baseline and clinical status at one-year follow-up. Ordinal regression analyses were conducted to investigate to what extent PA and DUP affected the relationship between CT and one-year outcome in FEP.

Results: 55% of the FEP sample reported moderate to severe CT, with significantly higher levels of CT in the no-ECR group compared to participants with full or partial early recovery. Ordinal regression analysis showed that CT was a significant predictor for belonging to a more severe outcome group (OR=4.25). After including PA and DUP in the model, the effect of CT weakened, suggesting that PA and DUP mediate the effects of CT on early indications of treatment resistance.

Discussion: Our findings support the importance of reducing treatment delay to mitigate adverse effects of CT on clinical outcomes and the inclusion of trauma assessment in FEP services.

F128. EXPLORING MENTAL HEALTH DATA SHARING PRACTICES AND PERSPECTIVES AMONG LATINX SPANISH SPEAKING COMMUNITY PARTNERS IN THE CALIFORNIA EARLY PSYCHOSIS INTERVENTION (EPICAL) NETWORK

Karina Muro^{*1}, Sophie A. McMullen², Kathleen E. Nye¹, Valerie L. Tryon³, Steven R. Lopez⁴, Adrian F. Asbun¹, Vanessa Merino-Castenada¹, Mark Savill¹, Laura M. Tully¹, Sabrina Ereshefsky¹, Tara A. Niendam¹

¹University of California, Davis, School of Medicine, ²University of California - San Francisco, ³UC Davis Medical Center, ⁴University of Southern California,

Background: Despite being the nation's second largest racial and ethnic group in the US, very little is known about the perspectives of mental health data sharing and privacy preferences among Latinx Spanish speaking populations in early psychosis (EP) care programs. Therefore, it is imperative to understand the unique preferences and perspectives of this population if early psychosis researchers and clinicians alike want to be equitable in serving marginalized Latinx populations utilizing eHealth technology tools with end user license agreements (EULAs). This study seeks to explore the specific preferences and concerns around data sharing for Latinx Spanish speaking consumers in California.

Methods: We conducted three qualitative focus groups (provider, service user, and support persons) exploring the attitudes, beliefs, and preferences of Latinx Spanish speaking community partners to address culturally affirming practices for ethical and equitable data use. All three groups were led by bilingual Spanish speaking group facilitators. Participants

included Spanish and English-speaking community partners involved in delivering or receiving EP care within California Early Psychosis Intervention (EPI-CAL), thus, the provider and support person focus groups were conducted primarily in Spanish and the service user group was conducted in English as the language preference for the group. Key themes were identified via a content analysis of focus group transcripts.

Results: Participants included 6 providers, 5 support persons, and 2 service users. Of note, most of the support person participants identified as a mother of a loved one in an EP care program. Across all three groups transparency and provision of relevant information, mental health stigma, control and agency of data, unfamiliarity with data sharing concepts, as well as data security and protections were considered of utmost importance when considering data sharing. Notable themes of the potential to help others, overall general mistrust of data sharing, and mistrust of technology were of significance for both the provider and support person group. Additionally, rapport with clinical providers was a critical theme for service users and their support persons.

Discussion: As the use of electronic and digital tools increases in both research and clinical EP settings, it is urgent to recognize the attitudes, beliefs, preferences, and concerns around data sharing for marginalized groups such as Latinx Spanish speaking communities. To better serve Latinx community partners in EP care during this era of eHealth technology tools we must recognize the concerns of mental health stigma, unfamiliarity with data sharing concepts, and the mistrust of technology that may potentially contribute to their unwillingness to utilize eHealth technology tools. We need to carefully consider how we are introducing mental health data sharing concepts if we want to build trust and promote the involvement of sharing data among Latinx community partners participating in EP programs. Future studies should consider exploring access to available digital tools and technology as well as incorporating educational forums to increase awareness of data sharing concepts.

F129. BRAIN-WIDE DISRUPTIONS OF ANATOMICAL CONNECTIVITY PREDICT LONGITUDINAL FUNCTIONAL OUTCOMES IN ANTIPSYCHOTIC-NAÏVE FIRST EPISODE PSYCHOSIS

Sidhant Chopra^{*1}, Priscila Levi², Alexander Holmes², Edwina Orchard¹, Shona Francey³, Brian O'Donoghue³, Vanessa Cropley⁴, Barnaby Nelson³, Jessica Graham³, Hok Pan Yuen³, Kelly Allott³, Mario Alvarez-Jimenez³, Susy Harrigan⁵, Christos Pantelis⁴, Stephen J. Wood³, Patrick McGorry³, Alex Fornito²

¹Yale University, ²Turner Institute of Brain and Mental Health, Monash University, ³Orygen, ⁴The University of Melbourne, ⁵Monash University

Background: Disruptions of axonal connectivity are thought to be a core pathophysiological feature of psychotic illness, but whether they are present early in the illness, prior to antipsychotic exposure, and whether they can predict clinical outcome remains unknown.

Methods: We acquired diffusion-weighted MRI to map axonal connectivity between each pair of 319 parcellated brain regions in 61 antipsychotic-naïve individuals with First Episode Psychosis (FEP; 15-25 years, 46% female) and a matched sample of 25 control participants, along with clinical follow-up data in patients 3 months and 12 months after the scan. We used connectome-wide analyses to map disruptions of inter-regional pairwise connectivity, coupled with connectome-based predictive modelling to predict longitudinal change in symptoms and functioning.

Results: Individuals with FEP showed disrupted connectivity in a brain-wide subnetwork linking all brain regions when compared with controls ($p\text{-FWE}=0.03$). Baseline structural connectivity significantly predicted change in functional outcome at 12 months ($r=.44$; $p\text{-FWE}=0.041$), such that lower connectivity within fronto-striato-thalamic systems predicted worse outcomes.

Discussion: Diffuse brain-wide reductions of structural connectivity exist during the early stages of psychotic illness and cannot be attributed to antipsychotic medication. Moreover, baseline measures of structural connectivity can predict change in patient functional outcomes up to one year after engagement with treatment services.

F130. INDIVIDUAL MEDICATION-TAKING BEHAVIOR IN EPI CARE AND SIDE EFFECT REPORTING CONCORDANCE WITH SUPPORT PERSONS

Katherine M. Pierce^{*1}, Kathleen Marshall¹, Regina Graham¹, Kathleen E. Nye¹, Valerie L. Tryon¹, Laura M. Tully¹, Stephania L. Hayes¹, Mark Savill¹, Sabrina Ereshefsky¹, Chelyah Miller¹, Madison J. Miles¹, Merissa Kado-Wilson², Khanh Linh H. Nguyen¹, Nitasha Sharma¹, Amanda P. McNamara², Christopher K. Hakusui¹, Viviana Padilla¹, Maliha Safdar², Rachel Lowey³, Daniel J. Shapiro¹, Khalima A. Bolden-Thompson¹, Karina Muro¹, Yi Zhang¹, Andrew Padovani¹, Leigh Smith¹, Adam B. Wilcox⁴, Lindsay M. Banks¹, Renata M. Botello¹, Rebecca Grattan¹, Joy Melnikow¹, Daniel J. Tancredi¹, Bonnie Hotz¹, Sonya Gabrielian⁵, Lisa Dixon⁶, Cameron S. Carter¹, Tara A. Niendam¹

¹University of California Davis, ²University of California, San Diego, ³University of California, San Francisco, ⁴Washington University in St. Louis, ⁵University of California, Los Angeles, ⁶Columbia University

Background: Medication side effects can impact individuals' perceptions of medication efficacy and subsequent medication taking behaviors. In early psychosis intervention (EPI), taking medications as prescribed and having a support person (e.g. family) involved in care are key factors associated with better outcomes. Facilitating communication regarding medication side effects between care providers, support persons, and individuals receiving care may assist in side effect management, shared decision making, and support healthy medication-taking behaviors. As such, it is important to identify whether individuals in care and their primary support person (PSP) report similar patterns of side effects, and whether there are areas for improved communication. The present study aimed to investigate whether there are differences in PSP and individual report of medication side effects, characterize any patterns in discordance, and identify areas for potential clinical intervention.

Methods: Within the first 6 months of EPI engagement, individuals and their PSPs were asked whether the individual is prescribed any medication. Those who endorsed having at least one prescription medication were administered a modified version of the Glasgow Antipsychotic Side-effect Scale (GASS). Paired samples T-test examined GASS sum scores to determine whether individuals were systematically reporting more side effects than PSPs. Individual and PSP GASS item level endorsement concordance was evaluated utilizing Cohen's Kappa. Finally, bivariate correlations were conducted between GASS scores and measures assessing intent to remain in EPI care and taking medication as prescribed. Concordance between PSP, individual, and clinician agreement on medication status was also examined.

Results: In a total sample of 114, agreement of medication prescription status between individuals and PSPs was high ($k = .84$, $p < .001$ at baseline, $k=1.00$, $p < .001$ at 6 months). Individuals who endorsed prescription medication and completed

the GASS were examined (n=54 at baseline, n=22 at 6 months of EPI engagement). At baseline, 78% of individuals (32 of 41) reported taking any medication as prescribed 0-25% of the time; at 6 months, 93% of individuals (13 of 14) reported taking medication as prescribed 0-25% of the time. Paired sample T-test results indicated that individuals and PSPs report similar rates of side effects; however, which side effects were endorsed differed. Of the 27 side effect items assessed, at baseline individuals and PSPs agreement performed above chance on 16 items (ranging from $k=.19$ to $k=.47$). At 6 months, only 7 items performed above chance (ranging from $k=.22$ to $k=.48$). GASS scores did not significantly correlate with intent to continue or complete EPI services, medication-taking behaviors, or medication related beliefs. However, individuals' distress regarding side effects was significantly correlated with concerns that taking medication will do more harm than good ($r=.32$, $p < .05$).

Discussion: In the present sample, most individuals reported they take medication as prescribed 25% of the time or less. These medication taking behaviors may impact the number of medication side effects individuals experience and reduce overall medication efficacy. Individual and PSP agreement on side effects was moderate to low at baseline and decreased over the course of EPI. Lack of PSP and clinician awareness and communication around individuals' medication taking behavior may contribute to poor outcomes. Therefore, increased communication between individuals, their support systems, and their care teams is crucial to address individuals' concerns regarding medication and increase shared decision making.

F131. CONNECTION LEARNING HEALTHCARE SYSTEM HUB OF THE EARLY PSYCHOSIS INTERVENTION NETWORK: PROGRAM AND PARTICIPANT CHARACTERISTICS

Monica Calkins^{*1}, Megan Jumper¹, Arielle Ered¹, Fanghong Dong¹, Deepak Sarpal², Krista Baker³, Donna Bencivengo¹, Russell Margolis³, Robert Buchanan⁴, Yasmine Boumaiz⁵, Elizabeth Burris⁶, Phillip Campbell¹, Roy Chengappa², Catherine Conroy¹, Akinyi Cooke⁷, Faith Dickerson⁸, Nyasia Flowers⁷, Mandy Fauble⁹, Richard Goldberg¹⁰, Alexander Harvin⁸, Carolyn Howell⁷, Christian Kelly¹¹, Julie Kreyenbuhl¹⁰, Lan Li⁵, Alicia Lucksted⁵, Jill Marsteller¹², Alexander Moxam¹³, Denise Namowicz¹⁴, Swati Nayar², Jamie Oko¹⁵, Jessie Riggs¹, Arunadevi Saravana⁵, Rachel Scheinberg³, William Smith¹, Richard States⁹, Timur Suhail-Sindhu³, Jerome Taylor¹³, Crystal Vatz¹, Max Wolcott⁷, Christian Kohler¹, Melanie Bennett⁵

¹University of Pennsylvania, ²University of Pittsburgh, ³Johns Hopkins School of Medicine, ⁴Maryland Psychiatric Research Center, University of Maryland School of Medicine, ⁵University of Maryland School of Medicine, ⁶Wesley Family Services First Episode Psychosis Program-ENGAGE, ⁷Johns Hopkins Bayview Medical Center Community Psychiatry Program, ⁸Sheppard Pratt, ⁹University of Pittsburgh Medical Center Western Behavioral Health at Safe Harbor, ¹⁰VA Capitol Health Care Network (VISN 5) Mental Illness Research, Education and Clinical Center (MIRECC), ¹¹University of Pittsburgh Medical Center, Western Psychiatric Hospital, ¹²Johns Hopkins Bloomberg School of Public Health, ¹³University of Pennsylvania and Children's Hospital of Philadelphia, ¹⁴Children's Service Center, ¹⁵Children's Hospital of Philadelphia

Background: Connection Learning Healthcare System (CLHS), one of eight hubs of the National Institute of Mental Health funded Early Psychosis Intervention Network (EPINET),

supports uniform data collection, analysis, feedback, and infrastructure development to promote a culture of continuous quality improvement across twenty-five Coordinated Specialty Care (CSC) programs serving young people experiencing first episode psychosis (FEP) and their families in Maryland and Pennsylvania, USA. This presentation describes the CLHS hub and its constituent programs, approach for developing and implementing a hub-wide core assessment battery harmonized with the national EPINET battery, and preliminary program and participant characteristics.

Methods: Twenty-five CLHS programs provide standard components of CSC, including intake assessment, crisis intervention services, pharmacotherapy, psychoeducation, family support, employment and education services, and individual therapy, for up to two years or longer. Program capacity ranges from 15 to GREATER THAN 150 individuals (mean=37). Participant age (minimum range=13-16 years, mean=14.9; maximum range=18-40 years, mean=29.4) and duration of untreated psychosis (DUP; range=12-60 months, mean=21.6 months) are eligibility criteria for all programs. Most programs are overseen by, or embedded within, community mental health centers (57%), hospitals (39%), or academic institutions (22%). Our hub developed and implemented a computerized core assessment battery, harmonized with the national EPINET battery, selecting measures based on domain coverage, clinical utility, reliability/validity, practical utility, and utility to multiple stakeholders. The battery assesses 5 core domains: (1) Socio-Demographic, Pathways to Care, Adverse Events; (2) Symptoms and Diagnosis; (3) Psychosocial Functioning and Recovery; (4) Physical Health, Medication, and Side-Effect Monitoring; and (5) Service Engagement and Satisfaction. The battery is administered by trained program staff at admission and every 6 months thereafter through program discharge. To assist with data monitoring and enhance the CAB's clinical utility, all sites receive licenses for Tableau, a data visualization system.

Results: Between January 2021 and May 2023, 803 participants were admitted to a CLHS program and a total of 912 complete and 1662 partially completed assessment batteries across time-points were collected. Completion rates are higher for clinician administered than participant self-report measures. Admission age ranges from 12.2 to 39.7 years (Mean=20.8, s.d.=4.0). At admission, most participants are male at birth (66%), identify as African American or other minority group (54%), have a high school diploma or less (64%), and have experienced a prior psychiatric hospitalization (80%; mean prior hospitalizations=2.2). Primary diagnoses at admission are predominantly Other Specified/Unspecified Schizophrenia Spectrum Disorders (46%), Schizophrenia (17%), Schizoaffective (11%), and mood with psychotic features (11%). Mean duration of untreated psychosis (defined as time in months between first threshold psychosis symptoms and admission to an FEP program) is 13.5 months. Clinical characteristics at admission reveal moderate psychiatric symptoms, serious to moderate impairment in role and social functioning, mild antipsychotic medication side effects, and relatively high service engagement.

Discussion: As part of our learning healthcare system to improve clinical services and outcomes across two states, CLHS has implemented standardized assessment across twenty-five CSC programs. Our efforts align with those of other EPINET hubs and show that CLHS serves a diverse cohort of young people experiencing FEP. Prospective data are now being analyzed to investigate critical topics in FEP CSC, including treatment engagement, medication prescription practices, substance use, suicidality, trauma, and family involvement. Given our overall success in implementing the battery, the many potential applications in clinical research and practice, and the resources the EPINET initiative provides to CSC programs outside of the network, we recommend CSC programs engage in standardized data collection, despite some challenges. Routine assessment allows programs to track individual and program progress and outcomes and offers the opportunity to discuss this progress with young people, families, administrators, and funders. The national EPINET dataset, aggregating

data from CLHS and the other seven EPINET hubs, constitutes a novel large-scale resource allowing powerful analyses that ultimately should inform and improve FEP practice and outcomes.

F132. ADDRESSING DISCRIMINATION IN A FIRST EPISODE PSYCHOSIS POPULATION: INDIVIDUAL AND PRACTITIONER PERSPECTIVES AT THE BEGINNING OF TREATMENT

Piper Meyer-Kalos*¹, Arundati Nagendra², Grace Owens¹, Melissa Fisher¹, Mara Russell¹, Sophia Vinogradov¹

¹University of Minnesota Medical School, ²Massachusetts General Hospital

Background: Experiences of discrimination for individuals with first episode psychosis (FEP) are common, with estimates ranging from 76% to 98%. These experiences may play a role in long-term outcomes, as international research suggests that illness-related stigma may be associated with demographic, clinical, and functioning variables. Those from minoritized communities (e.g., due to their sexual orientation or race) may experience the effects of compounded forms of discrimination. Such experiences, whether in their communities or in treatment, may contribute to observed poorer outcomes, such as by delaying help-seeking and interfering with treatment engagement. In this study, we aim to understand the impact of discriminatory experiences due both to illness and belonging to a minoritized community when a person is first entering FEP treatment. Secondly, we will evaluate practitioner perspectives on broaching the topic of discrimination in treatment and training needs to address experiences of discrimination.

Methods: The sample is collected from 6 coordinated specialty care (CSC; first episode psychosis) programs in Minnesota as part of the Early Psychosis Intervention Network (EPINET). The sample of 182 individuals includes individuals with schizophrenia spectrum diagnoses, affective disorders with psychosis, and unspecified psychosis diagnoses. When individuals enter treatment in the CSC programs, a routine assessment battery is collected as standard of care at baseline and every 6 months. This project evaluates data from the Intersectional Discrimination Index (InDI) which includes 3 subscales (anticipated, day-to-day, and major discrimination). We will evaluate the relationship between experiences of discrimination and key clinical and demographic variables including race/ethnicity, age, gender, diagnosis, duration of untreated psychosis, symptoms, functioning, and service utilization. Additionally, we developed an 11-item survey to evaluate how providers discuss discrimination in treatment. We will assess how frequently practitioners bring up discrimination compared to clients and how prepared practitioners feel to address experiences of discrimination in treatment. 29 providers from 4 of the 6 FEP clinics completed the survey.

Results: At the beginning of treatment, 68% (n=124) of individuals entering CSC reported an experience of discrimination in the last 12 months and 83% reported an experience of discrimination within their lifetime. The most commonly reported types of discrimination included experiencing jokes/laughter, treated as unfriendly/rude, and treated as less smart/capable. Results from the clinician survey found that 31% (n=9) of clinicians do not feel comfortable being the first to bring up topics related to discrimination and 17% (n=5) of clinicians feel uncomfortable when responding to clients who bring up topics related to discrimination.

Discussion: Our findings associated with lifetime experiences of discrimination align with other studies that have found high rates of discrimination experiences in FEP. Upon entering early intervention treatment, people with FEP are likely to be struggling with concerns about

current or anticipated illness-related discrimination in addition to psychotic symptoms. Beyond this, those from minoritized communities may have compounded discriminatory experiences and may need additional support. As such, assessing experiences of discrimination across groups for individuals entering a CSC program may inform targeted assessment and treatment interventions at entry into a CSC program. When provided with training and support, practitioners in CSC programs could play a pivotal role in addressing the needs of those experiencing multiple types of discrimination, in turn improving outcomes for those with FEP. These data will inform strategies and training for CSC practitioners to broach and address the impacts of discrimination for individuals with FEP.

F133. PARSING INSIGHT IN FIRST EPISODE PSYCHOSIS (FEP): AWARENESS AND JUDGMENT

Hadar Hazan*¹, Vinod Srihari²

¹*Yale Medical School*, ²*Yale University*

Background: Despite the progress made in measuring and quantifying insight, there remains a persistent gap between the theoretical conceptualization and the phenomena of insight. Even after more than three decades, the study of insight in individuals with psychosis continues to present significant challenges for researchers. Despite some correlation among some of the scale, they vary greatly in the aspects they include under the term insight. Insight scales may (or may not) include cognitive aspects (awareness of having a disorder, labeling oneself as ill, awareness of social consequences of illness), need for treatment (need for treatment, its effects and benefit) symptoms-specific aspects (awareness of specific symptoms and their attribution to illness), and temporal-related aspects (whether the three previous components of insight include the present time, the past, and the future course of illness). Scales also differ in their dichotomic vs. continuous view of rating and the rater (self-report vs. clinician-rated).

Methods: We explore the varied definitions and conceptualizations of insight, noting the discrepancy between theoretical constructs and the operationalization of insight measures. We systematically review six prominent insight scales: The Scale to Assess Unawareness of Mental Disorder (SUMD), The Comprehensive Assessment of Insight (CAI), The Insight and Treatment Attitudes Questionnaire (ITAQ), The Scale for Assessing Insight in Psychosis (SAP), The Psychotic Symptom Rating Scale (PSYRATS), and The Assessment of Insight (AOI).

Results: We discuss the strengths and limitations of each scale, including their psychometric properties, theoretical underpinnings, and clinical utility.

Discussion: We conclude by highlighting the need for a more comprehensive and unified approach to measuring insight in psychosis, encompassing both cognitive and affective aspects of insight.

F134. THE ANXIOLYTIC EFFECT OF ATYPICAL ANTIPSYCHOTICS IN PATIENTS WITH SCHIZOPHRENIA: A SYSTEMATIC REVIEW AND META-ANALYSIS

Ali Abdolizadeh^{*1}, Maryam Hosseini Kupaie², Yasaman Kambari¹, Aron Amaev¹, Vittal Korann³, Edgardo Torres-Carmona¹, Jianmeng Song¹, Fumihiko Ueno⁴, Teruki Koizumi⁵, Shinichiro Nakajima⁶, Sri Mahavir Agarwal⁷, Philip Gerretsen⁸, Ariel Graff-Guerrero⁸

Background: Despite the high prevalence of anxiety in schizophrenia (SCZ), no established guideline exists for the management of these symptoms. While adjunctive antidepressants could be useful for depressive and negative symptoms, their effectiveness on anxiety has not been well studied. Moreover, the evidence is limited to support the long-term use of gamma-aminobutyric acid-A (GABA-A) receptor modulator benzodiazepines in patients with SCZ, considering its potential addictive properties; however, GABA-A receptor dysfunction has been related to the neurobiology of SCZ. Furthermore, augmentations with novel agents such as amino acid L-theanine, pregnenolone, and cannabis derivatives require more research to conclude their clinically significant benefits for anxiety in SCZ. For the management of patients with SCZ and concurrent anxiety symptoms, it is suggested to consider treatment options that are effective for both conditions. Atypical antipsychotics (AAPs) are the recommended pharmacotherapy for SCZ, and their efficacy has been reported for the treatment of primary anxiety disorders and comorbid anxiety in mood disorders including bipolar disorder. To our knowledge, the anxiolytic effect of AAP in SCZ has not been systematically reviewed. We aimed to synthesize evidence on anxiolytic effects of AAPs in patients with schizophrenia.

Methods: We systematically searched Medline, Embase, PsycInfo, and Web of Science to identify randomized controlled trials of AAPs reporting anxiety measures in schizophrenia. The search was limited to English-language articles published before January 2023. Data were pooled using a random-effects model.

Results: Among 48 eligible studies, 29 (n=7712) were included in the meta-analyses comparing AAPs to placebo, haloperidol, or another AAP for their effect on anxiety. AAPs had a small anxiolytic effect versus placebo (SMD=-0.28 (95%CI [-0.34,-0.21], p LESS THAN .00001, I²=47%, n=5576), which were associated with efficacy for positive (z=5.679, p LESS THAN .001) and negative symptoms (z=4.490, p LESS THAN .001). Furthermore, AAPs were superior to haloperidol (SMD=-0.44, 95%CI [-0.75,-0.13], p=.005, n=1068) with substantial study-level heterogeneity (I²=85%). Excluding one study of quetiapine in first-episode patients (SMD=-3.05, n=73), AAPs showed a small anxiolytic effect versus haloperidol without heterogeneity (SMD=-0.23, 95%CI [-0.35,-0.12], p=.01; I²=%0). Risperidone's anxiolytic effect was comparable to olanzapine (SMD=-0.02, 95%CI [-.24,0.20], p=.87, I²=45%, n=753) and amisulpride (SMD=0.27, 95%CI [-1.08,0.61], p=.13, I²=50%, n=315).

Discussion: While AAPs showed a small anxiolytic effect, the findings are inconclusive due to scarcity of research on comorbid anxiety in schizophrenia, heterogeneity of anxiety symptoms, and the scales used to measure anxiety. Further studies employing specific anxiety scales are required to explore antipsychotics, considering their receptor affinity and augmentation with serotonin/norepinephrine reuptake inhibitors or benzodiazepines for managing anxiety in schizophrenia.

F135. GLOBAL THICKNESS ADJUSTMENT OF REGIONAL THICKNESS MEASURES YIELDS ERRONEOUS RESULTS IN SCHIZOPHRENIA

Jessica Hua*¹, Susanna Fryer², Barbara Stuart³, Rachel Loewy⁴, Sophia Vinogradov⁵, Daniel Mathalon²

¹San Francisco Veterans Affairs Medical Center, ²University of California, San Francisco,

³Department of Psychiatry, University of California, San Francisco; San Francisco, CA,

⁴University of California - San Francisco, ⁵University of Minnesota Medical School

Background: Recent studies in psychiatric disorders, including schizophrenia and bipolar disorder, as well as the clinical high-risk for psychosis (CHR-P) syndrome, have advocated that analyses of regional thickness covary for global thickness, to support conclusions about disease-related regional specificity. Moreover, recent efforts to disseminate analytic tools to conduct age- and gender-normative modeling have incorporated global brain covariation when deriving normatively-adjusted regional measurements. These analytic approaches have been applied to large datasets, yielding seemingly definitive estimates of disease effects on regional morphometry. The current study challenges this approach on conceptual and statistical grounds, formally demonstrating its misleading impact on psychiatric comparisons. We examined regional thickness profiles from two archival magnetic resonance imaging (MRI) studies and hypothesized that: 1) covarying for global thickness will attenuate or eliminate patient group regional thickness abnormalities, 2) especially when there are patient group abnormalities in global thickness and when global and regional thickness are highly correlated.

Methods: Study 1 consists of 90 healthy control (HC), 51 CHR-P (10 individuals converted to a psychotic disorder, 23 were followed clinically for ≥ 24 months without converting), and 78 early illness schizophrenia (ESZ) participants from the University of California San Francisco. Study 2 consists of 56 HC, 83 non-affective psychosis (NAff-P), and 30 affective psychosis (Aff-P) participants from the Human Connectome Project-Early Psychosis (HCP-EP). We examined global and regional thickness correlations, global thickness group differences, and regional thickness group differences with/without global thickness covariation.

Results: Global and regional thickness were strongly correlated across groups. Global thickness was lower in schizophrenia-spectrum groups versus other groups. Regional widespread schizophrenia-spectrum group differences (large effect sizes) were eliminated with global thickness adjustment. Global thickness adjustment so distorted profiles of schizophrenia-spectrum groups that, paradoxically, adjusted scores for some brain regions were rendered abnormally increased. Further, there was a trend for CHR-P converters to have decreased global thickness versus non-converters, with complete attenuation of regional differences with global thickness covariation. In contrast, CHR-P and Aff-P did not differ from HC in global thickness, and profiles remained similar with global thickness adjustment. This distortion was further demonstrated in permutation analyses in which global thickness was randomly shuffled within groups to attenuate the typical regional-global thickness correlation. This simulation showed that distortion of true group differences only arises when global and regional thickness are highly correlated, which in nature, is most of the time.

Discussion: Depriving regional thickness of the variance it shares with global thickness removes disease-related effects and leads to erroneous conclusions, particularly when widespread cortical deficits are characteristic of the disease. These analytical decisions are important to clarify because conclusions drawn from these studies inform our understanding of disease pathophysiology and identification of prognostic biomarkers. We recommend future studies examining cortical thickness in psychiatric disorders abandon the poorly conceived practice of global thickness adjustment, and that currently disseminated analytic tools provide the option to omit global thickness adjustment.

F136. ALTERED BRAIN ACTIVATION DURING MEMORY RETRIEVAL MEDIATES THE RELATIONSHIP BETWEEN DEVELOPMENTAL TRAUMA AND PSYCHOTIC SYMPTOM SEVERITY

Ava Mason^{*1}, William Palmer², Hengyi Cao², Jean Addington³, Carrie Bearden⁴, Kristin Cadenhead⁵, Barbara Cornblatt⁶, Diana Perkins⁷, Daniel Mathalon⁸, Elaine Walker⁹, Scott Woods², Tyrone Cannon²

¹University College London, ²Yale University, ³University of Calgary, ⁴University of California, Los Angeles, ⁵University of California, San Diego, ⁶The Zucker Hillside Hospital, ⁷University of North Carolina, ⁸University of California, San Francisco, ⁹Emory University

Background: Both developmental trauma and poorer episodic memory performance are associated with an increased risk of psychotic symptoms, but the mechanisms underlying these associations remain to be established. We sought to investigate whether both memory performance and fMRI activity during episodic memory retrieval statistically mediated the relationship between trauma severity and psychotic symptom severity in youth at clinical high risk for psychosis.

Methods: Data from 795 participants in the second phase of the North American Prodrome Longitudinal Study were analysed, including the Childhood Trauma and Abuse scale and neurocognitive measures (a paired-associate episodic memory task; fPAM, Hopkins Verbal Learning Task and Brief Visuospatial Memory task). In a subsample of 198 participants, functional activity from five regions of interest associated with memory processing (inferior parietal lobe, superior frontal gyrus, inferior frontal gyrus, superior temporal gyrus, medial temporal gyrus) and data from the Scale of Prodromal Symptoms were analysed. Linear regressions were conducted to measure whether 1) trauma severity predicted delusion and hallucination severity, 2) trauma severity predicted neurocognitive measures and 3) neurocognitive measures predicted hallucination or delusion severity. Statistical mediation analysis was conducted when all paths were significant. All findings controlled for age, sex, site, racial background, parental education, IQ, and antipsychotic medication.

Results: Trauma severity significantly predicted hallucination and delusion severity ($B=0.399$ and $B=0.368$, $p < .01$) and significantly predicted the number of correct true positives ('hits') in the fPAM task ($B=-0.006$, $p=.028$). Average functional activation in the five memory-associated regions mediated 8.74% of the association between DT and hallucination severity, and 7.02% between DT and delusion severity. Inferior parietal lobe activity specifically mediated 10.08% of the association between DT and hallucination severity, and 8.70% between DT and delusion severity.

Discussion: This is the first study to report memory-associated functional brain alterations to mediate the association between developmental trauma exposure and psychotic symptom severity. Average activity from the five regions of interest and from the inferior parietal lobe

specifically mediated this association for both delusion and hallucination severity. Regarding memory performance, increased trauma severity was associated with a significantly lower number of hits within the fPAM, and reduced visuospatial memory performance was significantly associated with increased delusion severity. These findings were significant after controlling for all covariates. This study suggests a role of episodic memory processing and inferior parietal lobe activation in the association between DT and psychosis. Focusing further on these measures could provide insight into the underlying mechanism of this association, and have clinical implications in trauma-exposed individuals with psychosis.

F137. RATES AND PREDICTORS OF SERVICE DISENGAGEMENT IN FIRST EPISODE PSYCHOSIS: RESULTS FROM A 2-YEAR FOLLOW-UP STUDY IN AN ITALIAN REAL-WORLD CARE SETTING.

Lorenzo Pelizza*¹, Enrico Plazzi¹, Emanuela Leuci², Emanuela Quattrone², Marco Menchetti¹
¹*Bologna University*, ²*AUSL di Parma*

Background: Service disengagement is a major concern for “Early Intervention in Psychosis” (EIP). Understanding predictors of engagement is also crucial to increase effectiveness of mental health treatments, especially in young individuals with First Episode Psychosis (FEP). The goal of this research was to assess service disengagement rate and predictors in an Italian sample of FEP subjects treated within an EIP program across a 2-year follow-up period, within a real-world clinical setting.

Methods: All patients were young FEP help-seekers, aged 12-35 years, recruited within the “Parma Early Psychosis” (Pr-EP) program in Northern Italy. At baseline, they completed the Positive And Negative Syndrome Scale (PANSS) and the Global Assessment of Functioning (GAF) scale. Univariate and multivariate Cox regression analyses were carried out.

Results: 489 FEP subjects were enrolled in this study. Across the 2-year follow-up period, a 26% prevalence rate of service disengagement was found. Particularly strong predictors of disengagement were living with parents, poor treatment adherence at presentation and a low baseline PANSS “Disorganization” factor score.

Discussion: More than a quarter of our FEP individuals disengaged the Pr-EP program during the first 2 years of intervention. The findings of this investigation showed that a low baseline acceptance of psychosocial interventions was one of the most robust predictors of service disengagement for FEP patients entered the Pr-EP program. This result supports the meta-analytic evidence on poor treatment adherence as consistent predictive factor related to leaving EIP services, and may reflect low trust in the specialized care that EIP protocols offer to the patient and/or family members, or misconceptions about the therapeutic models provided by some service providers. Another robust predictor of service disengagement from the Pr-EP program was living with parents. This showed that family may not necessarily represent a supportive environment and that a family supportively involved with treatment might not lead to a service-user internally driven motivation to engage. Finally, an additional robust predictor of service disengagement was the presence of lower severity levels in disorganization at entry. A possible solution to reduce disengagement and to facilitate re-engagement of these young patients might be to offer the option of low-intensity monitoring and support, also via remote technology and tele-mental health care.

F138. GOING FURTHER PROCESSING SPEED IN SCHIZOPHRENIA: IMPACT OF GENETIC SUSCEPTIBILITY AND CANNABIS CONSUMPTION IN PATIENTS, CONTROLS, AND SIBLINGS

Ángel Yorca-Ruiz*¹, Nancy Murillo-García², Rosa Ayesa-Arriola³

¹Valdecilla Research Institute, ²Valdecilla Biomedical Research Institute. Research Group on Mental Illnesses, ³Valdecilla Biomedical Research Institute IDIVAL Research Group on Mental Illness, Marqués de Valdecilla University Hospital, University of Cantabria

Background: Processing speed (PS) deficit observed in individuals with schizophrenia spectrum disorders is recognised as central aspects of the illness. Cannabis consumption in first-episode of psychosis (FEP) has been linked to PS deficit, however, this association remains under discussion as certain studies report no significant correlation between these two variables. Furthermore, the interplay that cannabis use and genetic factors may exert an influence on PS in individuals affected by schizophrenia is underexplored. This study aimed to investigate, in a family design study, whether genetic (polygenic score for schizophrenia) and environmental (cannabis use) factors influence PS.

Methods: The sample were a total of 388 participants from PAFIP-FAMILIAS project in Santander, Spain, consisting of 122 First Episode Psychosis (FEP) patients, 93 siblings, and 175 controls. Each participant provided a DNA sample, and information on cannabis use at the study's outset, and completed a neuropsychological assessment that included a PS measure: Digit Symbol Coding Test from WAIS-III. Standard quality control measures were implemented before Polygenic Risk Scores (PRS) calculation. The PRS for schizophrenia was determined using the PRS continuous shrinkage method (1). Two linear mixed models were applied, both with Digit symbol coding test scores as the outcome for PS. The first model incorporated variables such as group, intelligence, sex, and age, potentially linked to PS as fixed effects for PS, and family code as a random factor. The second model integrated polygenic scores and cannabis use as additional fixed effects.

Results: The first model explained 63% of the variance on PS ($R^2 = 0.63$), with group, intelligence, sex, age, and years of education, contributing significantly ($p < 0.05$) to the prediction of the outcome. The second model, including PRS for schizophrenia and cannabis use as predictors, significantly improved the predictive power up to 64% ($\chi^2 = 13.073$, $p < 0.001$). In this model, sex, intelligence, age, and years of education maintained significance as predictors of PS ($p < 0.010$) and cannabis was significant values as well.

Discussion: The results indicate that genetic susceptibility to schizophrenia and irregular cannabis use have significant associations with PS. Overall, more research is needed to fully understand the complex relationship between cannabis use and PS in schizophrenia, including the role of genetic factors and the timing and pattern of cannabis use.

F139. REMARKABLE COGNITIVE RESERVE IN WOMEN: A FAMILIAL MODEL ON FIRST-EPISODE PSYCHOSIS PATIENTS

Rebeca Magdaleno Herrero*¹, Nancy Murillo-García¹, Ángel Yorca-Ruiz¹, Rosa Ayesa-Arriola²

¹Marqués de Valdecilla University Hospital, IDIVAL, ²Marqués de Valdecilla University Hospital, Network Centre for Biomedical Research in Mental Health (CIBERSAM), Marqués de Valdecilla Research Institute (IDIVAL), University of Cantabria. Spain

Background: The constant need for adaptation to social, technological, and cultural changes is undeniable. In this dynamic context, Cognitive Reserve (CR) plays a crucial role in counteracting brain damage, providing greater resilience. This is especially evident in schizophrenia spectrum disorders (SSD), where higher CR was associated with a later onset and increased ability to compensate for psychotic damage. Research highlights that women showed a higher estimation of CR, influencing their approach to environmental and mental health challenges. CR, influenced by factors such as the environment and genetics, and is linked to contemporary challenges like education and healthy habits. Although a genetic influence is suggested, this relationship is imprecise. Familial aggregation, a result of genetic or environmental similarities, emerges as a crucial element by indicating familial phenotypic similarities. This study seeks to analyze CR variability by sex in patients with first-episode psychotic disorders (FEP) and their first-degree relatives, providing a comprehensive insight into how men and women experience CR and face challenges associated with the disease.

Methods: A total of 133 FEP patients and their 244 first-degree relatives (parents and siblings). The sample was divided by sex, being 170 males (82 FEP patients, 55 fathers, and 33 brothers) and 207 females (51 FEP patients, 91 mothers, and 65 sisters). CR was estimated for the entire sample by considering years of education and high-density lipoprotein (HDL) levels as proxies. Linear mixed-effects models, accounting for family identity and considering intelligence quotient (IQ) and age as random factors. Finally, the familiarity of CR was assessed through the Intraclass Correlation Coefficient (ICC).

Results: The participants who obtained the highest estimate of CR were the sisters (mean= 55.12), followed by the female FEP patients (mean= 51.50), brothers (mean= 49.61), mothers (mean= 49.37), fathers (mean= 46.68), and finally male FEP patients (mean= 45.35). Male FEP patients exhibit a significantly lower mean CR than the rest of the participants, except for their fathers. Additionally, females show a higher mean CR than males, especially female FEP patients and sisters. Specifically, female FEP patients and sisters display a significantly higher mean than male FEP patients and fathers. The levels of CR familiarity are moderate, with an ICC of 0.319. When dividing the sample by sex, we obtain a CR familiarity ICC of 0.322 for males (FEP patients, fathers, and brothers) and 0.442 for females (FEP patients, mothers, and sisters).

Discussion: Women, especially FEP patients and their sisters, exhibit higher CR and greater familial aggregation compared to men, suggesting superior adaptive capacity in the face of cognitive challenges, even during a FEP. Sex-based CR variability raises questions about the influence of familial aggregation, potentially linked to family dynamics. In Spain's social context, daughters' active participation and shared family moments are usually greater than in sons. It is plausible that they are exposed to more shared family time, thus strengthening their CR. This pattern could be more pronounced in the rural environment of Cantabria, where community cohesion and stress reduction act as protective factors. Complex family dynamics, coupled with biological and hormonal differences, could contribute to sex disparities in CR. This finding underscores the need to explore pattern transmission within families for targeted interventions addressing individual and familial factors influencing CR variability.

F140. THE IMPACT OF GENETIC BACKGROUND ON INFLAMMATORY RESPONSE IN SCHIZOPHRENIA

Philomena Hallford^{*1}, Antonia Pritchard¹, Ryan McLean¹

¹*University of the Highlands and Islands*

Background: Schizophrenia is a debilitating neurological condition with a prevalence of about 1% in the general population and with a heritability of between 64-81%. Familial high penetrance copy number variants (CNVs) have been identified that confer increased heritable risk to schizophrenia. Environmental and lifestyle are also important factors and several studies have suggested a role for the immune system in the development of schizophrenia.

Maternal immune activation during foetal development has been linked to the risk of developing schizophrenia: maternal circulating cytokines, TNF α , IL-1 β and IL-6, were elevated in the mothers of offspring who later developed psychosis. Previous studies have shown differences in response to IFN γ and cell type specific effects of IL-6 but not to IL-1 β between schizophrenia patients and controls. Human induced pluripotent stem cells (hiPSCs) have provided vital insights in the study of neurodevelopmental disorders in the past decade. A recent study showed that IFN γ -treatment of hiPSC- neural progenitor cells (NPCs) from healthy controls increased neurite outgrowth, a cellular phenotype associated with neurodevelopmental disorders. Examination of how CNVs associated with schizophrenia development are influenced by immune factors have not been undertaken.

Methods: The hiPSCs used in this study were cell lines from patients diagnosed with schizophrenia and (a) family members carrying the established schizophrenia associated 16p13.11 microduplication CNV; (b) siblings with defined CNVs without known association with schizophrenia; and control cell lines, with no known neurodevelopmental disorders and defined population CNVs. The hiPSCs were developed into embryoid bodies, and then further differentiated to NPCs by culturing with SMAD inhibitors and neural differentiation factors. Pro-inflammatory cytokines were used to treat hiPSC-derived NPCs, to mimic a maternal environmental change that may influence neurodevelopment. Phenotypes and parameters being examined included neurosphere migration assay; scratch migration assay; RNAseq; NPC cell toxicity and death assays.

Results: The hiPSC lines have been successfully differentiated to give neural progenitor cells and these have been characterised using immunohistochemistry and flow cytometry with antibodies against the NPC markers nestin and Pax-6: with the differentiated cells show high levels of expression of both. While experiments are currently still on-going, to date, the neurosphere migration assay, scratch migration assay and proliferation assays, have been carried out in cases and controls in response to IFN γ stimulation have been completed. Work is continuing to increase the numbers of both schizophrenia with defined CNVs and control hiPSC derived NPCs that will be examined for further parameters, including RNAseq and more assays.

Discussion: This study aims to address several hypotheses: There are differences in the cellular phenotypes and parameters between hiPSC-derived NPCs from patients with schizophrenia and control subjects; hiPSC-derived NPCs from schizophrenia patients show different response to inflammatory triggers and cytokines compared with those from control subjects; and there are differences in the response of hiPSC-derived NPCs to pro-inflammatory challenges between schizophrenia samples with different genetic backgrounds. While analyses are on-going, our early data currently suggests that differences reported in the literature of gene expression after treatment with IFN γ might be influenced by the CNVs present in schizophrenia patients. Future work will be to establish the precise gene(s) present in regions of CNV deletion/duplication that influence these responses.

F141. ASSOCIATION OF SCHIZOPHRENIA POLYGENIC RISK SCORES WITH TREATMENT-RESISTANCE

Clement Zai*¹, Kosar Teymouri², Mahbod Ebrahimi³, Ayesah Mohuiddin⁴, Pratyusha Attaluri⁴, Maria Tampakeras⁴, Natalie Freeman⁵, Gwyneth Zai⁶, Daniel Mueller⁴, James Kennedy⁴, Arun Tiwari⁴

¹University of Toronto and CAMH, ²Center for Addiction and Mental Health, ³Centre for Addiction and Mental Health, University of Toronto, ⁴Centre for Addiction and Mental Health, ⁵Centre for Addiction and Mental Health (CAMH), ⁶Centre for Addiction and Mental Health; University of Toronto

Background: Psychotic symptoms persist in a significant proportion of patients after at least two antipsychotic medication treatment trials. These patients are considered to be treatment resistant and clozapine is often prescribed for this patient population. Studies have attempted to examine the genetic factors underlying treatment resistant schizophrenia, with most recent studies reporting associations with polygenic risk score (SCZ-PRS) for schizophrenia based on summary statistics from earlier genome-wide association studies (GWAS).

Methods: We conducted a polygenic risk score analysis of treatment resistance using the latest (Phase 3) schizophrenia GWAS summary statistics in our sample of 156 schizophrenia or schizoaffective disorder patients of European ancestry. We used PRS-CS-auto to calculate standardized SCZ-PRS from summary statistics of the latest schizophrenia GWAS (leave-one-out; Trubetskoy et al, 2022). We ran logistic regression to test the effect of SCZ-PRS on the risk of treatment resistance based on clozapine use status, with sex, age, and the first two population principal components as covariates.

Results: We found higher SCZ-PRS to be associated with being treatment resistant (beta=0.54, SE=0.21, p=0.012). Patients in the top 10% of SCZ-PRS were at 4.76 folds the likelihood of being treatment resistant compared to the other patients (p=0.006), after adjusting for covariates.

Discussion: Our findings support the potential use of genetic risk scores for schizophrenia in predicting treatment outcomes. We will replicate these results in additional in-house samples and present a summary of the latest evidence in a meta-analysis.

F142. THE SPECIFICITY OF ENDOPHENOTYPES

Michael Herzog*¹, Simona Garobbio², Dario Gordillo³, Maya Roinishvili⁴, Eka Chkonia⁵, Andreas Brand²

¹EPFL, ²Brain Mind Institute, EPFL, ³École Polytechnique Fédérale de Lausanne (EPFL), ⁴Free University of Tbilisi, Beritashvili Centre of Experimental Biomedicine, ⁵Tbilisi State Medical University, Free University of Tbilisi

Background: Schizophrenia has a high heritability, still, single genetic mutations contribute very little to the disease. For this reason, endophenotypes, i.e., tests targeting aspects between the genotype and the phenotype, are of crucial interest.

Methods: We tested a visual backward masking procedure in ? patients, ? siblings, first-episode patient, ? depressive patients, and ?? controls. EEG was recorded during the task and blood taken for genetic analyses. In backward masking a target stimulus is presented for a few milliseconds and followed by a masking stimulus, which strongly impedes the visibility of the target. We also tested performance in the Wisconsin-Card sorting test and a body ownership task.

Results: Visual backward masking was strongly deteriorated in the patients compared to controls and their relatives. Effect sizes are large with a Cohen's d of ??. Relatives performed

significantly worse than controls, indicating that masking is, indeed, targeting trait rather state markers, which is crucial for an endophenotype. First episode patients were also deteriorated compared to controls further supporting the notion that masking deficits are present before disease onset. Depressive patients showed no differences to controls indicating that masking is specifically sensitive to schizophrenia. The N1 amplitudes of the EEG were strongly diminished in the patients compared to controls. Genetically, we found that a mutation in the nicotinic alpha 7 receptor explained the masking deficits in the patients. Based on these results, we conclude that patients are impaired in enhancing weak neural signals, e.g., related to the shortly presented target, which usually goes unnoticed if there is no special need to attend to it. Importantly, performance in the masking endophenotype did not correlate with performance in the two other endophenotypes, i.e., the WCST and the body ownership task

Discussion: Visual backward masking is a promising endophenotype of schizophrenia, which relates genetic insights to the phenotypes of the disease. Cholinergic dysfunctions may explain a wide range of deficits in schizophrenia, in particular, abnormalities wherever information needs to be stabilized. Backward masking performance does not correlate with performance in other tests indicating that there are many trait deficits at work. Combining endophenotypes may, hence, be a promising tool to understand the heterogeneity of the disease in a high dimensional space spanned by a battery of tests.

F143. ASSOCIATION BETWEEN SLEEP-RELATED POLYGENIC SCORES AND LITHIUM RESPONSE IN BIPOLAR DISORDER

Marina Zafrilla-López

Background: Bipolar disorder (BD) has disrupted circadian rhythms, affecting sleep, arousal, and inducing evening chronotype. Moreover, genetic risk factors for BD susceptibility overlap with risk for sleep disorders and determinants of chronotype (Rohr and McCarthy., 2022). Lithium (Li) treatment is the first-line choice of long-term mood-stabilizing therapy in BD although only between 24%-45% of the patients are excellent responders (ExRp) (Riedinger et al., 2023). Li also seems to stabilize sleep and activity rhythms in ExRp by affecting cellular circadian rhythms, increasing morningness and having beneficial effects in sleep (Rohr and McCarthy., 2022). This study aimed to evaluate the polygenic burden of seven sleep-related traits in a group of BD patients excellent responders (ExRp) to Li compared to non-responders (non-Rp).

Methods: We estimated the polygenic burden of morningness, sleep duration, ease of getting up, napping, daytime dozing, insomnia, and snoring in a sample of 96 European BD patients (DSM-IV-TR) recruited from the Bipolar Disorder Program of the Hospital Clinic of Barcelona and Mental Health Services in Oviedo, that were categorized as Ex-Rp (N=58; 50% females) and non-Rp (N=38; 44.74% females) based on the reduction of 50% of the episodes. Whole-genome profiles were obtained using Infinium Global Screening Array-24 v3.0 BeadChip (Illumina) in peripheral blood. Polygenic Scores (PGS) were calculated with PLINK based on the results of the Genome-wide analysis of Jansen et al., (2019) with the clumping-and-thresholding approach. Logistic regression models were calculated with R Studio 4.1.2. To estimate the risk increase, the sample was divided into quartiles of increasing polygenic load, and the extreme quartiles were compared using SPSS 27.0.

Results: Morningness, insomnia, daytime dozing, and napping are associated with Li response in our sample, and they explain, respectively 6.28% (p-value= 0.032), 1% (p-value= 0.008), 5.15% (p-value= 0.049), and 1.01% (p-value= 0.007). No association was found when using the PGS for sleep duration, ease of getting up, or snoring (p-value GREATER THAN 0.05). In addition, a higher genetic load of morningness and napping increased the probabilities of being an ExRp (OR= 3.40; 95% CI (1.027-11.257); χ^2 p-value= 0.042, and OR= 6.86; 95% CI (1.448-17.271); χ^2 p-value= 0.009, respectively), and insomnia of being an non-Rp (OR= 0.22; 95% CI (0.062-0.794); χ^2 p-value= 0.017), but there was not significative tendency for daytime dozing.

Discussion: Our results align with previous studies indicating that ExRp to Li have more polygenic burden for morningness (Rohr and McCarthy., 2022). As this is a genetic risk, it could indicate that the mechanisms by which Li exerts responsiveness overlap with those that cause the chronotype shift. Also, BD has a higher prevalence of sleepiness than controls (Walz et al., 2022), and Li is used to treat some sleep-related disorders for its beneficial effects on sleep (Miller and McCall., 2022), being consistent with our dozing and insomnia results. Also, short naps improved cognitive performance (Dutheil et al., 2021).

F144. THE DIFFERENTIAL ASSOCIATIONS OF NEGATIVE SYMPTOM DIMENSIONS AND CORTICAL THICKNESS IN FIRST EPISODE PSYCHOSIS

Background: Recent work has linked negative symptoms to cortical thickness (CTh) alterations in several brain areas, particularly in frontal and temporal regions. To our knowledge, no studies to date, have investigated how these may relate to underlying negative symptom dimensions: Expressive Deficit (ED) and Social-Amotivation (SA). We examined the associations between these dimensions and cortical thickness in a large sample of antipsychotic-naïve or minimally treated patients with First-Episode Psychosis (FEP).

Methods: T1-weighted structural MRI brain scans were acquired from 178 antipsychotic - naïve or minimally treated patients recruited as part of the multi-center OPTiMiSE study. CTh was examined using FreeSurfer version 6.00, QDEC (Query, Design, Estimate Contrast) tool, using the General Linear Model (GLM). Site, age and Total Intracranial Volume were used as covariates and, multiple comparisons were corrected via Monte Carlo z-field simulation at p LESS THAN 0.05 (2-tailed).

Results: The SA dimension was associated with reduced CTh in the left superior frontal gyrus ($p = 0.005$), the left precentral gyrus ($p = 0.003$), the left rostral middle frontal gyrus ($p = 0.01$), the left medial orbitofrontal gyrus ($p = 0.02$), and the right cuneus ($p = 0.002$). The DE was associated with only one region, the right postcentral gyrus ($p = 0.001$).

Discussion: Our findings indicate that negative symptom dimensions are differentially associated with cortical thickness. The results are unlikely to be affected by treatment or illness chronicity since they are evident in predominantly untreated FEP patients.

F145. THE SHARED GENETIC ETIOLOGY OF ANTISOCIAL BEHAVIOUR, SCHIZOPHRENIA, SUBSTANCE USE AND RELATED BRAIN MORPHOLOGY

Megan Campbell^{*1}, Alexey Shadrin², Olivia Wootton¹, Dennis van der Meer³, Markos Tesfaye³, Natalia Tesli⁴, Ole Andreassen³, Dan Stein¹, Unn Haukvik³, Jaroslav Rokicki⁵

¹University of Cape Town, ²NORMENT, Institute of Clinical Medicine, University of Oslo and NORMENT, Oslo University Hospital, ³University of Oslo, ⁴University of Oslo and Oslo University Hospital, ⁵SIFER Centre of Research and Education in Forensic Psychiatry, and NORMENT Norwegian Centre for Mental Disorders Research, Oslo University Hospital

Background: Individuals with antisocial behaviour (ASB) exhibit increased risk of substance use disorders, likely linked to shared genetic vulnerabilities and overlapping neural pathways involved in reward processing and impulse control. This susceptibility is further accentuated by the comorbidity of ASB with a number of psychiatric disorders, a finding that again points

to the potentially important role of shared genetic underpinnings. Despite this there remains a paucity of work examining the shared genetic etiology of ASB, related neuropsychiatric traits and relevant brain regions.

Methods: Using GWAS of ASB ($n=50,252$), surface area and thickness of cortical frontal regions, volumes of the amygdala nuclei, and psychiatric and substance use phenotypes, we utilized Linkage Disequilibrium Score Regression (LDSC) to assess the genetic correlation between these phenotypes. We then leveraged genetic overlap to boost discovery of genomic loci associated with ASB, and to identify specific variants associated with both ASB and each phenotype, using the conditional/conjunctional false discovery rate (cond/conjFDR) approach. FUMA was used for functional analyses.

Results: Using LDSC, we identified significant genetic correlations between ASPD and drinks per week ($r_g=0.28$; $p=1.33 \times 10^{-9}$), cannabis ($r_g=0.37$; $p=1.91 \times 10^{-8}$), bipolar disorder (BD, $r_g=0.20$; $p=1.95 \times 10^{-5}$), major depressive disorder (MDD, $r_g=0.53$; $p=1.09 \times 10^{-15}$) and marginally significant correlations with caudal anterior cingulate surface area ($r_g=-0.17$; $p=0.04$), superior frontal surface area ($r_g=0.18$; $p=0.03$), and global measures of cortical surface area ($r_g=-0.15$; $p=0.02$) and thickness ($r_g=-0.13$; $p=0.04$) and ICV ($r_g=-0.2$; $p=0.01$). A total of 54 loci, representing 127 independent variants, became significant after conditioning on related psychiatric disorders (8 SCZ, 7 BD, 11 MDD), substance use traits (18, drinks per week; 10, cannabis use) and the corpus callosum (11 anterior, 7 mid anterior, 8 central, 6 mid posterior, 9 total CC). These variants have been associated with schizophrenia, disruptive behaviour, risk taking behaviours, substance use disorders and cortical surface area in prior GWAS. Two biological processes were implicated: ethanol oxidation and metabolism.

Discussion: Our results reveal a complex genetic relationship between substance use, psychiatric traits, and ASB. We provide strong evidence for existence of distinct genetic loci exhibiting pleiotropic effects in both ASB and related traits. Our findings provide convergent evidence to suggest that substance use traits and psychiatric disorders have shared genetic underpinnings with ASB.

F146. THE ROLE OF ANXIETY AND DEPRESSIVE SYMPTOMS IN THE RELATIONSHIP BETWEEN COVID-19 PERSEVERATIVE COGNITION AND SUBCLINICAL PSYCHOTIC SYMPTOMS: A SERIAL MEDIATION ANALYSIS

Natalie Wing Tung Chu¹, Ryan Sai Ting Chu¹, Joe Kwun Nam Chan¹, Corine Sau Man Wong¹, Gabbie Hou Sem Wong¹, Janet Hiu Ching Lei¹, Yuen Kiu So¹, Vivian Shi Cheng Fung¹, Albert Kar Kin Chung¹, Calvin Pak Wing Cheng¹, Krystal Chi Kei Lee¹, Heidi Ka Ying Lo¹, Wai Chi Chan¹, Wing Chung Chang^{*1}

¹*The University of Hong Kong*

Background: The COVID-19 pandemic has affected almost every aspect of human lives. Widespread fear of disease infection and social-distancing policies may lead to perseverative cognition, a repetitive and uncontrollable thought on negative content. Psychotic-like experiences are subclinical delusional ideas and perceptual disturbances that serve as a risk factor for the development of mental health disorders like psychosis, depressive disorders and anxiety disorders. Prior studies suggested that perseverative cognition is associated with a higher risk of experiencing these subclinical psychotic symptoms (PS), but the potential roles of mediators were understudied. This study aimed to investigate the mediating role of anxiety and depressive symptoms on the relationship between perseverative cognition with COVID-19 and subclinical PS among the public during the fifth wave of the pandemic in Hong Kong.

Methods: 13,964 community-dwelling adults aged 18 or above completed a survey between March 15 to April 3, 2022 to understand their mental wellbeing and adaptation to the fifth wave of the COVID-19 pandemic. The fifth wave of the pandemic was the most disastrous wave and peak of the COVID-19 pandemic in Hong Kong. Serial-mediation models were adopted to investigate the role of potential mediators, anxiety and depressive symptoms, on the relationship between COVID-19 perseverative cognition and subclinical PS with socio-demographics as covariates. Perseverative cognition with COVID-19 was assessed by The Obsession with COVID-19 Scale (OCS) while psychotic-like experiences were assessed by items from The Community Assessment of Psychic Experiences-Positive scale (CAPE-P15) questionnaire. A weighted score of subclinical PS for each participant was derived by multiplying frequency and distress scores from 4 CAPE positive symptom items that measured persecutory ideation, bizarre experiences, and auditory and visual perceptual abnormalities. Depressive and anxiety symptoms were assessed by the Patient-Health-Questionnaire-9 (PHQ-9) and the Generalised-Anxiety-Disorder-7 scale (GAD-7) respectively.

Results: COVID-19 perseverative cognition, anxiety and depressive symptoms were all positively correlated with one another. The serial mediation model revealed a partial mediation effect of anxiety ($\beta=0.047$ [0.031–0.063]), depressive symptoms ($\beta=0.007$ [0.004–0.011]), and anxiety-depressive symptoms ($\beta=0.087$ [0.071–0.105]) on the relationship between COVID-19 perseverative cognition and subclinical PS. Among the three mediation paths, the majority of mediation effects can be attributed to the anxiety-depressive symptoms pathway (62%), followed by the anxiety (33%) and depressive symptoms (5%) pathway.

Discussion: The current study affirms the importance of anxiety and depressive symptoms in mediating the relationship between perseverative cognition and subclinical PS. It is essential to develop strategies targeting anxiety and depressive symptoms to reduce the occurrence of subclinical PS in view of stressors such as a pandemic. Our current findings imply that such strategies may be applicable in preparation for future pandemics.

F147. LONG-TERM PATIENT FUNCTIONING AND ILLNESS BURDEN ASSOCIATED WITH COGNITIVE IMPAIRMENT AND NEGATIVE SYMPTOMS IN SCHIZOPHRENIA

Kira Griffiths¹, Min Min Chan¹, Theresa Cassidy^{*2}, Mayowa Oyesanya¹, Rifqi Alkhatib¹, Suzanne St. Rose², Rashmi Patel³

¹Holmusk Technologies Inc, ²Boehringer Ingelheim Pharmaceuticals, Inc., ³King's College London

Background: Cognitive impairment (CI) and negative symptoms (NS) are core features of schizophrenia, but the evidence base for specific treatments is limited. Research typically uses standardized psychometric scales to measure these symptom domains, and studies have reported significant associations with long-term outcomes such as treatment resistance, hospitalization, unemployment, and increased risk of poor treatment adherence. The current study analysed real-world data from electronic health records (EHR) to identify clinician-reported CI and negative symptoms in a large and representative sample of patients with schizophrenia and to investigate associations with real-world clinical outcomes.

Methods: This is a retrospective study using de-identified electronic health record data from patients receiving mental healthcare across 25 mental health providers in 15 US states between 1999-2021. NeuroBlu v22r3 was used to assemble a cohort of adult (GREATER THAN 18years) patients with schizophrenia (ICD-9: 295*; ICD-10: F20*). Index date (baseline) was

defined as the first recorded schizophrenia diagnosis and baseline variables were extracted at index ± 14 days. Presence of cognitive impairment, negative symptoms or positive symptoms was defined as having one or more clinician-documented symptom within these symptom domains derived from free-text documented during mental status examination (MSE) using natural language processing (NLP) models. Cox and negative binomial regression were used to investigate associations between baseline symptom presentation and 1) time to first psychiatric hospitalization 2) number of unique inpatient visits and 3) total duration of inpatient days. For time to psychiatric hospitalization, data were censored at 18-months. For frequency of inpatient visits, patients with follow-up LESS THAN 3 months were excluded and an offset term was included in each model whereby the follow-up duration for a patient was defined as time from index to last recorded visit date. For descriptive statistics, the duration of inpatient visits was defined as the total duration of days spent in an inpatient setting calculated from the mean length of inpatient hospitalization by averaging the annualized cumulated length of day across all patients. Covariates included age, gender, race, year of index, clinic type, plus baseline psychotherapy exposure, illness severity (CGI-S), functioning (GAF) pharmacological prescriptions, psychiatric comorbidities, and social features.

Results: Patients with CI at baseline were at increased risk of psychiatric hospitalization (total $n = 4,469$ patients, Hazard Ratio (HR) = 1.19, 95% CI = 1.04-1.37, $p = 0.01$), and had a significantly higher total length of inpatient stay ((total $n=3,799$ patients, Incidence Rate Ratio (IRR) = 1.23, 95% CI = 1.06-1.43, p LESS THAN 0.01) compared to patients without documented cognitive symptoms. The mean (SD) annualized total number of inpatient days for those with CI was 30.7 (53.2) days, compared to 29.0 (49.4) days for those without documented CI. Presence of both positive symptoms and negative symptoms were also associated with increased risk of hospitalization (positive: HR= 1.65, 95% CI = 1.39-1.96, p LESS THAN 0.01; negative: HR=1.61, 95% CI=1.37-1.89, p LESS THAN 0.01) and increased frequency and length of inpatient stays across follow-up (positive: visits: HR=1.57, 95% CI=1.32-1.88; duration: IRR = 1.60, 95% CI = 1.34-1.92, all p LESS THAN 0.0000001; negative: visits: IRR = 1.55, 95% CI = 1.32-1.89; duration: HR = 1.59, 95% CI = 1.35-1.89, all p LESS THAN 0.0000001). Other covariates associated with increased risk of hospitalization included higher baseline illness severity (CGI-s) and lower baseline functioning (GAF). Prescription of a mood stabilizer, negative housing features and negative financial features also increased hospitalization risk. Similar associations were found between these clinical features and number of days of inpatient hospitalization. Exposure to psychotherapy at baseline was associated with substantially reduced risk of psychiatric hospitalization (HR=0.35, 95% CI = 0.28-0.43, p LESS THAN 0.01) across follow-up, plus a reduced number and duration of inpatient visits.

Discussion: Results demonstrate that patients with clinician-documented negative and cognitive symptoms are at increased risk of poor outcomes and higher inpatient resource utilization and that this effect is in part independent of positive symptoms. These findings support the growing body of evidence that implicates cognitive impairment in the long-term illness burden of schizophrenia. Additionally, cognitive and negative symptoms in schizophrenia are likely underreported in RWD sources. The potential overlapping relationship between cognitive and negative symptoms in schizophrenia highlights the need to measure each of these symptom domains to better identify patient sub-groups for treatment. Treatments which target these symptom domains hold potential to reduce personal and economic burden associated with the disorder. Associations between psychotherapy and better outcomes may reflect a cohort who are relatively more well and less likely to experience an exacerbation in illness across follow-up.

Funding: Funding for the studies presented was provided by Boehringer Ingelheim.

F148. MULTIPLE EXPOSOME-WIDE ASSOCIATION STUDIES OF PSYCHIATRIC DISORDERS IN THE UK BIOBANK

Angelo Arias-Magnasco^{*1}, Lotta-Katrin Pries¹, Bochao D. Lin², Sinan Guloksuz³

¹*School for Mental Health and Neuroscience, Maastricht University Medical Centre*, ²*School for Mental Health and Neuroscience, Maastricht University Medical Centre, Brainclinics Foundation, Institute of Biomedical Informatics, Bioinformatics Center, School of Basic Medical Sciences, Henan University*, ³*Maastricht University Medical Centre, Yale School of Medicine*

Background: Investigating non-genetic factors in mental health has traditionally followed a hypothesis-driven approach targeting selected exposures. By conducting multiple Exposome-Wide Association Studies (ExWAS) using the UK Biobank data, this study aims to systematically explore the complex network of nongenetic factors associated with psychiatric disorders including psychotic disorders.

Methods: In this study, we analyzed the Mental Health Survey data from the UK Biobank (UKB project number: 55392). The outcomes were self-reported presence of psychotic disorders, anxiety disorders, bipolar manic episode, depressive disorders, eating disorders, personality disorders (PD), and neurodevelopmental disorders. After quality control, 315 predictors were included in the analyses. First, an ExWAS of each psychiatric disorder was conducted in two equally split discovery and replication datasets, applying stringent Bonferroni correction to adjust for multiple testing ($P \text{ LESS THAN } 1.59 \times 10^{-4}$). Subsequently, variables associated with each psychiatric disorder were tested in a multivariable model per outcome.

Results: The study included 155,247 participants (57% females; mean age 55.94 years). In the discovery dataset, significant associations were identified across psychiatric disorders: 72 variables (23%) for psychosis, 61 variables (19%) for mania, 186 (59%) for depression, 170 variables (54%) for anxiety, 77 variables (24%) for personality disorders, and 45 variables (14%) for neurodevelopmental disorders. The replication dataset confirmed these associations with high replication rates: 78% for psychosis, 92% for anxiety, 74% for bipolar mania, 94% for depression, 81% for eating disorders, 85% for personality disorders, and 67% for neurodevelopmental disorders. Subsequent multivariable analyses revealed significant associations for 26 variables in psychosis, 65 in anxiety, 21 in bipolar mania, 80 in depression, 35 in eating disorders, 23 in personality disorders, and 16 in neurodevelopmental disorders. Strikingly, these analyses consistently showed associations of both childhood and adulthood traumatic experiences, as well as sleep issues, with each of the psychiatric disorder category. Cannabis use was also significantly associated with psychosis, bipolar mania, anxiety, and depression but not with personality disorders, eating disorders, and neurodevelopmental disorders. Uniquely, eating disorders showed specific associations with dietary patterns, such as reduced meat consumption, and gastrointestinal issues. For the neurodevelopmental disorders, a particular association observed was increased time spent on the computer.

Discussion: Our systematic investigation revealed unique and shared associations of mental health outcomes with both well-studied and unexplored variables. Our findings particularly highlight the importance of traumatic experiences for all mental health disorder categories. Our study offers a systematically constructed map of nongenetic factors associated with psychiatric disorders to guide the future work.

F149. VALIDATION OF THE KOREAN VERSION OF THE MALTREATMENT AND ABUSE CHRONOLOGY OF EXPOSURE (MACE) SCALE

Hyejin Sim^{*1}, Hyeyoon Kim¹, Seoyoung Kim², Euitae Kim²

¹Seoul National University, ²Seoul National University Bundang Hospital

Background: Adverse childhood experiences (ACE) during critical stages of brain development can result in a lifelong susceptibility to a broad spectrum of adverse health outcomes. In contrast to existing tools designed for the retrospectively assessment of early adversity in adults, the Maltreatment and Abuse Chronology of Exposure (MACE) scale investigates exposure to various adverse childhood experiences. It also explores the timing and duration of this exposure, which is useful for identifying developmental periods, particularly sensitive to childhood adversity. The present study aims to provide a Korean version of the MACE and to evaluate its psychometric properties.

Methods: The 52-item MACE was translated from English to Korean and administered as a self-report measure through an online survey. Participants also completed the Childhood Trauma Questionnaire (CTQ) and other psychiatric symptom-related scales to investigate convergent and predictive validity. To investigate test-retest reliability, participants completed MACE a few weeks later.

Results: The results from Rasch analysis and Anderson likelihood ratio tests showed that a 52-item version reliably captures exposure to the 10 types of ACEs. The MACE severity and multiplicity scores exhibited excellent convergent validity with the CTQ scores. Also, as compared to CTQ total scores, the MACE scores were more strongly associated with psychiatric symptoms.

Discussion: Overall, the Korean version of the MACE-52 comprehensively assessed past exposure to early childhood adversity in adults, had acceptable psychometric properties, and is a reliable tool for addressing sensitive periods for childhood adversities and associations with other mental health problems.

F150. BIOPSYCHOSOCIAL EXPOSURE TO THE COVID-19 PANDEMIC AND THE RELATIVE RISK OF SCHIZOPHRENIA: INTERRUPTED TIME-SERIES ANALYSIS ON A NATIONALLY REPRESENTATIVE

Stephen Levine^{*1}, Arad Kodesh¹, Yael Travis-Lumer², Yair Goldberg², Sophia Frangou³, Avi Reichenberg⁴

¹University of Haifa, ²Israel Institute of Technology, ³Icahn Medical School, Mt. Sinai Hospital, University of British Columbia, ⁴Icahn School of Medicine at Mount Sinai

Background: Studies of the association between biopsychosocial exposure to the COVID-19 pandemic and the risk of schizophrenia have yielded conflicting results. These studies were conducted early in the pandemic and did not take into account factors such as lockdowns or actual COVID-19 infection. Consequently, we investigated the link between COVID-19 biopsychosocial exposure and the onset of schizophrenia.

Methods: Interrupted time-series study design (that is quasi-experimental) was conducted based on Israeli electronic health records from 2013 to 2021 with national coverage. The interval of the COVID-19 pandemic biopsychosocial exposures from March 2020 to February 2021 was classified as exposed, otherwise unexposed. The effect of the COVID-19 pandemic on incident schizophrenia was quantified by fitting a Poisson regression and modeling the

relative risk (RR) and 95% confidence intervals (CI). Projections were made for three scenarios spanning from the third lockdown to a 10-month period, aiming to forecast incident schizophrenia rates and establish their corresponding 95% prediction intervals (PI).

Results: The population (N = 736,356) yielded 4,310 cases of incident schizophrenia over time. In the primary analysis the period exposed to the COVID-19 pandemic compared to unexposed was associated with a reduced RR (RR = 0.81, 95% CI = 0.73, 0.91, p LESS THAN 0.001). This conclusion was not attenuated in 12 sensitivity analyses, including scrutinizing lockdowns and COVID-19 infection status. Two of three forecast scenarios projected an incident increase post-pandemic over 10 months (6.74, 95% PI = 5.80, 7.84; 7.40, 95% PI = 6.36, 8.60).

Discussion: The decreased risk of schizophrenia observed during the pandemic implies that there was no immediate triggering of new onsets, either by the virus itself or the psychosocial challenges induced by the pandemic. However, the anticipated increase in presentations following the relaxation of restrictions holds significance for clinicians and healthcare policy.

F151. PERCEPTUAL JUDGMENTS AND METACOGNITIVE EFFICIENCY IN SCHIZOPHRENIA

Alexandra Straková*¹, Vladimír Ivančík¹, Natália Čavojská¹, Hana Hollá Kutlíková¹, Ján Pečeňák¹, Anton Heretik¹, Michal Hajdúk¹

¹*Comenius University,*

Background: Previous findings have underscored the multidimensional nature of impairments in individuals with schizophrenia (SCZ), encompassing perceptual, metacognitive, and neurocognitive deficits. Moreover, visual perceptual abnormalities contribute to distressing experiences associated with psychosis. Metacognitive deficits are increasingly recognized as a key aspect explaining real-world functioning in SCZ, yet with mixed evidence on the nature of the impairment. This study aims to compare the performance of individuals with SCZ and healthy controls (HC) on a perceptual judgment task including a metacognitive assessment of one's performance. A secondary aim was to analyze associations among task performance, symptoms, and neurocognition.

Methods: Sample consists of 38 individuals with schizophrenia spectrum disorders (age M = 36.66; SD = 8.86; 55% female) and 38 age- and sex-matched HC (age M=36.40; SD=8.82; 55% female). Psychopathology was assessed with the Brief Psychiatric Rating Scale (BPRS) and Community Assessment of Psychic Experiences (CAPE-42). Snowy Picture Task was used to assess perceptual judgments (total score, d-prime, response bias). Metacognitive parameters were computed using meta-d (sensitivity) and M-ratio (efficiency). Neurocognition was assessed using Symbol Coding, Trail Making Test, and Verbal Fluency Test and was administered only to a part of the sample (N=25). Group differences were analyzed using t-test and Mann-Whitney U test. Associations between variables were analyzed using Spearman's rank correlation.

Results: SCZ group had a significantly lower total score in perceptual task (U=942.5; p=0.021, r=0.305). There was no significant group difference in d-prime, response bias, meta-d, and M-ratio. In SCZ group, agitation and mania (BPRS) were associated with poorer perceptual judgments (rs=-0.338; p=0.038), lower perceptual sensitivity (rs=-.342; p=0.036), and lower M-ratio (rs=-.411; p=0.024). M-ratio was further negatively correlated with positive symptoms (BPRS) (rs=-0.435; p=0.016). Self-reported psychotic symptoms (CAPE-42) were not associated with perceptual and metacognitive judgments in SCZ. However, meta-d was negatively correlated with subjective reports of positive (rs=-0.652; p LESS THAN 0.001),

negative ($r_s=-0.683$; $p < 0.001$), and depressive symptoms ($r_s=-0.608$; $p < 0.001$) in HC. In SCZ group, aberrant perceptual discriminability and d-prime were negatively associated with neurocognitive deficits (r_s from -0.42 to -0.51). There was no significant association between neurocognitive and metacognitive deficits in SCZ group.

Discussion: Individuals with SCZ showed deficits in visual discrimination. Altered visual perception was associated with symptoms of agitation, mania and neurocognitive deficits. We found no significant differences in metacognitive performance between groups. However, M-ratio was linked to objectively assessed positive symptoms, agitation and mania in SCZ but not to self-reported psychotic symptoms. Lower meta-d was accompanied by more frequent self-reported psychotic experiences in HC but not in SCZ, suggesting that this mechanism may be affected by other factors in SCZ.

F152. PATIENTS WITH SEVERE MENTAL ILLNESS IN THE GENERAL EMERGENCY DEPARTMENT: CLINICAL CHARACTERISTICS, QUALITY OF CARE AND CHALLENGES

Sharon Taub^{*1}, Noa Menkes-Caspi², Shiri Kamhi- Neshet³, Amir Krivoy³

¹Geha Mental Health Center, ²Geha Data Research Center, ³Geha Mental Health Center, Tel-Aviv University

Background: Morbidity and mortality rates are notably higher in individuals with schizophrenia and other severe mental illnesses (SMI) compared to the general population. The causes to this excess morbidity include increased risk of cardio-vascular disease, metabolic syndrome and other causes, such as infectious diseases and malignancy. People with SMI often have a lower access to health care services and the medical care they receive is known to be suboptimal due to various reasons, including psychosocial stressors and negative stigma of care providers. Consequently, treatment in the acute care setting, rather than community setting, is relatively more common among people with SMI. Yet, data on the characteristics of the treatment given in the general emergency department (ED) for this population is prominently lacking. This study aims to explore the medical care in the ED for people with SMI compared to control population. We hypothesize that patients diagnosed with SMI will differ in their complaints, course of ED workout and length of stay in comparison to control population.

Methods: In this nested case- control study data was retrieved from the largest health maintenance organization in Israel – Clalit Health Services (CHS). We extracted data on all adult patients (age 18-65 years) CHS members who referred to general ED in CHS hospitals during the years 2018-2022. Patients diagnosed with SMI (ICD-10 codes for schizophrenia, schizoaffective disorder and bipolar disorder) were randomly matched with a control group of ED patients without SMI, based on age, sex, socioeconomic status, Charlson comorbidity index and ED facility, in a 1:3 ratio. The two groups were compared regarding parameters of ED management and outcomes, including workout (lab tests and imaging), specialist consultations, length of ED stay, hospitalization and mortality. Main complaints at ED arrival were clustered into seven categories: traumatic injury, pain, weakness, fever, cardiac symptoms, gastrointestinal symptoms and respiratory symptoms. The comparisons were further conducted for each cluster separately. Significance was set at $p < 0.05$ for all statistical tests and computer software used for data analyses were R and SPSS.

Results: The total sample ($n=92,848$) included ED patients with SMI ($n= 23,212$) and without ($n= 69,636$). Most common ED admission reasons in both groups were pain (29.2% of all ED

visits, and 26.5% among people with SMI), traumatic injury (20.5% and 17.2%) and cardiac symptoms (8.4% of all ED visits and 7.8% among people with SMI). Patients in the SMI group had higher rates of diagnosed diabetes mellitus and chronic obstructive pulmonary disease compared to the control group (14.2% vs. 12.3% and 4.4% vs. 2.3%, respectively, $p < 0.001$). ED workout for patients with SMI lasted longer with mean length of stay of 4.1 hours compared to 3.6 hours ($p < 0.001$) in the control group and significant time differences were observed for most ED admission reasons. No significant differences were observed between groups regarding rate of imaging in respiratory cases and troponin blood level measurement when presented with cardiac complaints. ED management in the SMI group included more specialist consultations for trauma cases (12.8% vs. 8.1%), cardiac (9% vs. 6.7%) and weakness complaints (33.2% vs. 29.5%) compared to controls. Additionally, Individuals with SMI presented with respiratory symptoms and fever needed hospitalization in higher rates. Mortality over time was almost twice as high among SMI group (5.7% vs. 2.7%). **Discussion:** ED workout was similar between patients with and without SMI for most main complaints. Yet, people with SMI needed more specialist consultations, their ED visits were more prolonged and they were hospitalized more often. All of which is linked with higher rates of morbidity and complexity in treatment. As expected, mortality rates during follow-up period were higher among this group. We conclude that, on average, individuals with SMI treated in the ED received treatment as good as people without SMI in most of the study parameters, despite possible stigma. Nevertheless, special awareness and more integrated resources are required in order to improve the management and the physical health care of people with SMI.

F153. VALIDATING ICD-CODE-BASED CASE DEFINITIONS FOR PSYCHOTIC ILLNESS ACROSS THREE HEALTH SYSTEMS

Background: Early detection of psychosis is critical to improve outcomes. Increasingly, algorithms derived from electronic health record (EHR) data are being developed to predict or detect untreated mental health outcomes such as psychosis. The performance of such algorithms depends on the validity of the case definitions they use, which are typically based on diagnostic codes. To date, data on the validity of psychosis-related diagnostic codes has been limited. In this study, as part of an effort to develop algorithms to detect undiagnosed psychosis, we evaluated the positive predictive value of ICD codes for psychotic illness across three independent healthcare systems.

Methods: Using EHRs at three large health systems in the Boston area, ICD codes comprising primary psychotic disorders and mood disorders with psychosis were grouped into five higher-order groups: schizophrenia - unspecified state, schizoaffective disorder, other unspecified psychosis and/or psychotic disorders, major depressive disorder with psychosis, and bipolar disorder with psychosis. For each of the five code groups, the first instance of a psychosis diagnostic code was selected for evaluation. Up to 100 patient records from each group at each health system (total records = 1,133) were sampled for chart review and clinical confirmation by experienced clinicians using the full EHR and a structured chart review tool. Positive predictive values (PPVs, the probability of chart-confirmed psychosis given ICD psychosis codes from each diagnostic code group) were calculated across multiple treatment settings at the three participating health systems.

Results: Overall, PPVs across all diagnostic groups exceeded 70% and were comparable across the three hospital systems including Massachusetts General Brigham (MGB) 0.72 [95% CI 0.68-0.77], Boston Children's Hospital (BCH) 0.80 [0.75-0.84], and Boston Medical Center (BMC) 0.83 [0.79-0.86]. Of the five diagnostic code groups, schizoaffective disorder PPVs were consistently the highest across sites: 0.80 [0.69-0.90] at MGB, 0.90 [0.80-1.01] at BCH, and 0.92 [0.87-0.97] at BMC. PPVs for major depressive disorder with psychosis showed the greatest variation across sites: MGB 0.57 [0.45 – 0.69], BCH 0.73 [0.64 – 0.83], BMC 0.79 [0.71 – 0.87]. To increase the likelihood that the first documented code indeed captured first-episode psychosis (FEP), we further excluded cases with any prior chart evidence of a previously diagnosed psychotic disorder or treatment for psychosis. PPVs for FEP were substantially lower (0.08 – 0.62) when these restrictions were applied.

Discussion: Using EHRs from three health systems, we found that the first documented diagnostic (ICD) code for psychotic illness accurately captures true episodes of psychosis but was a poor index of FEP. These data have important implications for the development of risk prediction models designed to predict or detect undiagnosed psychosis.

F154. PREMATURE MORTALITY IN INDIVIDUALS WITH NON-AFFECTIVE PSYCHOSIS: A 20-YEAR RETROSPECTIVE EVALUATION OF A FIRST EPISODE PSYCHOSIS COHORT

Paloma Fuentes Pérez¹, Claudia Ovejas Catalán¹, Jorge Romay González², Marcos Gómez-Revuelta², María Luz Ramírez Bonilla³, Rocio Perez-Iglesias³, Paula Suárez Pinilla², Benedicto Crespo-Facorro⁴, Javier Vázquez-Bourgon*⁵

¹*Instituto de Investigación Marqués de Valdecilla (IDIVAL), Universidad de Cantabria,*
²*University Hospital Marqués de Valdecilla - Instituto de Investigación Marqués de Valdecilla (IDIVAL), Universidad de Cantabria,* ³*University Hospital Marqués de Valdecilla - Instituto de Investigación Marqués de Valdecilla (IDIVAL),* ⁴*School of Medicine, University Hospital Virgen del Rocío-IBiS, Centro de Investigación Biomédica en Red en Salud Mental (CIBERSAM),* ⁵*University Hospital Marques de Valdecilla -IDIVAL; University of Cantabria; CIBERSAM*

Background: People with schizophrenia and other psychoses have a 2-3 times higher risk of premature mortality (Gronholm et al., 2021), with a life expectancy that is 10 to 15 years shorter compared to the general population (Liu et al., 2017). Despite the overall increase in life expectancy in recent decades, the mortality gap between individuals diagnosed with schizophrenia and the general population has persisted or even increased in recent years, according to the most recent studies (Yung et al., 2021). The primary causes of premature death in psychotic disorders are attributed to natural causes, primarily related to cardiovascular diseases, respiratory diseases, and cancer (Correll et al., 2022). Additionally, there has been evidence of an association between premature mortality and non-natural causes, especially suicide or accidents (Dua et al., 2017). Premature mortality in psychosis has received limited research attention in Europe, necessitating studies that provide data to determine the factors associated with premature mortality (Kiejna et al., 2023). The aim of this study was to analyze the characteristics of premature mortality in a cohort of patients with a first episode of psychosis.

Methods: A retrospective study was conducted on a cohort of non-affective psychosis patients from the PAFIP Program. The cohort data was obtained through retrospective analyses of the clinical records of those treated, between 2001 and 2018, in the longitudinal intervention program for first-episode psychosis called PAFIP (Early Intervention in Psychosis Program), at the Marqués de Valdecilla University Hospital in Cantabria (Spain). Patients who met the inclusion criteria and their families provided written informed consent before their inclusion in the program. Information on deaths was obtained by reviewing the patients' medical records in February 2023. The medical records of 677 patients (374 males and 294 females) with a first episode of psychosis that occurred 5-22 years ago were reviewed.

Results: The results revealed a premature mortality rate in the PAFIP cohort of 4.3% (N=29). The average age at the time of death was 41.8 years (range: 19-67 years). The average time to premature death in these patients was 6.6 years from the onset of their psychotic condition (range: 1-192 months). The cause of death was traumatic (non-natural) in 11 (37.9%) cases, including 9 suicides (31%) and 2 accidents (6.9%). In 11 (37.8%) cases, the death was due to natural causes, including 5 due to cancer (17.2%), 2 due to cardiovascular pathology (6.9%), 2 due to digestive pathology (6.9%), 1 due to renal pathology (3.4%), and 1 due to neurological pathology (3.4%). In 7 (24.1%) cases, the cause of death was not recorded in the medical records.

Discussion: We observed an excess of premature mortality in patients with psychosis, although lower than that described in previous studies. The lack of information about the causative event in medical records is noteworthy, which hinders the conduct of studies that could improve this outcome. Improving access to and follow-up in healthcare, as well as early prevention and intervention, may help to reduce the mortality rate among individuals with psychosis.

F155. EVALUATION OF THE CLINICAL EFFECTIVENESS OF AN INTENSIVE HOME PROGRAM FOR THE ACUTE TREATMENT OF PATIENTS WITH PSYCHOSIS IN THE COMMUNITY

Leila Palé^{*1}, Ana María Besoain², Jara López³, Lucía Alonso³, Sonia Sáez³, Sofia Torrejón³, Saray Palma³, Inmaculada Ruiz³, Ignacio Aznar²

¹*Equipo de Atención Domiciliaria Intensiva Llobregat Centre*, ²*Health Technology Assessment in Primary Care and Mental Health (PRISMA) Research Group, Teaching, Research and Innovation Unit, Parc Sanitari Sant Joan de Déu, Institut de Recerca Sant Joan de Déu*, ³*Intensive Home Care Service of the Baix Llobregat Center area, Parc Sanitari Sant Joan de Déu*,

Background: Home mental health hospitalization has begun to be widely developed in recent years. Despite the lack of studies providing objective data, there is a general consensus on the potential benefits of home treatment. Experiences in the United Kingdom and the Netherlands confirm that these programs allow an increase in the portfolio of services, reduces the trauma frequently experienced in hospital care and allows the development of coping strategies for patients in their own environment. The bulk of these teams' activity is on patients with severe mental health problems and many of them are suffering from psychotic symptoms. The aim of our study is to assess clinical changes in patients with psychosis who are admitted to a mental health intensive home program.

Methods: A single cohort observational study was conducted on patients who received care from the Intensive home treatment team (IHTT) of the Parc Sanitari Sant Joan de Déu in Barcelona. The sample included patients suffering from an acute disorder with psychotic comorbid symptoms and that met criteria for admission in the program for one year. The diagnosis of the psychotic symptoms was made by clinicians of the team. The patients were evaluated using the PANSS scale and the GAF clinical scale on admission and at discharge. The SUMD scale was evaluated at discharge. Sociodemographic characteristics were also reported. The outcome variables were analyzed by intention-to-treat (ITT) as well as per protocol (PP).

Results: From January 2021 to December 2021, 108 patients with psychotic symptoms were referred to the IHTT and included in the sample. Only 98 of them completed the whole program and were included in the PP analysis. Mean age was 40 and 54,6% were men. The PANSS total mean was reduced by 16 points (from 72,4; 22,0% reduction) in the ITT analysis and by 18 points (from 71,0; 25,4% reduction) in the PP analysis. Both results, were statistically significant (P LESS THAN 0,001). In the ITT analysis the mean of the GAF scale was 44,1 at admission (44,7 in PP analysis) and 59,1 at discharge (61,3 in PP analysis) with a total increase of 33,9% (37,1% in PP analysis). The total mean of the SUMD scale was 9.

Discussion: The profile of patients attended by the IHTT had serious acute disorders with severe psychotic symptoms at admission (PANSS GREATER THAN 70) and very low functioning (GAF LESS THAN 50). The intensive home treatment proved clinical efficacy with GAF levels improving 34%-37% after the treatment and a 22%-25% reduction in the PANSS scale. The level of insight in psychotic patients after being admitted to the IHTT is slightly above the median value. It represents quite low insight levels even with the intensive psychotherapeutic approach. Despite the positive results, there are some limitations that should be considered for future investigations. Although SUMD values at admission were disregarded, it would be interesting to collect these data as well as other follow-up measures. Moreover, the comparison between samples of psychotic patients treated by IHTT and those receiving usual treatment within the hospital would provide much more evidence to the literature regarding this area of knowledge.

F156. THE REAL-WORLD UTILISATION OF MOOD STABILISERS AS AN AUGMENTATION STRATEGY IN PSYCHOSIS: A MIRROR IMAGE DESIGN

Emma Butler*¹, Daisy Kornblum², Rashmi Patel³, Oliver Howes⁴, Alice Egerton⁵

¹South London and Maudsley, ²BRC Nucleus, South London and Maudsley NHS Foundation Trust, UK, ³Institute of Psychiatry, Psychology, and Neuroscience, King's College London, ⁴MRC LMS and KCL, ⁵King's College London

Background: Across the globe, 5-24% of people on an antipsychotic will be prescribed an anticonvulsant / mood stabiliser, and this may be increasing (1–3). There is most evidence for Carbamazepine, Sodium Valproate, Lamotrigine and Topiramate as augmentation agents in Schizophrenia(3). Meta-analysis of RCTs showed an improvement in symptoms for those given an anticonvulsant augmentation of Clozapine(4). However, evidence is still limited with little literature on the longitudinal impact of this practice (5). To assess the real-world impact of mood stabiliser augmentation strategies in the management of psychotic disorders

Methods: Using electronic health records of South London and Maudsley NHS Trust to conduct a naturalistic mirror comparison of service use and clinical outcomes, for the 2 years before and after the combination of antipsychotic and mood stabiliser.

Results: 1224 patients were identified from electronic health records of South London and Maudsley NHS Trust who had taken a combination of antipsychotic and mood stabiliser for a minimum of 6 months. Overall, service use outcomes and symptoms were significantly worse in the 2 years after the start of this combination compared to the 2 years before. Admissions (+0.146), Bed days (+53.787), Attended medical events (+7.086) and Home treatment team (HTT) involvement (episodes +0.079, Days +2.022) showed a mean increase in two years after compared to before augmentation ($p=0.005$ - LESS THAN 0.0001). The mean change for Positive (+0.358) and Negative symptoms (+0.414) of psychosis also showed a worsening of symptoms in the two years after augmentation (p LESS THAN 0.0001). Sodium Valproate had significant increase in admissions (+0.194), bed days (+55.052), attended medical events (+7.168), positive symptoms (+0.365), negative symptoms (+0.396), yet some improvement in agitated behaviours (- 0.288) ($p=0.035$ - LESS THAN 0.0001). Lithium and Lamotrigine showed similar increases in service use and symptoms ($p = 0.042$ - LESS THAN 0.0001). Of note, those with high number of treatment episodes (GREATER THAN 9) showed improvement in symptoms; HoNOS Total (-1.972), Agitation (-0.428) and Hallucination (-0.302) in two years following augmentation, while showing no significant change in admission numbers, number of attended medical events or HTT involvement. However, number of bed days (+100.673) did still show a significant increase (p LESS THAN 0.001), along with NLP Positive (+0.385) and Negative Symptoms (+0.554), ($p=0.035$ -0.007). Those with low number of treatment episodes (LESS THAN 4) showed no significant change in HoNOS total or individual items, but did show significant increases in admissions (+0.353), bed days (+76.601), attended medical events (+19.098) and HTT episodes (+0.216), alongside increases in positive (+0.798) and negative (+0.915) symptoms ($p=0.028$ - LESS THAN 0.0001).

The longer a patient was on mood stabilisers the larger the improvement from the 2 years before augmentation on Admissions ($rs(1222)=0.063, p=0.027, CI: 0.007-0.119$), Bed days ($rs(1222)=0.091, p=0.001, CI: 0.040-0.145$), and negative symptoms ($rs(1222)=0.062, p=0.028, CI: 0.011-0.119$), with a small but significant positive correlation for improvement in these outcomes.

Discussion: Conclusions: The polypharmacy approach of a combination of antipsychotic and mood stabilisers to treat psychotic symptoms may only be appropriate of specific subsets of patients, in particular those who have trialled multiple antipsychotics previously.

F157. RISK FACTORS OF LATE-ONSET PSYCHOSIS

Joseph Skinner*¹, Lauren Moran²

¹Brigham and Women's Hospital, ²Harvard Medical School/ McLean Hospital

Background: Previous studies suggest that the onset of schizophrenia occurs after the age of forty in up to twenty percent of cases. Despite being well established as clinically distinct from Early-Onset Schizophrenia (EOS), risk factors for Late-Onset Schizophrenia (LOS) remains an understudied area. Specifically, studies often neglect utilizing an appropriate age matched comparison group when investigating risk factors for LOS.

Methods: In a case control study using electronic health records (EHR), individuals over the age of 40 years with an encounter at Mass General Brigham for a first episode of psychosis were initially defined by an encounter with an ICD code for psychotic disorders between the years 2013 and 2021. All patients were required to have at least 3 outpatient visits to a primary care physician or psychiatrist prior to the date of the first ICD diagnosis code for psychosis, with one encounter in the previous year, to capture patients with high EHR continuity. Chart review was conducted to ensure patients had a true episode of LOS. After review of charts for 575 patients with an initial psychosis code, 142 were included as true LOS cases. The 142 cases of LOS were matched 1:4 to 568 patients without psychosis receiving outpatient care at MGB on age, sex, race, and year of encounter.

Covariates for the primary analysis included age at encounter, sex, year of encounter, race/ethnicity, insurance type, alcohol use disorder, cannabis use, and polysubstance use. Binary covariates for the presence or absence of past psychiatric diagnoses and medications preceding the encounter were included. Additionally, binary covariates for the presence or absence of psychosocial factors preceding initial onset of symptoms were also included. Conditional logistic regression models were used to assess the odds of late onset psychosis with the potential risk factors. Adjusted odds ratios (aOR) with 95% confidence intervals (CI) are presented.

Results: Compared with matched controls, the odds of late-life onset psychosis were increased by immigration (aOR 3.30, 95% CI 1.56-6.98), depression (aOR 3.58, 95% CI 2.01-6.38), anxiety (aOR 2.12, 95% CI 1.20-3.75), cannabis use (aOR 3.00, 95% CI 1.36-6.61), alcohol use disorder (aOR 5.46, 95% CI 2.41-12.36), polysubstance use (aOR 4.22, 95% CI 1.30-13.7), history of severe trauma (aOR 2.29, 95% CI 1.08-4.48) and caregiver burden (aOR 15.26, 95% CI 3.85- 60.48).

Discussion: These risk factors can help clarify potential points of intervention for LOS. More research is needed with appropriate comparator groups for these patients to parse out in which ways the etiology of LOS is distinct from other conditions.

F158. INFLAMMATION IN SCHIZOPHRENIA IS ASSOCIATED WITH VASCULAR REMODELLING AND EXTRACELLULAR MATRIX INCREASES ALONGSIDE REDUCED NEUROGENESIS

Hayley North*¹, Cynthia Shannon Weickert²

¹Neuroscience Research Australia/ University of New South Wales, ²Neuroscience Research Australia: Schizophrenia Research Laboratory

Background: Schizophrenia is a heterogeneous disorder and while the pathogenesis is unclear, elevated inflammation is implicated in the aetiology and the neuropathology of a subgroup of schizophrenia cases. Inflammation regulates neurogenesis, and markers for stem cells and neuronal progenitors are reduced in the high inflammation subgroup of schizophrenia in the subependymal zone (SEZ) – the brain’s largest region of neurogenesis. Neurogenesis in the SEZ is highly dependent on the niche microenvironment whereby neural stem and progenitor cells receive signals from the vasculature and extracellular matrix (ECM) that influence their proliferation and differentiation. This research employed RNA sequencing to discover differences in the SEZ between high and low inflammation subgroups of schizophrenia.

Methods: We performed total RNA sequencing in the SEZ of 27 post-mortem schizophrenia brains previously designated into low inflammation (n=13) and high inflammation (n=14) subgroups, based on cluster analysis of inflammation gene expression (IL6, IL6R, IL1B, IL1R1, CXCL8 and SERPINA3). An average sequencing depth of 109 million unique paired-end reads was attained per sample and the average read depth did not differ between comparison groups [t(25)=0.02, p=0.49]. We have also performed single nuclei RNA sequencing (snRNAseq) from the young and adult human brain SEZ to determine the cellular origin of transcripts of interest.

Results: 718 genes were differentially expressed (DE) in high compared to low inflammation schizophrenia (FDR p LESS THAN 0.05). DE genes with increased expression in high inflammation schizophrenia were most significantly over-represented in the pathway ‘Hepatic Fibrosis/Hepatic Stellate-Cell Activation’. Genes in this pathway encompass those important for ECM stability [(including ten collagens, FN1 and TIMP1) (all FDR p LESS THAN 0.04)] and for vascular remodelling [(VEGFA, VEGFR1, VEGFR3, END1, MYH11) (all FDR p LESS THAN 0.02)]. Upregulation of these mRNA factors suggests ECM stiffening and increased angiogenesis with inflammation in the SEZ in schizophrenia. snRNAseq data suggests that the majority of DE ECM and angiogenesis related transcripts are produced by ependymal and endothelial cells. In contrast, VEGFA mRNA is expressed in a variety of neurogenic cell types of the SEZ including neural stem cells, neuroblasts and oligodendrocyte progenitor cells.

Discussion: This discovery-driven comparison of inflammatory subgroups elucidates how inflammation in schizophrenia most significantly contributes to changes in the SEZ microenvironment. We find a potentially pre-fibrotic ECM along with higher levels of angiogenesis in high inflammation schizophrenia. Further, our findings suggest that neural stem cells and neuroblasts may be upregulating angiogenesis promoting factor VEGFA. Considering other angiogenesis genes are also upregulated in endothelial cells, increased angiogenesis may be linked to the reduced neurogenesis we found in people with schizophrenia in an inflammatory state. These findings suggest that anti-inflammatory treatment could lead to restoration of a normal neurogenic subependymal zone microenvironment for this subgroup.

F159. FIRST EPISODE PSYCHOSIS: ALTERED ENERGY PATHWAYS IN THE IMMUNE SYSTEM

Jaana Suvisaari^{*1}, Martina Jonsson², Linnea Hartwall², Kirsi Sepponen², Heikki Laurikainen³, Maija Lindgren¹, Jarmo Hietala³, Jarno Honkanen²

¹*Finnish Institute for Health and Welfare*, ²*University of Helsinki*, ³*University of Turku*

Background: Psychotic disorders are associated with immunological changes, including elevations of inflammatory cytokines and chemokines in blood and cerebrospinal fluid (CSF),

alterations in monocyte and T-cell activation, and increased expression of pro-inflammatory genes in peripheral blood cells, CSF as well as in post-mortem brain tissue. However, there is still limited understanding on the immune system dysfunction at a cellular level in patients with first psychotic episode.

Methods: In two Finnish first-episode psychosis studies from Helsinki and Turku area, we collected peripheral blood mononuclear cells (PBMCs) from first episode psychosis (FEP) patients (n=29) and matched healthy controls recruited from the general population (n=31). From the PBMCs we analyzed the frequencies of monocytes, CD141(-) and CD141(+) myeloid dendritic cells (mDC1 and mDC2, respectively) and plasmacytoid dendritic cells (pDCs), regulatory T helper cells (Tregs) and effector T helper cells (Teffs) and purified the cell populations with flow cytometry. The purified cell populations were analyzed with RNAseq.

Results: Analysis of the FACS data showed that patients had elevated monocyte levels and decreased T helper cell frequencies in peripheral blood. When the global RNA expression of the purified cell populations was analyzed and the list of differentially expressed genes (DEGs) was subjected to an Ingenuity Pathway Analysis (IPA, Qiagen), monocytes from FEP patients showed inhibition of pathways associated with mitochondrial electron transport chain and oxidative phosphorylation (for e.g., ATP5F1A, COX6C, COX7B, NDUFA3 and NDUFV5). In the IPA analysis of Tregs and Teffs, FEP patients showed alterations in TCR-mediated activation pathways of T cells. When dendritic cells were analyzed we observed aberrancies in co-stimulatory pathways of dendritic cells regulating T cell activation, OX40-OX40L pathway being the most affected pathway. RNAseq analysis of dendritic cell populations also revealed highly activated antigen-presentation pathways (HLA class I and II) in FEP patients.

To further study the functioning of the mitochondria in the monocytes we collected another set of blood samples from FEP patients (n=11) and matched controls (n=11) recruited from the Turku area who were scanned with positron emission tomography and the translocator protein radiotracer (TSPO)[¹¹C]PBR28 at the time of collecting the blood samples. Regional distribution volume (DV) of [¹¹C]PBR28 was used as a proxy for TSPO expression in the outer membrane of mitochondria. From the PBMCs we analyzed the mitochondrial mass and mitochondrial reactive oxygen species production in the untreated and LPS-stimulated monocytes with FACS using MitoSox superoxide indicator (Thermo Fisher). We also purified monocytes, mDC1s, mDC2s, pDCs, Tregs and Teffs for transcriptomics analysis. IPA of the differentially expressed genes revealed mitochondrial pathways to be affected, thus replicating the observation of mitochondrial dysfunction made in the first phase of the study. FEP patients showed comparable level of superoxide positivity in untreated monocytes, whereas FEP patients showed similar mitochondrial mass compared to healthy controls. Patients had equal levels of superoxide-positive monocytes compared to healthy controls in unstimulated monocytes. When the monocytes were stimulated with LPS, patients showed lower level of superoxide-positive monocytes compared to the healthy controls. Interestingly, the frequencies of superoxide positive monocytes correlated with TSPO-PET DV whereas no such correlations could be observed in the FEP patients.

Discussion: Our data suggest that FEP patients have aberrant immune activation in the peripheral immune system at cellular level and that aberrancies in the energy production in innate immune cells may contribute to abnormal immune responses in FEP patients. Mitochondrial dysfunction and poor energy production could lead to weak immune responses against invading pathogens, thus making FEP patients susceptible to reoccurring and elongated infections causing low-grade inflammation. Our findings are also consistent with previous post-mortem brain studies and suggest that mitochondrial dysfunction may have a role in the etiology of psychotic disorders.

F160. HYPERACTIVATION OF GQ SIGNALING IN PREFRONTAL ASTROCYTES IMPAIRS COGNITION VIA ACTING ON THE KYNURENINE PATHWAY

Tina Notter*¹, Sina Schalbetter¹, Kim Ferrari¹, Johanna Furrer¹, Viktor Beilmann¹, Bruno Weber¹, Urs Meyer¹

¹*University of Zurich, Institute of Pharmacology and Toxicology,*

Background: Astrocytes are an integral part of the tripartite synapse and regulate behavior and cognition by modulating neuronal signaling. Abnormalities in prefrontal astrocytes appear to be involved in the pathophysiology of psychosis-related disorders. It remains elusive; however, how aberrant activity of prefrontal astrocytes contribute to behavioral and cognitive dysfunctions implicated in these disorders.

Methods: We used the designer-receptor-exclusively-activated-by-designer-drugs (DREADDs) system to selectively manipulate astrocyte activity in the prefrontal cortex of mice and explored its consequences on behavior, cognition and brain metabolites of the kynurenine (KYN) pathway.

Results: Chemogenetically induced hyperactivation of Gq signaling in prefrontal astrocytes impaired sensorimotor gating, working memory and temporal order memory in both male and female mice without affecting basal locomotor behavior and anxiety-like behavior. Furthermore, overstimulation of prefrontal astrocytes resulted in elevated levels of kynurenic acid (KYNA), a key metabolite of the KYN pathway acting as endogenous antagonist of N-methyl-D-aspartate (NMDA) receptors. Finally, pharmacological inhibition of kynurenine aminotransferase II, which is the key enzyme mediating the transamination of KYN into KYNA, reinstated the deficits in sensorimotor gating, working memory and temporal order memory after chemogenetically induced hyperactivation of Gq signaling in prefrontal astrocytes.

Discussion: Our study suggests that overstimulation of astrocytic Gq signaling in the prefrontal cortex impairs cognitive functions via acting on the KYN pathway. By identifying a causal link between hyperactivation of prefrontal astrocytes, increased production of KYNA, and disruption of cognitive functions, our study provides preclinical evidence supporting a pathophysiological role of aberrant astrocyte functions in psychotic disorders and beyond.

F161. THE ROLE OF ASTROCYTES IN POSTNATAL SYNAPTIC REFINEMENT OF THE MEDIAL PREFRONTAL CORTEX

Johanna Furrer*¹, Sina Schalbetter¹, Sarai Fischer¹, Viktor Beilmann¹, Urs Meyer¹, Bruno Weber¹, Tina Notter¹

¹*University of Zurich*

Background: Functional and structural abnormalities of the prefrontal cortex (PFC), a brain region providing executive top-down control of a variety of cognitive processes and sociability, have been implicated in major psychiatric disorders, including schizophrenia (SZ). During its protracted maturation throughout adolescence, the PFC undergoes substantial synaptic rearrangement where superfluous synapses are eliminated to optimize neuronal circuits underlying adult cognitive functions. According to a prevailing hypothesis, the etiopathology of SZ involves excessive synaptic pruning resulting in miswiring of the brain. In support of

this are the observed decreases in synaptic densities in prefrontal regions of SZ patients. The exact underlying mechanisms of prefrontal synaptic pruning remain, however, unknown. Recent findings in mice have shown that microglia can shape medial PFC (mPFC) maturation during adolescence and thereby alter the trajectory of cognitive development. Alike microglia, astrocytes have been shown to actively contribute to postnatal synaptic refinement of the visual and somatosensory system. However, the extent to which astrocytes actively contribute to the functional maturation of the mPFC remains currently unknown. In this study, we aim to elucidate the dynamics of prefrontal synaptic density and composition during adolescence to define the sensitive period of synaptic refinement in this brain region. Further, we explore how prefrontal astrocytes contribute to synaptic refinement along adolescence and thereby modulate cognitive development.

Methods: Using immunohistochemistry and confocal microscopy synaptic density and composition were extensively studied in postmortem tissue of C57BL6 mice collected along adolescence (postnatal day (PND) 21 – PND 56) and adulthood (PND 91). The role of astrocytes in prefrontal synaptic maturation was explored by selectively manipulating the Gq-protein-coupled receptor (GPCR) signaling pathway during the sensitive period by either enhancing (hM3DGq-DREADD) or attenuating (iβARK) this pathway in prefrontal astrocytes of C57BL6 male and female mice. Upon reaching adulthood, the animals were subjected to a battery of behavioral and cognitive tests, followed by measuring synaptic composition and density in postmortem tissue using immunohistochemistry and confocal microscopy.

Results: Overall synapse density in the prefrontal cortex most prominently decreased between PND 28 – PND 49 in females and PND 35 – PND 56 in males. This decrease was driven by the loss of excitatory synapses. Transient manipulation of astrocytes during this sensitive window of synaptic refinement resulted in persistent and sex-specific behavioral deficits in adulthood, including deficits in pre-attentive filtering and sociability.

Discussion: While previous studies have documented protracted synaptic pruning in the prefrontal cortex, our research contributes unique insights through detailed synapse analyses, enhancing the comprehension of synaptic refinement in male and female wildtype C57BL6 mice. Furthermore, our findings are the first to suggest an active involvement of astrocytes in the functional maturation of the mPFC, suggesting that astrocytes could be involved in the pathophysiological mechanisms underlying major psychiatric disorders such as schizophrenia.

F162. PREDICTING TREATMENT RESPONSE USING MRI MEASURES OF DOPAMINE AND GLUTAMATE

Cecelia Shvetz^{*1}, Rami Hamati², Reggie Taylor³, Nour Kanaa⁴, Greg Dance⁴, Clifford Cassidy³, Lauri Tuominen³

¹Carleton University, ²Department of Cellular and Molecular Medicine, University of Ottawa, ³University of Ottawa Institute of Mental Health Research, ⁴Department of Neuroscience, Carleton University

Background: One in three schizophrenia patients do not respond adequately to first-line antipsychotic treatment such as olanzapine¹. Currently, there is no tool to identify patients who respond favorably to first-line treatments from those who will need clozapine. Such a tool could reduce delay to start clozapine. Here, we propose a combined testing and development of the most promising biomarkers for treatment response: dopamine and glutamate⁴ using quick and non-invasive MRI methods. We predict that individuals responding to olanzapine will have higher dopamine turnover, and lower glutamate concentration relative to clozapine users. We

also hypothesize that these measures carry independent information so that in combination, they can be used to more reliably differentiate the two groups.

Methods: Thus far, 3 participants taking olanzapine treatment (first-line treatment respondent), and 4 participants taking clozapine treatment (first-line treatment-resistant) have completed a clinical interview to characterize symptom severity using the Positive and Negative Syndrome Scale⁶ and an MRI scan. Dopamine signal in the substantia nigra was measured using neuromelanin-MRI and glutamate concentration in the dorsal anterior cingulate cortex was measured with magnetic resonance spectroscopy.

Results: No significant differences were found between groups in terms of age, sex, or symptom severity (all p GREATER THAN 0.05). Preliminary results show no significant differences between individuals on olanzapine ($M = 13.22$, $SD = 1.78$) and individuals on clozapine ($M = 15.01$, $SD = 2.14$) in neuromelanin signal in the SN ($t(4.87) = 1.21$, $p = 0.28$), nor between olanzapine ($M = 0.68$, $SD = 0.07$) and clozapine groups ($M = 0.67$, $SD = 0.01$) in glutamate concentration in the dACC ($t(3.21) = 0.30$, $p = 0.79$). Logistic regression showed moderate power at predicting treatment group membership ($AUC = 0.75$).

Discussion: Our preliminary results show promise in predicting response to antipsychotic treatment. No significant differences were found in dopamine signal in the substantia nigra, nor glutamate concentration in the dorsal anterior cingulate cortex between treatment groups. Further data collection is ongoing.

⁴VUmc, Amsterdam, ⁵UMC AMC, Amsterdam, ⁶Maastricht University Medical Centre

Background: Psychotic disorders (PD) are highly heritable and have long been linked with aberrant neural oscillations, particularly heightened theta power. Relative theta power, in turn, also might be influenced by genetics. This study aims to explore the association between polygenic risk scores for schizophrenia (PRS-SCZ) and relative theta power, while also examining potential mediation effects.

Methods: Resting-state EEG (rsEEG) was recorded in 1041 participants (459 females) admitted to a psychiatric hospital: patients with a mood disorder (MD), psychotic disorder (PD), and substance use disorder (SUD). SCZ-PRS of 666 participants was generated with PRSice-2 and was based on published genome-wide association data. General linear models (GLM) were performed to assess the difference in relative theta power between PD and non-PD patients, and the relationship between SCZ-PRS and relative theta power. Finally, mediation regression analysis was conducted to examine the relative associations between SCZ-PRS, theta power, and PD.

Results: rsEEG relative theta power was higher in PD compared to non-PD ($F(1, 1036) = 17.28$, $p < .001$, $\eta^2 = 0.16$). A positive association was found between SCZ-PRS and relative theta power ($p\text{-threshold} = 5.0E3$; standardized regression coefficient, $\beta = 0.10$, $p = .012$). Importantly, relative theta power significantly mediated the relationship between SCZ-PRS and PD.

Discussion: Findings reveal that polygenic risk for schizophrenia is associated with increased relative theta power in a psychiatric population. Moreover, the mediation analysis highlights the role of relative theta power as a mediator in the association between polygenic risk score for schizophrenia and the manifestation of psychotic disorders.

F164. ALTERED WHITE MATTER MICROSTRUCTURE OF WHITE MATTER LANGUAGE PATHWAYS AND SEMANTIC COGNITION DEFICIENCIES IN EARLY PSYCHOSIS

Werner Surbeck^{*1}, Noemi Dannecker¹, Anna Steiner¹, Robin Samuel², Allegra Gasser¹, Dominic Fabian¹, Niklaus Denier³, Tobias Bracht³, Peter Brugger¹, Philipp Homan¹

¹*Psychiatric Hospital of the University of Zurich*, ²*University of Luxembourg, Esch-sur-Alzette, Luxembourg*, ³*Translational Research Center, University Hospital of Psychiatry and Psychotherapy, University of Bern*

Background: Semantic processing anomalies, clinically manifested by disorganized speech, constitute a core symptom of schizophrenia-spectrum disorders. Semantic cognition relies on two principal interacting neural systems: one for representation and another for control. Recent evidence pointing to a selective impairment of semantic control, rather than semantic representation, in individuals with early psychosis suggests the potential presence of an anatomical substrate associated with this characteristic feature of schizophrenia. Tract specific abnormal maturation and accelerated aging of the inferior fronto-occipital fasciculus (IFOF), a component of the ventral language stream, have been recently reported in comparison to control subjects. Notably, the IFOF is considered a potential candidate for executive and semantic control over conceptual knowledge, thereby offering a plausible anatomical correlate for this specific deficit within a subsystem of semantic cognition in schizophrenia-spectrum disorders.

Methods: Semantic representation was examined using the multiple-choice word test. Control of semantic cognition was tested using a semantic verbal fluency task as well as by the Camel

and Cactus Test. DTI combined with manual fiber tractography were applied in 40 early psychosis patients and 80 healthy controls. The latter were divided into individuals with high schizotypy (40) and low schizotypy (40) based on the Oxford-Liverpool Inventory of Feelings and Experiences. For the ventral language stream, we assessed the left IFOF, while the left arcuate fasciculus (AF) was used as representative of the dorsal language stream. Since not associated to language, the left corticospinal tract was used as control tract.

Results: Using Poisson regression models adjusted for attention and executive function, age, gender, and education, diffusion measures FA and MD of the three tracts examined showed no significant ($p < 0.05$) association with semantic representation either within the patient group or within the control groups. In contrast, some FA and MD measures were mostly negatively associated with verbal fluency as measured with naming items within one minute (IRR .903 to 1.080, $p < 0.05$) within all groups, except for early psychosis patients, using Poisson regression models and random-effects multinomial logit models, as appropriate and as adjusted as above. However, this was not specific to the IFOF but also found for the AF. No significant correlations were found with regard to the CST.

Discussion: For both patients and healthy controls, no significant association of semantic representation was found regarding white matter microstructure as measured by DTI. In contrast, a correlation between microstructural alteration and semantic control ability, assessed through the semantic verbal fluency task, was observed in healthy individuals with low and high schizotypy, respectively. Remarkably, this correlation was not evident in early psychosis patients. Furthermore, these findings related to semantic control were not specific to the IFOF but were observed with a similar pattern in relation to the AF. While these results suggest that the control of semantic information in healthy individuals is not exclusively mediated by the ventral language pathways but involves the entire perisylvian white matter language connectivity, this does not hold true for individuals with early psychosis. For the latter, there was no corresponding evidence for either the ventral or dorsal language stream. A detailed analysis of the ventral language stream, encompassing indirect pathways (inferior longitudinal and uncinate fasciculi), and the inclusion of homologous contralateral pathways (for the analysis of the relative anatomical changes in the left language pathways compared to the opposite side) could potentially offer more clarity regarding this unexpected finding. The corresponding results will be available by the congress date and will be presented.

F165. INTRA- AND INTER-NETWORK DYSCONNECTIVITY AMONG RESTING STATE GLOBAL FUNCTIONAL NETWORKS IN INDIVIDUALS AT ULTRA-HIGH-RISK FOR PSYCHOSIS: COMPARISON WITH ULTRA-HIGH-RISK FOR BIPOLAR DISORDER AND HEALTHY CONTROLS

Burcu Verim^{*1}, Cemal Demirlek¹, Nabi Zorlu², Muhammed Demir¹, Berna Yalincetin¹, Merve Gurbuz¹, Ezgi Cesim¹, Simge Uzman Ozbek¹, Tevhide Ekin Sut¹, Emre Bora¹

¹Dokuz Eylul University, ²Katip Celebi University

Background: Schizophrenia and bipolar disorder are chronic psychiatric illnesses associated with aberrations in functional connectivity during rest. Compared to chronic and first episode phases, information about the prodromal stages of these illnesses is scarce. The aim of this study was to investigate how functional connectivity patterns change in individuals at ultra-high-risk for psychosis (UHR-P) in comparison to individuals at ultra-high-risk for bipolar disorder (UHR-BD) and healthy controls (HC).

Methods: Thirty two individuals with UHR-P who meet the criteria of the Turkish version of Structured Interview for Prodromal Syndromes (SIPS), 26 individuals with UHR-BD who meet the criteria of the Turkish version of the Bipolar Prodrome Symptom Interview and Scale-Full Prospective (BPSS-P) from the Early Diagnosis and Intervention Service at Dokuz Eylul University Hospital/Department of Psychiatry and 19 HC were included in this study. All participants underwent clinical interviews and 3 Tesla resting state functional MRI scanning sessions. Network-based statistics (NBS) toolbox was used to analyze global network properties. For multiple comparisons, corrections were applied (10000 permutations, $p < 0.05$). Additionally, gender and age were included as covariates in the analyses.

Results: NBS analyses revealed hypoconnectivity between default mode and salience networks, between default mode and frontoparietal networks along with decreased connectivity within the default mode network in the UHR-P group compared to HC. Moreover, the most prominent findings regarding hyperconnectivity in the UHR-P group compared to HC are between the default mode and the visual networks, between the salience and the visual networks, and lastly, between the cingulo-opercular and the visual networks. There was no statistically significant difference between UHR-P and UHR-BD as well as UHR-BD and HC groups.

Discussion: This study demonstrated distinctive neural signatures associated with the prodromal stage of psychosis but it didn't find any significant difference between clinical risk groups and also between individuals at clinical high risk for bipolar disorder and healthy controls. Given the heterogeneity of these groups, longitudinal studies with larger samples are needed in order to shed light onto their neurobiology and inform the development of more targeted diagnostic and therapeutic strategies.

F166. FUNCTIONAL CONNECTIVITY CORRELATES OF GAMMA-AMINOBUTYRIC ACID IN ANTIPSYCHOTIC MEDICATION-NAÏVE FIRST EPISODE PSYCHOSIS PATIENTS

Genelle Samson^{*1}, Jose Maximo¹, Eric Nelson¹, Seyedeh Adnani², Adil Bashir², Adrienne Lahti¹

¹The University of Alabama at Birmingham, ²Auburn University

Background: Functional connectivity, the temporal correlation between neurophysiological events in different brain regions, is significantly altered in patients with psychosis spectrum disorders. Gamma-aminobutyric acid (GABA) is the primary inhibitory neurotransmitter in the central nervous system, and its role in psychosis spectrum disorders is under-investigated, as is its relationship to functional connectivity in these patients. Data from animal and postmortem studies suggest GABAergic dysfunction in psychosis spectrum disorders, but little is known about GABA pathology at the early stages of illness, especially prior to treatment. The relationship between GABA levels within the anterior cingulate cortex (ACC), a region implicated in a number of complex cognitive functions frequently impaired in psychosis spectrum disorders, and functional connectivity among different key brain networks may play a pivotal role in the pathophysiology of psychosis spectrum disorders. We hypothesize that GABA's relationship with functional connectivity will differ between patients and healthy controls.

Methods: We used magnetic resonance spectroscopy (MRS) with a MEGA-PRESS sequence to quantify GABA in the ACC of 67 antipsychotic medication-naïve first-episode psychosis patients (FEP) and 110 healthy controls (HC). Whole brain functional connectivity (FC) analyses were performed in CONN (version 20b) within the default mode (DMN, posterior

cingulate cortex seed), salience (SN, ACC seed), dorsal attention (DAN, right intraparietal sulcus seed), and executive control (ECN, right posterior parietal lobule seed) networks. We then assessed ACC GABA-FC correlations in each sample and tested these between HC and FEP.

Results: We performed a one-way ANCOVA controlling for age, gender, and smoking (as measured by packs per day) to compare ACC GABA levels between groups, and did not find a significant difference in GABA levels between FEP and HC ($p = 0.125$). However, when examining ACC GABA-FC, significant clusters showed group interactions in the SN and ECN where GABA concentration positively correlated with FC for HC, but this relationship was inverse in FEP.

Discussion: Our findings support that GABA concentration in the ACC plays a significant and differential role in FC in key brain networks. Our data add to the growing body of evidence suggesting GABA's significant role in psychosis spectrum disorders, especially as it relates to FC. Further investigation of how GABA's role in FC within and between these networks differs between FEP and HC is merited. Examination of longitudinal trajectories of GABA over the course of treatment can also further elucidate this model. Our data support that GABA and FC work differently in FEP as compared to HC, which calls for further exploration of the mechanisms underlying altered activation and connectivity in psychosis spectrum disorders.

F167. BRAIN ACTIVATION AND ABERRANT EFFECTIVE CONNECTIVITY IN THE MENTALIZING NETWORK OF PREADOLESCENT CHILDREN AT FAMILIAL HIGH-RISK OF SCHIZOPHRENIA OR BIPOLAR DISORDER

Hospital Bispebjerg, Institute for Clinical Medicine, University of Copenhagen, ¹⁴ University Hospital of Lausanne, Switzerland, ¹⁵ Child and Adolescent Mental Health Center Capital Region of Denmark, ¹⁶ Center of Functionally Integrative Neuroscience, Institute of Clinical Medicine, Aarhus University, ¹⁷ Mental Health Centre Copenhagen, The Lundbeck Foundation Initiative for Integrative Psychiatric Research (iPSYCH), ¹⁸ Psychosis Research Unit, Aarhus University Hospital, ¹⁹ Center of Functionally Integrative Neuroscience, Aarhus University

Background: Schizophrenia and bipolar disorder are associated with impairments in social cognition and recent research has identified alterations of the social brain in both disorders. However, it is unknown whether familial high-risk of these mental disorders is associated with neurobiological alterations already present in childhood.

Methods: As part of The Danish High Risk and Resilience Study – VIA 11, we examined a cohort of same-aged children at familial high-risk of schizophrenia (FHR-SZ, n = 121) or bipolar disorder (FHR-BP, n = 75) and population-based controls (PBC, n = 128). Using functional magnetic resonance imaging (fMRI) and dynamic causal modeling (DCM), we investigated brain activation and effective connectivity during the social cognition paradigm from the Human Connectome Project.

Results: We found similar activation of the mentalizing network across the three groups, including visual area V5, dorsomedial prefrontal cortex (dmPFC), and posterior superior temporal sulcus (pSTS). Nonetheless, both familial high-risk groups showed aberrant brain connectivity compared with PBC. Both groups had increased feedforward connectivity from left V5 to pSTS. Children at FHR-SZ had reduced intrinsic connectivity in bilateral V5, whereas children at FHR-BP showed reduced intrinsic connectivity in right pSTS and reduced reciprocal connectivity between right dmPFC and pSTS.

Discussion: Our results provide first-time evidence of aberrant brain connectivity in the mentalizing network of preadolescent children at FHR-SZ or FHR-BP compared with PBC. We identified both shared and unique profiles of aberrant brain connectivity in children at FHR-SZ or FHR-BP relative to PBC. This suggests that abnormal synaptic mechanisms may be present before alterations in regional brain activation or marked behavioral deficits, indicating that mentalizing deficits may have a neurodevelopmental origin. Longitudinal research is warranted to clarify whether aberrant brain connectivity during mentalizing constitutes an endophenotype associated with the development of a severe mental disorder later in life. To this end, our cohort follow-up study at age 15 (VIA 15) is currently under way.

F168. LONGITUDINAL CHANGES IN HIPPOCAMPAL SUBFIELD VOLUMES ARE NOT RELATED TO GLUTAMATE LEVELS IN ANTIPSYCHOTIC-NAÏVE FIRST EPISODE PSYCHOSIS PATIENTS

Eric Nelson*¹, Nina Kraguljac², Adil Bashir³, Jose Maximo¹, William Armstrong¹, Adrienne Lahti¹

¹University of Alabama at Birmingham, ²The Ohio State University, ³Auburn University,

Background: Postmortem and neuroimaging studies have implicated hippocampal abnormalities in the neuropathology of psychosis spectrum disorders. Reduced hippocampal volume has been reported across all illness stages, and this atrophy has been hypothesized to be the result of glutamatergic excess. To test this hypothesis, we measured hippocampal subfield volumes and hippocampal glutamate levels in antipsychotic naïve first episode patients (FEP) and the progression of volume decline and changes in glutamate levels over a 16-week antipsychotic drug (APD) trial. We aimed to determine if subfield volumes at baseline

linked with glutamate levels, and if baseline glutamate levels were predictive of change in subfield volumes over time.

Methods: We enrolled ninety-three medication-naïve FEP patients and eighty matched healthy controls (HC). T1 and T2 weighted images and magnetic resonance spectroscopy (MRS) data from a voxel prescribed in the left hippocampus were collected from participants at baseline and after 6 and 16 weeks of APD treatment. Hippocampal subfield volumes were assessed using FreeSurfer 7.1.1., while glutamate levels were quantified using jMRUI version 6.0. Data were analyzed using linear mixed models.

Results: We found regional subfield volume deficits in the CA1 ($p = 0.008$), and PR subiculum ($p < 0.001$) in FEP at baseline, that further expanded to include the molecular and granule cell layer of the dentate gyrus (GC/ML/DG) ($p = 0.026$) and CA4 ($p = 0.004$) by weeks 6 and 16, respectively. Baseline hippocampal glutamate levels in FEP were not significantly different than those of HC ($p = 0.117$), and there was no effect of treatment on glutamate ($p = 1.000$). Glutamate levels were not related to initial subfield volumes or volume changes over 16 weeks.

Discussion: We report a progressive loss of hippocampal subfield volumes over a period of 16 weeks after initiation of treatment, suggestive of early progression in neuropathology. Our results do not suggest a role for glutamate as a driving factor. This study underscores the need to further research the mechanism(s) underlying this phenomenon as it has implications for early intervention to preserve cognitive decline in FEP patients.

F169. NEUROMELANIN ON SALIENCE NETWORK EFFECTIVE CONNECTIVITY IN FIRST EPISODE SCHIZOPHRENIA

Jessica Ahrens^{*1}, Sabrina Ford², Betsy Schaefer³, David Reese⁴, Ali Khan⁴, Philip Tibbo⁵, Clifford Cassidy⁶, Lena Palaniyappan⁷

¹Douglas Research Centre, ²University of Western Ontario, ³Western University, Robarts Research Institute, ⁴Robarts Research Institute, ⁵Dalhousie University, Halifax, NS Canada, ⁶University of Ottawa, ⁷Douglas Mental Health University Institute

Background: Basic cognitive processes, such as working memory and attention, are notably impaired in those with schizophrenia. There is a strong association between cognitive impairment and a reduction in quality of life; however, available interventions for schizophrenia are not effective in reversing this impaired cognition. Emerging evidence points to two mechanisms for explaining these cognitive deficits within this population: (1) disruptions of a brain network called the salience network, which includes the anterior insula and the anterior cingulate cortex; and (2) increased dopamine turnover, which has been found to be implicated in the positive symptoms of schizophrenia, such as hallucinations and delusions. I propose to use measures of effective connectivity to examine the relationship between these two mechanisms and test if they lie on the same causal pathway of impaired cognition in schizophrenia. Generating this knowledge will provide the in vivo markers of target engagement for many emerging pro-cognitive treatments. Recent work suggests neuromelanin sensitive MRI (NM-MRI) may provide a proxy measure of dopamine system function, based on the tendency of neuromelanin, which is a breakdown product of dopamine, to accumulate in the substantia nigra. NM-MRI is both practical and non-invasive, providing a highly feasible and acceptable approach to study patients living with schizophrenia. Therefore, this study aims to: (1) investigate if prior research results on excess neuromelanin in established schizophrenia extends to a sample of those with first episode schizophrenia; and (2) determine

the effect of dopaminergic turnover on the connectivity of the salience network. I hypothesize that: (1) first episode patients will have higher NM-MRI signal than healthy controls; and (2) patients with higher NM-MRI signal will have reduced effective connectivity between areas of the salience network.

Methods: N=30 first episode schizophrenia patients and N=30 healthy controls were recruited from the Prevention and Early Intervention Program for Psychosis in London, Ontario and the community surrounding. Groups were matched on sex, gender, age, education, and parental socioeconomic factors. Participants underwent a resting state functional MRI scan and a NM-MRI scan. A Bayesian statistical approach that allows for the direction and strength of the connectivity between brain areas, Dynamic Causal Modeling, will be used to quantify the effect that any individual neuromelanin differences may have on the salience network.

Results: Second-level (group; group-with-neuromelanin) dynamic causal modelling results to be determined. Neuromelanin of each voxel and mean of the substantia nigra has been quantified and first-level dynamic causal models have been specified for each participant.

Discussion: To date, no studies have addressed the modulatory effect(s) of neuromelanin on the salience network. This work is essential to understand how dopamine may influence the salience network and thus clarify a promising mechanism for the cognitive deficits in schizophrenia. Additionally, current global efforts focused on neuromelanin in schizophrenia have highlighted the value of using this as a marker in upcoming clinical trials, which can significantly enhance therapeutic options for patients.

F170. THE RELATIONSHIP BETWEEN CAT OWNERSHIP, TOXOPLASMA, AND PSYCHOTIC EXPERIENCES IN YOUNG PEOPLE

Jehanita Jesuthasan^{*1}, Kate Merritt¹, Sarah Ashley¹, Pedro Luque Laguna², Anthony David¹

¹*Institute of Mental Health, UCL*, ²*CUBRIC*

Background: Schizophrenia and related disorders have been associated with cat ownership, a relationship hypothesised to be mediated by *Toxoplasma gondii*, a parasite transmitted to humans by cats. This study therefore examined the associations between cat ownership, toxoplasma serology, and psychotic experiences, as well as structural brain changes associated with *T. gondii*.

Methods: Using the Avon Longitudinal Study of Parents and Children (ALSPAC) birth cohort, we studied 6,716 individuals for whom data on psychotic experiences at age 18, cat ownership in early life (8 weeks gestation to 33 months), and toxoplasma serology was available. Associations were examined using univariate ANOVA, t-tests, and chi-square. Voxel-based morphometry examined whether MRI measures of grey matter volume were associated with *T. gondii* among 87 individuals aged 20 years with psychotic experiences (n = 30 suspected, n = 34 definite, n = 23 psychotic disorder) and 201 controls.

Results: Cat ownership was not associated with positive toxoplasma serology sampled in adolescence (age 11: $t = -1.38$, $p = 0.167$; age 15: $F = -1.44$, $p = 0.151$) or with psychotic experiences ($\chi^2 = 0.84$, $p = 0.840$). Toxoplasma serology was not associated with psychotic experiences when samples were taken at age 11 ($F \text{ LESS THAN } 0.001$, $p = 0.997$); or age 15 ($F = 0.40$, $p = 0.526$). In the neuroimaging sample, neither toxoplasma at age 11 ($p\text{FWEs} \geq 0.876$, $Z_s \leq 4.38$) nor toxoplasma at age 15 ($p\text{FWEs} = 1.000$, $Z_s \leq 3.18$) were associated with volumetric changes.

Discussion: Overall, our results suggest that exposure to *T. gondii* is not associated with an increased risk of developing psychotic experiences. Future work examining the relationship between toxoplasma and schizophrenia should focus on serology rather than cat ownership as

a proxy measure of *T. gondii* exposure, as there was no association between cat ownership and toxoplasma.

F171. REDUCED INTER-SUBJECT SYNCHRONIZATION IN PATIENTS WITH SCHIZOPHRENIA DURING EMPATHIC ACCURACY TASK ARE ASSOCIATED WITH NEGATIVE SYMPTOMS

Yi Wang^{*1}, Ding-ding Hu², Xiao-dong Guo², Cheng-cheng Pu³, Raymond C.K. Chan¹

¹*Institute of Psychology Chinese Academy of Sciences*, ²*Institute of Psychology Chinese Academy of Sciences; University of Chinese Academy of Sciences*, ³*Peking University Sixth Hospital, Peking University, Institute of Mental Health, NHC Key Laboratory of Mental Health, National Clinical Research Center for Mental Disorders*

Background: The Empathic Accuracy Task (EAT) captures how accurately an individual understands emotions of others while watching naturalistic video stimuli. Previous studies suggested that schizophrenia (SCZ) patients exhibiting altered brain activations in the precuneus, middle frontal gyrus and thalamus during EAT. Our study aimed to adopt inter-subject correlation (ISC) analysis, a method measuring the consistent neural activity among individuals engaging in naturalistic stimuli, to examine neural synchronization during the EAT in SCZ patients compared to healthy controls.

Methods: Forty-three patients with SCZ and forty-one matched healthy controls (HC) were recruited to undergo the Chinese version of EAT in a 3T GE MR750 scanner. During EAT, all participants watched four videos (two positive, two negative) of a target telling his/her autobiographical stories in the scanner while continuously rate the emotional valence of the target. Empathic accuracy (EA) was calculated using the Spearman's correlation between the ratings of target and each participant. Clinical symptoms of SCZ patients were assessed using the Positive and Negative Syndrome Scale (PANSS) and the Clinical Assessment Interview for Negative Symptoms (CAINS). Preprocessing of the functional MRI data were performed using the SPM12. ISC analyses were conducted by correlating the blood oxygen level dependent (BOLD) time-series of one participant and the average time-series of remaining participants in the same group at each voxel of whole brain. The correlation coefficients were fisher-z transformed for further analyses. Group comparisons of the ISC in HC and SCZ group were performed using independent sample t-tests. Threshold for significance were set at peak-level uncorrected $p < 0.001$ and cluster-level FWE corrected $p < 0.05$. Clusters with significant group differences were defined as regions of interests and we calculated the corresponding ISC values of all SCZ patients with HC group mean to examine clinical correlations with the PANSS and CAINS. Bonferroni corrections were used to control for multiple comparisons.

Results: Significant group differences of ISC in brain activations while performing EAT were found, with SCZ group showing weaker ISC than HC group in bilateral inferior frontal gyrus (IFG, right: $t = 6.84$, $p < 0.001$; left: $t = 5.25$, $p = 0.013$), right dorsomedial prefrontal cortex (dmPFC, $t = 5.92$, $p < 0.001$), caudate head ($t = 5.50$, $p < 0.001$), precentral gyrus ($t = 4.67$, $p = 0.039$), middle temporal gyrus (MTG, $t = 4.38$, $p = 0.005$), as well as in left fusiform gyrus ($t = 5.83$, $p = 0.032$), precuneus ($t = 5.20$, $p < 0.001$), middle occipital gyrus (MOG, $t = 5.10$, $p = 0.010$) and cerebellum Crus I ($t = 4.72$, $p = 0.024$). The ISC of SCZ patients with HC group mean in left cerebellum Crus I were negatively correlated with negative ($r = -0.53$, $p < 0.001$) and general ($r = -0.48$, $p = 0.001$) symptom dimensions of the PANSS, as well as CAINS expression dimension ($r = -0.54$, $p < 0.001$).

Discussion: These findings revealed reduced ISC in brain activations of SCZ patients in social brain network (e.g., dmPFC, precuneus), sensory processing regions (e.g., MTG, fusiform gyrus), and cerebellum, suggesting altered neural synchronization of SCZ patients when performing EAT. Moreover, the ISC of SCZ patients exhibited negative associations with negative symptoms. These findings highlight the underlying neural mechanisms of social cognition deficits in SCZ patients, and provide new perspectives on understanding negative symptoms and social cognition in schizophrenia.

F172. THE LONGITUDINAL EFFECT OF ANTIPSYCHOTIC DRUGS ON STRIATAL DOPAMINE SYNTHESIS CAPACITY IN DRUG-NAIVE FIRST-EPIISODE PSYCHOSIS

Seoyoung Kim¹, Euitae Kim^{*1}

¹*Seoul National University Bundang Hospital*

Background: Antipsychotic drugs are known to be effective treatment for majority of first episode psychosis (FEP), yet its longitudinal effect is less investigated where previous studies have shown inconsistent results. While dopamine hypothesis is suggested as leading neurobiological mechanism underlying psychotic disorders, and all antipsychotic drug is dopamine antagonist, an effect of specific antipsychotic drug on dopamine synthesis capacity is unclear. Predicting treatment response to antipsychotic drugs is important in improving the prognosis of psychosis and monitoring presynaptic dopamine synthesis capacity in FEP after antipsychotic treatment might give some clue regarding treatment responsiveness. The aim of this study was to prospectively observe the change in striatal dopamine capacity during 1-year treatment with amisulpride and three months after switching to aripiprazole.

Methods: Twenty-seven antipsychotic-naive FEP patients, aged 19 or more and less than 45, were enrolled, along with 31 age- and sex-matched healthy controls. Striatal dopamine activity was assessed as k_{ic} value using [18F]DOPA PET, before initiating treatment (baseline) and after 6 weeks and 1 year of amisulpride treatment and 3 months after switching to aripiprazole. Healthy controls also underwent [18F]DOPA PET scans according to the corresponding schedule of the patients. Patients were clinically assessed regularly with Positive and Negative Symptom scale (PANSS) and Clinical Global Impression-severity scale (CGI-S) at baseline and after 2, 4, 6, 12, 24 weeks and 1 year of amisulpride treatment. Information regarding pharmacological treatment were obtained on every study visit.

Results: There were no significant difference in demographic characteristics between FEP patients and healthy controls. Mean PANSS total score of FEP patients at baseline, 6-week and 1-year follow-up were 67.8, 47.8, and 40.0, respectively. All patients showed treatment response after 6-week treatment of amisulpride, while 2 patients had worsening of psychotic symptom and 1 patient had switched to another antipsychotic drug due to adverse effect, afterwards. The mean dose of amisulpride at 1-year follow-up was 198mg. The change in k_{ic} value over time significantly differed between FEP patients and healthy controls.

Discussion: Significant change in dopamine synthesis capacity were found after 1-year amisulpride treatment but not after 6-week treatment in FEP patients. These results suggest that the effect of antipsychotics treatment on dopamine neurotransmission might be related to a delayed change of striatal dopamine synthesis capacity. Longer prospective study is needed to confirm the antipsychotic effect on the dopamine synthesis capacity in FEP.

F173. CHANGES IN RESTING CEREBRAL BLOOD FLOW IN PEOPLE WITH CHRONIC SCHIZOPHRENIA: STRIATAL HYPERPERFUSION ACCOMPANYING WIDESPREAD CORTICAL HYPOPERFUSION

Stephanie Hare^{*1}, Bhim M. Adhikari², Hwiyoung Lee¹, Shuo Chen¹, Deanna L. Kelly¹, Laura M. Rowland³, Robert W. Buchanan¹

¹Maryland Psychiatric Research Center, ²UTHealth Houston, McGovern Medical School,

³National Institute of Mental Health

Background: Magnetic resonance imaging (MRI) has been an important tool to improve understanding of the brain pathophysiology of schizophrenia. Yet, the copious amount of functional MRI studies that have been performed have yielded mixed results supporting a hypothesis of widespread brain dysconnectivity in people with schizophrenia (PSz), wherein changes in functional connectivity are reported across the entire brain (rather than a localized set of brain regions). This leaves open the questions of (1) whether blood oxygen level dependent (BOLD) fMRI signal(s) are predominately increased or decreased in PSz and (2) whether consistent, replicable patterns of activity in PSz can be mapped to specific circuits. Arterial spin labeling (ASL) imaging is a less utilized MRI measure that can be used to quantify resting brain cerebral blood flow (rCBF) and is sensitive to pharmacological manipulation and related to metabolic demand and cognitive function. In this data-driven analysis, we identify significant differences in rCBF in PSz vs. healthy control (HC) participants.

Methods: This study included 37 participants that met DSM-IV-TR/DSM 5 criteria for either schizophrenia, schizoaffective, or schizophreniform disorder and 32 HC participants. CBF data was obtained by performing a pseudo-continuous ASL scan. Eight participants' ASL data was did not pass quality control assessment (Final N = 61; 31 HC and 30 PSz). Data preprocessing included normalization, smoothing (5 mm FWHM), motion and partial volume corrections. The average CBF signals (in ml/100 g/min) for 246 brain regions of interest were extracted using the Brainnetome atlas. During the study, the MR scanner was upgraded from a Siemens Trio 3T MR system to a Siemens PRISMA 3T MR system. The scanner upgrade resulted in different scales of measured CBF intensity for values obtained from the Trio vs. PRISMA scanner. To harmonize these values, we applied the NeuroCombat harmonization procedure. To account for the patterns of co-dependence of CBF in nearby regions, we applied the innovative Fase autoregressive model to examine PSz vs. HC differences in rCBF; P-values were FDR-corrected for multiple tests.

Results: In PSz (relative to HC), rCBF was significantly decreased across 115 cortical brain areas and significantly increased in two subcortical striatal regions in PSz: left ventromedial putamen and right dorsolateral putamen. Exploratory linear regression analyses in the PSz revealed that rCBF in these two striatal regions was not significantly associated with overall symptom severity (total score on the Brief Psychiatric Rating Scale) nor an estimate of current antipsychotic medication dose (chlorpromazine equivalent dose).

Discussion: Our findings fall in line with a recent meta-analysis of rCBF studies of PSz reporting that the strongest effects were decreased rCBF in frontal and other cortical areas, and increased rCBF in the putamen relative to controls (du Sert et al. 2023). Intriguingly, a single dose of antipsychotic medication in healthy individuals was shown to boost CBF in the putamen (Selvaggi et al. 2019). Future research is needed to learn how the observed patterns of resting CBF in PSz are influenced by chronic administration of antipsychotic medications and how changes in rCBF may relate to severity of different symptoms.

F174. RESTING-STATE FUNCTIONAL CONNECTIVITY WITHIN SOCIAL BRAIN NETWORKS SHOW DIFFERENTIAL ASSOCIATIONS WITH NEGATIVE SYMPTOM DOMAINS IN SCHIZOPHRENIA

Anna Knippenberg*¹, Lauren Luther¹, Gregory P Strauss¹, Lawrence Sweet¹

¹*University of Georgia*

Background: Negative symptoms of schizophrenia (SZ) are currently defined as two broad dimensions within the DSM-5 (i.e., Volition and Diminished Expression). However, recent factor analyses support a 5-domain conceptualization of negative symptoms (i.e., asociality, anhedonia, avolition, alogia, blunted affect). Although each negative symptom domain is likely driven by unique neural mechanisms, it is currently unclear which specific neural processes drive abnormalities in each domain. The current study examined the validity of the 5-domain conceptualization by evaluating the selectivity of the association with resting-state functional connectivity (RS-FC) within five large-scale brain networks previously shown to be important for social functioning.

Methods: 39 outpatients with schizophrenia completed clinical symptom ratings and resting-state magnetic resonance imaging (rsMRI). RS-FC analyses were employed to evaluate the synchrony between regions of interest (ROIs) in five social brain networks – aversion, affiliative, perception, mentalizing, and mirror networks.

Results: Results indicated a selective association between asociality and increased synchrony within the aversion, affiliative, perception, and mirror networks that was not observed with other negative symptom domains. Worse social cognition was uniquely associated with increased network synchrony.

Discussion: Findings suggested that resting state social brain networks governing social behavior in healthy individuals have a unique association with the negative symptom domain of asociality in SZ. Findings support the 5-domain conceptualization and that they're associated with distinct mechanisms. Domains may require different mechanistic approaches to treatment and the DSM-5 conceptualization of negative symptoms may need to be reconsidered to account for recent evidence supporting a more granular structure.

F175. EFFECTS OF DIAZEPAM ON HIPPOCAMPAL BLOOD FLOW IN PEOPLE AT CLINICAL HIGH RISK FOR PSYCHOSIS

Nicholas Livingston*¹, Amanda Kiemes¹, Gabriel A. Devenyi², Samuel Knight¹, Paulina Lukow³, Luke Jelen¹, Thomas Reilly⁴, Aikaterini Dima¹, Maria Antonietta Nettis¹, Cecilia Casetta¹, Tyler Agyekum², Fernando Zelaya¹, Thomas Spencer¹, Andrea De Micheli¹, Paolo Fusar-poli¹, Anthony A. Grace⁵, Steven C.R. Williams¹, Philip McGuire⁴, Alice Egerton¹, M. Mallar Chakravarty², Gemma Modinos¹

¹*Institute of Psychiatry, Psychology, and Neuroscience, King's College London*, ²*Cerebral Imaging Center, Douglas Mental Health University Institute, McGill University*, ³*Institute of Cognitive Neuroscience, University College London*, ⁴*University of Oxford*, ⁵*University of Pittsburgh*,

Background: Elevated regional cerebral blood flow (rCBF) of the hippocampus has been robustly observed in individuals at clinical high-risk for psychosis (CHR-P), which may be a novel target for intervention. Preclinical studies demonstrated that administration of a GABA-enhancing compound such as diazepam could downregulate hippocampal hyperactivity and

prevent the emergence of psychosis-like phenotypes. Mechanistic evidence of the effects of diazepam on hippocampal hyperactivity in CHR-P is lacking. The aim of this study was to determine whether an acute dose of diazepam compared to placebo can reduce and normalise rCBF in the hippocampus and its subfields in CHR-P individuals.

Methods: We conducted a within-subject, double-blind, placebo-controlled, randomised, cross-over design study in 24 CHR-P individuals. Participants underwent two MRI sessions, three weeks apart; once under a single dose of diazepam (5 mg) and once under placebo (50 mg ascorbic acid). rCBF was measured using a pseudocontinuous arterial spin labelling sequence and a previously collected dataset of 21 healthy controls (HC) was used for comparison. Subject-specific hippocampus and subfield masks were generated using the MAGeT Brain toolbox. Using the minc-toolkit-v2/1.9.18, these masks were registered and resampled to the individual's respective rCBF map, and the mean rCBF value was extracted per hemisphere in native space from the following regions: whole hippocampus, CA1, subiculum, CA4/dentate gyrus, and total brain grey matter. Mixed ANCOVAs (covarying for global rCBF, age, and sex) and linear mixed-effects models (participant ID as random effect) investigated the effect of group (HC vs. CHR-P placebo and HC vs. CHR-P diazepam) and condition (CHR-P placebo vs. CHR-P diazepam), respectively, on hippocampal/subfield rCBF per ROI. Significance was set at pFDR LESS THAN 0.05. Exploratory analyses assessed broader diazepam effects on voxel-wise grey matter rCBF (linear mixed-effects model), and whether baseline clinical characteristics were associated with diazepam-induced changes in hippocampal rCBF (Pearson's correlations).

Results: Under the placebo condition, CHR-P individuals (mean[$\pm$ SD] age: 24.1[$\pm$ 4.8] years, 15F) showed significantly elevated rCBF compared to HC (mean[$\pm$ SD] age: 26.5[$\pm$ 5.1] years, 11F) in the hippocampus ($F(1,36)=8.2$, pFDR=0.004) and across its subfields (all pFDR LESS THAN 0.01). Following diazepam, rCBF in the hippocampus (and subfields, all pFDR LESS THAN 0.001) was significantly reduced ($t(69)=-5.1$, pFDR LESS THAN 0.001) and normalised to HC levels ($F(1,41)=0.3$, pFDR=0.225). Exploratory analyses revealed additional widespread reductions in rCBF by diazepam across several cortical and subcortical regions (e.g., medial/dorsolateral prefrontal cortex, nucleus accumbens, amygdala), and suggested that CHR-P individuals with highest attenuated psychotic symptom severity ($r=0.598$, $p=0.003$) and poorest social functioning ($r=-0.538$, $p=0.008$) at baseline had the smallest changes in diazepam-induced hippocampal rCBF.

Discussion: Our study shows that diazepam can normalise hippocampal hyperperfusion in CHR-P individuals, consistent with evidence implicating medial temporal GABAergic dysfunction in the pathophysiology of psychosis. Our results suggest the development of more hippocampal-selective GABAergic pharmacological agents as a promising strategy for preventing psychosis development.

F176. BRAIN METABOLITES IN THE PREFRONTAL AND MEDIAL TEMPORAL CORTICES IN CHILD AND ADOLESCENT OFFSPRING OF PATIENTS WITH BIPOLAR DISORDER

María Ortuño^{*1}, Adriana Fortea¹, Irene Martínez¹, María Muriel¹, Patricia Camprodon¹, Elena De la Serna², Roger Borràs³, Isabel Valli¹, Daniel Ilzarbe¹, Mireia Masias⁴, Inmaculada Baeza³, Josefina Castro-Fornieles³, Gisela Sugranyes¹

¹Fundació Clinic Recerca Biomèdica - Institut d'Investigacions Biomèdiques August Pi i Sunyer, Clinical and Experimental Neuroscience, ²Centro de Investigación Biomédica En Red

de Salud Mental CIBERSAM, Child and Adolescent Psychiatry, ³Institute of Neurosciences, University of Barcelona, ⁴BCN-MedTech, Universitat Pompeu Fabra

Background: The offspring of patients with bipolar disorders are at an increased risk of developing both their parental disorder and any other mental disorder during their lifetime [1]. Meta-analytical findings have described anomalous levels of metabolite concentrations in several brain areas in bipolar disorders. Examining the neurometabolic profile in child and adolescent offspring of patients with the disorder allows us to understand the neural correlates of familial risk for the disease and identify changes associated with the early stages of the illness. The aim of this study was to assess differences in measures of neurometabolites in two brain regions relevant to the disease between offspring of patients with bipolar disorder (BpO) and controls, and their relationship with age and psychosocial functioning.

Methods: 43 BpO (mean age 16.7 ± 4.7 , 58% females) and 139 healthy subjects (mean age 16.5 ± 3.4), all aged between 6 to 25 years old were recruited in the Hospital Clinic of Barcelona. No BpO met criteria for bipolar disorder. Every subject underwent the acquisition of two magnetic resonance imaging (MRI) sequences on a 3T scanner: a T1-weighted sequence and a magnetic resonance spectroscopy sequence (MRS) in two volumes of interest (VOIs) located in the lateral prefrontal cortex (PFC) ($2 \times 2 \times 2 \text{ cm}^3$) and the medial temporal lobe (mTL, $3 \times 2 \times 2 \text{ cm}^3$). MRS data was processed employing LCModel in order to obtain the creatine-corrected ratios of glutamate, glutamate + glutamine (Glx), N-acetylaspartate (NAA+NAAG), choline (GPC+PCh) and inositol (mIns). Moreover, all participants underwent an evaluation of functioning employing the Global Assessment of Functioning (GAF) scale. Linear models were conducted in R with metabolite as the dependent variable and group, GAF, sex and age and the interaction between them as fixed effects.

Results: A significant main effect of group by age was observed in NAA+NAAG levels in the PFC ($\beta = 0.01$, SE LESS THAN 0.01, $t = 2.30$ $p = 0.02$), whereby NAA+NAAG levels increased significantly with age in BpO compared to controls. In addition, there was a significant negative effect of levels of mIns in the PFC on GAF scores ($\beta = -0.002$, SE LESS THAN 0.01, $t = -2.03$ $p = 0.04$) in BpO. Moreover, a significant interaction between group and age was found in mIns levels in the mTL ($\beta = 0.01$, SE=0.01, $t = 2.186$, $p = 0.03$), whereby mIns levels increased more pronouncedly with age in BpO compared to controls.

Discussion: Our results show abnormal NAA+NAAG and mIns level increases with age in BpO relative to controls. Further, these findings indicate a negative relationship between mIns and psychosocial functioning in non-bipolar BpO. NAA+NAAG is a marker of neuronal density and function, hence increased levels of this metabolite in BpO could be due to protective mechanisms in healthy BpO. Likewise, mIns is implicated in intracellular second messenger systems and is related to glial proliferation and therefore higher levels could reflect variations in signaling pathways in the BpO population. Nevertheless, although studying the neurometabolic profile of BpO holds promise to gain a better knowledge of the biological alterations associated with risk and resilience in this population, future research needs to further disentangle the phenotypic correlates of these neurometabolic changes.

This study was funded by Instituto de Salud Carlos III co-funded by the EU (PI1800976, PI2100330, PI2100519), and by the EU grant (101057529), TV3_SalutMental_21 (202232-30), Alicia Koplowitz Foundation, CIBERSAM and 2021 SGR 01319.

F177. EXPLORING NEURAL CORRELATES OF NMDA RECEPTOR HYPOFUNCTION THROUGH MULTIMODAL IMAGING POST-KETAMINE

ADMINISTRATION: INVESTIGATING MARKERS OF GLUTAMATERGIC NEUROTRANSMISSION MODULATION

Shenton³, Gregor Leicht¹

¹University Medical Center Hamburg-Eppendorf, ²University of California, San Francisco, ³Brigham and Women's Hospital, Harvard Medical School, ⁴Massachusetts General Hospital, Harvard Medical School, ⁵Justus-Liebig University

Background: Schizophrenia is characterized by a complex interplay of neurobiological alterations, comprising glutamatergic dysfunction and consequently excitatory-to-inhibitory (E/I) imbalance. A key component is the hypofunction of the N-Methyl-D-Aspartate Receptor (NMDAR), which can be effectively modeled by administering ketamine to healthy volunteers. However, the field lacks robust methods for assessing the individual extent of this hypofunction and evaluating responses to targeted therapies such as glycine, a co-agonist of the NMDAR. Our research builds on recent advances that highlight low gamma activity (30-50 Hz), evoked via an attention-demanding auditory choice reaction task in electroencephalography (EEG), as a promising biomarker indicative of NMDAR functionality. Incorporating a multimodal imaging strategy, we combine diffusion magnetic resonance imaging (dMRI) with simultaneous EEG/functional MRI (fMRI), to explore the neural correlates of NMDAR hypofunction and their potential as a biomarker for individualized therapy in schizophrenia.

Methods: In this longitudinal, placebo-controlled study, 32 healthy volunteers were administered ketamine to simulate NMDAR hypofunction. Each participant experienced three imaging sessions: a baseline with placebo, followed by two sessions involving either intravenous glycine or placebo pretreatment before ketamine infusion. Sessions were spaced at least a week apart, with the order of pretreatments counterbalanced. We focused on low gamma activity changes using simultaneous EEG/fMRI during an auditory choice reaction task and subsequently conducted dMRI to assess white-matter properties. Our statistical analysis employed linear mixed models (LMM) and incorporated covariates such as age and cannabis use. For the analysis of our fMRI data, we employed Generalized Linear Models (GLM).

Results: Ketamine administration resulted in an increase in schizophrenia-like symptoms, reflected in elevated Positive and Negative Syndrome Scale (PANSS) scores, and task-related error rates. This was paralleled by reduced activity in attention-related brain regions in fMRI and diminished gamma activity in EEG, coupled with an increase in whole-brain fractional anisotropy (FA). Glycine did not affect these MRI changes; however, it notably impacted task-related error rates, specifically mitigating the ketamine-induced increases which were otherwise apparent in the placebo condition. Additionally, glycine attenuated the effects on gamma activity, resulting in a neurophysiological state distinct from the placebo and ketamine conditions.

Discussion: Our results align with the conjecture that reductions in task-associated activity in fMRI and EEG reflect NMDAR hypofunction. The increase in FA post-ketamine, although surprising, mirrors trends seen in major depressive disorder, and may be linked to astrocyte plasticity. Importantly, the modulation of EEG-monitored gamma activity by glycine offers a nuanced perspective on the E/I balance. This suggests that such EEG markers could potentially provide a deeper understanding of individual response to glutamatergic therapies in schizophrenia.

F178. THE ASSOCIATION OF TOBACCO SMOKING AND METABOLITE LEVELS IN THE ANTERIOR CINGULATE CORTEX OF FIRST-EPISODE PSYCHOSIS PATIENTS: A CASE-CONTROL AND 6-MONTH FOLLOW-UP 1H-MRS STUDY

Merel Koster*¹, Marieke van der Pluijm¹, Elsmarieke van de Giessen¹, Anouk Schrantee¹, Carmen F. M. van Hooijdonk², Jean-Paul Selten², Jan Booij¹, Lieuwe de Haan¹, Tim Ziermans³, Jentien Vermeulen¹

¹Amsterdam UMC, ²University of Maastricht, ³Universiteit van Amsterdam

Background: Tobacco smoking amongst patients with schizophrenia is 2-3 times higher compared to the general population [1], and it is associated with worse clinical outcomes such as relapse and readmission [2]. Remarkably, few neuroimaging studies have explored the effect of tobacco on the brain in psychosis. In particular limited studies have assessed the effect of tobacco on the levels of different neurometabolites, whilst neurometabolites such as glutamate and choline have been implicated in psychosis and tobacco smoking separately. The current study therefore aimed to investigate the influence of chronic smoking on neurometabolite levels in the anterior cingulate cortex (ACC) of first-episode psychosis (FEP) patients and controls, as shared ACC abnormalities may contribute to the development or maintenance of smoking in schizophrenia.

Methods: 59 FEP patients and 36 controls were included in the study. Proton magnetic resonance spectroscopy (1H-MRS) was acquired using a Point Resolved Spectroscopy (PRESS) pulse sequence on a 3 Tesla Philips MRI scanner. Associations between smoking status (i.e. smoker yes/no) or average number of cigarettes smoked per day in the past year and Glx (glutamate + glutamine, as proxy for glutamate) and total choline (tCh) levels were assessed at baseline in both groups separately using analysis of covariance (ANCOVA) and linear regressions. For 37 patients, six months follow-up data were acquired to assess longitudinal changes in neurometabolite levels using linear mixed models. We controlled for the use of cannabis in all analyses, considering the strong correlation of cannabis use with tobacco smoking.

Results: No significant differences in Glx or tCh levels in the ACC were found between smoking (n=28) and non-smoking (n=31) FEP patients, at baseline nor in longitudinal analyses. Negative associations were observed between cigarettes smoked per day, and Glx (pFDR=0.025) and tCh levels (pFDR=0.019) in controls but not in FEP patients.

Discussion: We found that tobacco smoking is associated with differences in neurometabolite levels in controls but not in FEP patients. Schizophrenia patients already appear to have an aberrant glutamate system and show dysregulated nicotine acetylcholine receptor (nAChR) expression. Nicotine, the primary addictive substance in tobacco, exerts its effects on the brain through the activation of nAChRs, and chronic tobacco exposure results in desensitization, inactivation, and upregulation of these receptors [3]. In addition, it has been hypothesized that abnormalities in neurometabolite signalling in schizophrenia are due to divergent nAChR signalling [4]. Thus, possibly, pre-existing disease-related neurometabolite deficits or alterations at nAChR level in FEP patients underlie the differences in tobacco-related effects on glutamate and choline levels. However, MRS does not allow for observation of neurometabolite function at receptor level. Future research for example through PET-imaging, could focus on investigating nAChR dysfunctioning to elucidate underlying reasons for the absence of differences in neurometabolites between smoking and non-smoking FEP patients.

F179. GLUTAMATE AND GABA LEVELS IN THE ANTERIOR CINGULATE CORTEX IN TREATMENT RESISTANT FIRST EPISODE PSYCHOSIS PATIENTS

Marieke Van der Pluijm^{*1}, Maartje Alting¹, Anouk Schrantee¹, Richard Edden², Jan Booij¹, Lieuwe De Haan¹, Elsmarieke Van de Giessen¹

¹*Amsterdam UMC, University of Amsterdam*, ²*Johns Hopkins University*,,

\

Background: Around 30% of schizophrenia patients do not respond sufficiently to conventional antipsychotic treatment. Glutamate and γ -aminobutyric acid (GABA) may be implicated in treatment resistant (TR) patients. Previous research indicates that TR patients show increased glutamate levels compared to responders, but findings are inconclusive and limited in the early disease stage. Furthermore, the two neurotransmitters have rarely been assessed in conjunction. We therefore aimed to investigate the role of glutamate and GABA in first episode TR patients and explore whether these neurometabolites could be potential predictive markers for treatment resistance in schizophrenia.

Methods: We used proton magnetic resonance spectroscopy (MRS) to assess Glx (glutamate + glutamine) and GABA+ (GABA including macromolecules) in the anterior cingulate cortex (ACC) of 58 first episode psychosis patients. A short-TE Point Resolved Spectroscopy (PRESS) pulse sequence was used to acquire the metabolite spectra for Glx measurements and GABA-edited proton J-difference spectra were acquired using a Mescher-Garwood Point Resolved Spectroscopy (MEGA-PRESS). At six months follow-up treatment response was determined. Patients were considered TR when, despite adequate treatment with a minimum of two trials of different antipsychotics, at least one of the following items of the Positive and Negative Syndrome Scale was scored moderate or higher: delusions (P1), conceptual disorganization (P2), hallucinatory behaviour (P3), mannerisms and posturing (G5) and unusual thought content (G9). In a subgroup of 33 patients a follow-up MRS scan was acquired to assess changes in neurometabolite levels over six months.

Results: At six months follow-up 12 patients were classified as TR and 46 patients as responders. The two groups did not significantly differ on gender, IQ, use of medication, and substance use. The TR patients had longer duration of antipsychotic use and higher symptom severity scores. Glx and GABA+ levels were not significantly different between TR patients and responders at baseline and the levels did not change at six months follow-up. The groups differed in voxel fractions of white matter (WM) and cerebral spinal fluid (CSF), with TR patients showing lower WM and higher CSF fractions.

Discussion: Our findings do not provide evidence that glutamate or GABA levels in the ACC differ between TR patients and responders in the early disease stage of schizophrenia. However, differences in WM and CSF voxel fractions may have influenced our results. Previous studies and our results also suggest that MRS measurements of glutamate and GABA are susceptible to multiple confounders including tissue fractions, illness duration, medication dose, and clozapine responsiveness. This complicates disentangling the role of glutamate and GABA in treatment resistance schizophrenia. Future research should take these confounders into account and particularly focus on clozapine responsiveness, inclusion of medication-naïve patients and longitudinal follow up/medication effects to better understand the complex interplay of glutamate and GABA in treatment resistant schizophrenia.

F180. ASSOCIATION BETWEEN INCREASED ANTERIOR CINGULATE GLUTAMATE AND PSYCHOTIC-LIKE EXPERIENCES, BUT NOT AUTISTIC TRAITS IN HEALTHY VOLUNTEERS

Verena Demler*¹, Elisabeth F. Sterner¹, Martin Wilson², Claus Zimmer¹, Franziska Knolle¹

¹*Technische Universität München*, ²*Centre for Human Brain Health and School of Psychology, University of Birmingham*

Background: Despite many differences, autism spectrum disorder and schizophrenia spectrum disorder share environmental risk factors, genetic predispositions as well as neuronal abnormalities, and show similar cognitive deficits in working memory, perspective-taking, or response inhibition. These shared abnormalities are already present in subclinical traits of these disorders. The literature proposes that changes in the inhibitory GABAergic and the excitatory glutamatergic system could explain underlying neuronal commonalities and differences, but only few studies explored changes of neurotransmitter concentrations associated to psychotic-like experiences and autistic traits.

Methods: Using magnetic resonance spectroscopy (1H-MRS), we therefore investigated the associations between glutamate concentrations in the anterior cingulate cortex (ACC), the left/right putamen, and left/right dorsolateral prefrontal cortex and psychotic-like experiences (Schizotypal Personality Questionnaire) and autistic traits (Autism Spectrum Quotient) in 53 healthy individuals (26 women, aged 18-35 years). To investigate the contributions of glutamate concentrations in different cortical regions to symptom expression and their interactions, we first performed two linear regression models, using psychotic-like experiences and autistic traits as outcome variables, with glutamate levels from the ACC, left DLPFC, and right DLPFC as predictor variables, while accounting for age and sex. Levels of glutamate could not be reliably estimated in the putamen. To investigate non-linear relationships between clinical traits and glutamate concentrations, we dichotomised the clinical scores by a median split (psychotic-like experiences, median=75; autistic traits, median=22) and performed logistic regression analyses corrected for age and sex.

Results: We found that levels of glutamate in the ACC significantly predicted psychotic-like experiences, but not autistic traits. Whereas glutamate concentrations in the DLPFC did not yield any significant results. Supporting this finding, a binomial logistic regression predicting median-split high and low risk groups for psychotic-like experiences (PLE-group ~ Glu DLPFC_R + Glu DLPFC_L + Glu ACC + age + sex) revealed ACC glutamate levels as a significant predictor for group membership. There was a 33.1% increase in the odds of an individual being in the high psychotic-like experiences group for every one-unit rise in ACC glutamate, with all other predictor variables held constant. The effects of the linear and logistic regressions both survived Bonferroni multiple comparison correction (level of significance, $p < 0.025$, correcting for two tests each).

Discussion: This study provides evidence for both a dimensional and a non-linear relationship, highlighting a positive linear correlation between the intensity of psychotic-like experiences and ACC glutamate levels across the entire sample. ACC glutamate also serves as a predictor for an individual's classification as a high-risk or low-risk individual, suggesting qualitative distinctions in the neuropathology of various disease stages. However, further exploration of this phenomenon is necessary in future research. Taken together, these results suggest that glutamate levels may be a potential candidate for identifying early-risk individuals prone to developing psychotic-like experiences.

F181. REPEATED TESTING INDUCES A DIFFERENTIAL STRIATAL RESPONSE DURING REWARD ANTICIPATION AND REWARD RECEPTION IN A LARGE GROUP OF PATIENTS WITH SCHIZOPHRENIA

Mariia Kaliuzhna*¹, Fabien Carruzzo¹, Noémie Kuenzi¹, Philippe N. Tobler², Matthias Kirschner³, Tal Geffen⁴, Teresa Katthagen⁴, Kerem Böge⁴, Marco M. Zierhut⁴, Florian Schlagenhauf⁴, Stefan Kaiser³

¹University of Geneva, ²Laboratory for Social and Neural Systems Research, University of Zurich, ³University Hospitals of Geneva, ⁴Charite University Medical Center Berlin, ,

Background: Improving treatment options in schizophrenia relies on the identification of biomarkers, i.e. characteristics robustly associated with a given dysfunction. Such biomarkers are of particular importance for negative symptoms of schizophrenia where treatment options are especially limited. Deficits in reward processing have been shown to be promising candidates as such biomarkers. Indeed, motivation relies on the ability to successfully integrate reward-related information. One important process is reward anticipation. In order to engage in goal-directed behaviours one needs to represent the potential reward it could bring. Another aspect is the ability to adequately represent the rewarding value of a stimulus once the reward is obtained. Adaptive coding of reward is the mechanism underlying this ability. Our work has assessed these processes in patients with schizophrenia.

Methods: We used the Monetary Incentive Delay (MID) task during functional magnetic resonance imaging (fMRI), in a large sample of patients (N=86) and healthy controls (N=66), recruited in two centres in Switzerland and Germany. Participants were tested twice, 3 months apart, to evaluate the stability of the effects in time. Our analyses focused on the phase of the task before the reception of reward, to evaluate reward anticipation, and on the feedback phase to evaluate adaptive coding of reward.

Results: During reward anticipation, in patients with schizophrenia as compared to healthy controls we found reduced activity in the ventral and dorsal striatum as well as the posterior putamen, bilaterally. In addition, patients also had reduced activation in the thalamus, amygdala, right anterior cingulate cortex and left calcarine gyrus. Similarly reduced activity was also found upon re-test. We found no correlations between striatal activity and motivational negative symptoms (apathy), positive and depressive symptoms or cognition, at either the first or second testing sessions. In patients, higher striatal activity correlated with higher amounts won on the task. During the outcome phase of the task, we also found reduced adaptive coding in patients in striatal regions. Specifically, patients' BOLD response increase to increasing rewards was less steep than that of controls in the reward context where fewer items needed to be represented and thus a steeper BOLD increase slope was to be expected. Interestingly, upon re-test, patients improved, showing adaptive coding to the same extent as controls. At re-test adaptive coding in patients correlated with negative symptoms, due to some patients showing overadaptation – BOLD response slopes that are too steep.

Discussion: Our findings are consistent with the hypothesis that ventral striatal activity reflects modulation of motivational saliency during reward anticipation and that these processes are impaired in patients with schizophrenia. Similarly, reward adaptation is impaired in schizophrenia and, in a subgroup of patients, might reflect faster saturation and an inability to adequately represent the full range of rewards. Interestingly, while the striatal response during reward anticipation remained consistent between sessions, there was an apparent improvement in striatal reward adaptation upon re-test, suggesting potential distinct mechanisms within the same brain regions. We provide additional evidence for the use of ventral striatal hypoactivity as a biomarker candidate for schizophrenia, but also raise critical issues that would need to be

resolved before this measure can be considered as a biomarker, in particular with respect to negative symptoms.

F182. DORSOLATERAL PREFRONTAL CORTEX ACTIVATION AND CONNECTIVITY IN PSYCHOSIS AND THE RELATION TO TREATMENT RESPONSE

Lara Wallenwein^{*1}, Alexander Sahm¹, Daniela Mier¹

¹*University of Konstanz*

Background: Cognitive impairments are a common symptom in psychotic disorders. They are often present before the onset of illness and constitute a predictor of poor functional outcomes. Aberrant activation and connectivity related to working memory performance has been found in psychosis. While neurocognitive abilities have been linked to treatment response, few studies investigated the predictive value of accompanying neural activation and connectivity.

Methods: In this ongoing study, 17 patients with psychotic disorders participated in functional magnetic resonance imaging during an in-patient stay in a psychotherapy ward. Fifteen healthy control participants served as comparison. During fMRI scanning, participants performed the Callicott n-back working memory task. Group differences in the 2-back GREATER THAN 0-back contrast in activation and gPPI connectivity with left and right dorsolateral prefrontal cortex (dlPFC) as seed regions were assessed on a whole-brain level. Moreover, activation within left and right dlPFC and connectivity with inferior and superior parietal lobule were correlated with changes in psychopathology and level of functioning. For the latter, difference scores in Positive and Negative Syndrome Scale and Global Assessment of Functioning were calculated between admittance and discharge from psychiatric care. FMRI data were acquired on a 3T Siemens Magnetom Skyra and analysed with SPM12. General task activation is reported FWE corrected p LESS THAN .05, connectivity results and group comparisons with an exploratory threshold of p LESS THAN .001 uncorrected, cluster size threshold 20 voxels.

Results: The preliminary results show strong task-based activation in the fronto-parietal network, insula, thalamus, and cerebellum over both groups, but no group differences. Also, no differences in performance were found. Task-based connectivity of dlPFC with frontal regions, superior parietal lobule, occipital cortex, cerebellum, and amygdala was found over both groups in gPPI analyses. On a whole-brain level, patients showed reduced connectivity between left dlPFC and left orbitofrontal cortex as well as between right dlPFC and right superior frontal cortex compared to the control group. Activation in bilateral dlPFC was able to predict improvements in general functioning over the course of in-patient treatment but was not related to changes in positive or negative pathology. Functional connectivity of dlPFC with inferior and superior parietal lobule could neither predict changes in level of functioning nor psychopathology.

Discussion: The activation and connectivity within the fronto-parietal network during performance of a working memory task is in line with pertinent literature. While differences in connectivity were present, we found no differences in performance and activation between groups. However, our analyses indicate that activation but not connectivity of dlPFC during working memory performance is predictive for treatment response in psychosis. Although our results warrant validation in a larger sample, they point towards complementary information of activation and connectivity and the importance of neurocognitive functions for therapeutic success in psychosis.

F183. EXAMINING AFFECTIVE AND NON-AFFECTIVE PSYCHOSIS USING FUNCTIONAL CONNECTIVITY MRI FOLLOWING TREATMENT IN FIRST EPISODE PSYCHOSIS PATIENTS

Jose Maximo*¹, Adrienne Lahti¹

¹*University of Alabama at Birmingham*

Background: The clinical phenotype of first episode psychosis (FEP) is rather heterogeneous and current diagnostic criteria suggest a clear boundary between affective (major depressive and bipolar disorders) and non-affective psychotic disorders (schizophrenia and schizophrenia-related disorders). Furthermore, the impact that antipsychotic treatment may have on these subgroups may differ from one another. The present study measured resting state functional connectivity (rsFC) from brain networks deemed crucial for higher-order cognition: default mode (DMN), salience (SN), dorsal attention (DAN), and executive control network (ECN). Patients were dichotomized into affective and non-affective psychosis groups. Participants were scanned prior to treatment (baseline), 6 weeks, and 16 weeks following antipsychotic treatment. A group of healthy controls (HC) was also scanned. We hypothesized that affective and non-affective groups would show differential rsFC compared to HC throughout the trial.

Methods: Data from 87 antipsychotic medication-naïve FEP patients (non-affective = 65; affective = 22) and 87 HC were used. Medication-naïve patients received antipsychotic treatment for sixteen weeks. rsFC of the default mode (DMN), salience (SN), dorsal attention (DAN), and executive control network (ECN) was assessed prior to treatment, 6, and 16 weeks after treatment. We used linear mixed models to test group by time interactions within each network.

Results: Significant changes in rsFC (p LESS THAN 0.05, corrected) were found within the SN where affective patients showed reduced rsFC compared to HC and non-affective patients at baseline; at week 6 both affective and non-affective patients showed rsFC increases, but then at week 16 affective patients showed rsFC decrease whereas non-affective patients showed increases in rsFC. Interestingly, within the ECN both affective and non-affective groups showed decreased rsFC at baseline compared to HC and then a steady increase in rsFC throughout the antipsychotic trial.

Discussion: Here, we found that changes in intrinsic brain network rsFC were impacted by affective traits in medication-naïve FEP patients. Together, our data suggests modulation of affective traits should be taken into consideration when attempting to associate intrinsic brain network connectivity as a mechanism underlying FEP.

F184. CORTICAL AND SUBCORTICAL STRUCTURAL DIFFERENCES BETWEEN FIRST-EPISODE PSYCHOSIS AND FIRST-EPISODE BIPOLAR DISORDER

Cemal Demirlek*¹, Muhammed Demir², Berna Yalincetin¹, Burcu Verim¹, Ezgi Cesim¹, Merve S. Gurbuz¹, Nabi Zorlu³, Emre Bora⁴

¹*Institute of Health Sciences, Dokuz Eylul University*, ²*Dokuz Eylul University*, ³*Katip Celebi University, Ataturk Education and Research Hospital*, ⁴*Dokuz Eylul University, School of Medicine*,

Background: This study aims to explore the differences in cortical and subcortical structures between healthy controls (HC), patients with first-episode psychosis (FEP), and first-episode

bipolar disorder (FEM). The study's focus on these specific patient groups provides insights into the neurobiological underpinnings of these psychiatric conditions.

Methods: The study included 19 HCs, 23 patients with FEM, and 32 patients with FEP. Participants underwent interviews using the Structured Clinical Interview for the DSM-IV Axis I Disorders (SCID-I). Brain imaging was performed using a 3 T MR scanner with an 8-channel head matrix coil. T1 images were analyzed using FreeSurfer software. Data from each participant was processed through the standard FreeSurfer workflow using the 'recon-all' script. Structural brain differences between groups were determined using the General Linear Model (GLM). Cortical thickness maps were smoothed with a 10 mm full-width half-maximum Gaussian kernel. Group differences were examined using GLM with Monte Carlo z-field simulation, correcting for multiple comparisons at a threshold of $p < 0.05$.

Results: There were statistically significant increases in various brain regions in FEM patients compared to HCs, including left hemisphere inferior parietal surface area ($p = 0.005$), left paracentral surface area ($p = 0.01$), left inferior parietal volume ($p = 0.01$), right hemisphere frontal pole surface area ($p < 0.001$), right precuneus surface area ($p = 0.008$), right precentral surface area ($p = 0.005$), right inferior parietal surface area ($p = 0.01$), right lateral orbitofrontal volume ($p < 0.001$). A significant decrease was observed in the volume of the right hemisphere's lingual region in FEP patients compared to HCs ($p = 0.005$). A significant increase was found in the volume of the right hemisphere's parahippocampal region in FEM patients compared to FEP patients ($p = 0.02$). Comparisons between groups revealed significant differences in subcortical structures, particularly in the thalamus and amygdala. Left thalamus volume was decreased in FEP patients compared to HC ($p = 0.04$). Left Thalamus ($p = 0.01$) and right thalamus ($p = 0.03$) were increased in FEM patients compared to FEP. Right amygdala volume was increased in FEM patients compared to FEP ($p = 0.01$).

Discussion: The findings indicate distinct structural differences in both cortical and subcortical regions among patients with FEM or FEP. These differences might contribute to the understanding of the pathophysiology underlying these psychiatric disorders. The increased volumes in specific brain regions in FEM patients as compared to FEP patients and HCs suggest potential biomarkers for bipolar disorder. The study underscores the importance of neuroimaging in psychiatry and highlights the need for further research in this area to better understand these complex disorders.

F185. BRAIN STRUCTURE IN FAMILIAL HIGH RISK FOR PSYCHOSIS, ULTRA-HIGH RISK FOR PSYCHOSIS AND FIRST-EPISODE PSYCHOSIS

Cemal Demirlek^{*1}, Muhammed Demir², Berna Yalincetin², Merve S. Gurbuz¹, Ezgi Cesim², Burcu Verim², Nabi Zorlu³, Emre Bora⁴

¹*Institute of Health Sciences, Dokuz Eylul University,* ²*Dokuz Eylul University,* ³*Katip Celebi University, Ataturk Education and Research Hospital,* ⁴*Dokuz Eylul University, School of Medicine,*

Background: The study aimed to compare brain structures among individuals at familial high risk (FHR-P), ultra-high risk for psychosis (UHR-P), and those experiencing first-episode psychosis (FEP) using T1-weighted brain magnetic resonance imaging (MRI).

Methods: Participants underwent interviews using the Structured Clinical Interview for DSM-IV Axis I Disorders (SCID-I). The Turkish version of the Structured Interview for Prodromal Syndromes (SIPS) was used to identify UHR-P. The study included individuals with FHR-P, defined as those with a first-degree relative diagnosed with schizophrenia but not meeting

UHR-P or FEP criteria. Brain MRI was conducted using a 3T MR scanner with an 8-channel head matrix coil. T1-weighted images were analyzed using the FreeSurfer's 'recon-all' command. General Linear Model (GLM) was utilized to identify structural brain differences between groups. Cortical thickness maps were smoothed using a 10 mm full-width half-maximum Gaussian kernel. Group differences were examined using a Monte Carlo Z-field simulation with a threshold of $p \text{ LESS THAN } 0.05$ for multiple comparisons, adjusted for age and gender as covariates. Volumes of subcortical structures were extracted using FreeSurfer's automated procedure ('aseg.vol').

Results: This study included 19 healthy controls, 19 individuals at FHR-P, 20 individuals at UHR-P, and 32 patients with FEP. A statistically significant difference in the thickness of the left hemisphere cuneus between individuals at FHR-P, UHR-P, and those with FEP ($p = 0.01$). Patients with FEP showed a statistically significant reduction in the volume of the right hemisphere lingual region compared to healthy controls ($p = 0.005$). In FEP patients, compared to UHR-P individuals, there was a significant reduction in the thickness of the left hemisphere rostral middle frontal region ($p = 0.01$) and the volume of the left hemisphere superior temporal region ($p = 0.01$). UHR-P individuals showed a significant increase in the thickness of the left hemisphere cuneus ($p = 0.007$) and the right hemisphere pericalcarine thickness ($p = 0.04$) compared to those at FHR-P. The left thalamus volume was significantly reduced in FEP patients compared to healthy controls ($p = 0.04$). A similar reduction in the left pallidum volume was noted in individuals at familial risk compared to healthy controls ($p = 0.03$) and in UHR-P compared to FHR-P individuals ($p = 0.01$).

Discussion: The study highlights distinct structural brain differences in individuals at different stages of psychosis risk and manifestation. The findings suggest that specific brain regions undergo changes not only in FEP but also in stages leading up to full-blown psychosis. This has implications for early detection and intervention strategies in psychosis. Further research is needed to understand the causal relationships and the potential for these brain structure changes to serve as biomarkers for psychosis risk.

F186. NEUROANATOMICAL CORRELATES OF MENTAL STATE REASONING IN SCHIZOPHRENIA: A MULTIMODAL IMAGING STUDY

Cemal Demirlek^{*1}, Burcu Verim², Merve Karakilic³, Ecenaz Sarikaya³, Berna Yalincetin², Adem Bayrakci³, Funda Gulyuksel³, Elif Oral³, Fazil Gelal², Nabi Zorlu³, Emre Bora⁵

¹*Institute of Health Sciences, Dokuz Eylul University,* ²*Katip Celebi University, Ataturk Education and Research Hospital,* ⁵*Department of Psychiatry, Dokuz Eylul University Medical School, Izmir, Turkey*

Background: Schizophrenia is characterized by established deficits in theory of mind. The ability to reason about mental states involves integrating contextual and past knowledge through representational systems. This study, employing multimodal neuroimaging, seeks to explore the neuroanatomical underpinnings of theory of mind's mental state reasoning component in both individuals with schizophrenia and healthy controls (HCs), utilizing T1-weighted and diffusion-weighted (DTI) magnetic resonance imaging (MRI).

Methods: The study comprised 62 individuals diagnosed with schizophrenia and 34 HCs. Mental state reasoning was assessed using Hinting tests. T1-weighted structural MRI scans were analyzed using FreeSurfer, while diffusion-weighted MRI scans were analyzed using FSL. Correlations between theory of mind's mental state reasoning components and cortical

parameters (thickness, volume, surface area) or DTI scalars (fractional anisotropy, axial diffusivity, radial diffusivity) underwent cluster-based correction for multiple comparisons.

Results: Within the schizophrenia group, the Hinting test scores exhibited favorable associations with cortical volumes in two distinct clusters. These clusters encompassed the left superior temporal sulcus volume extending to the inferior frontal region ($p = 0.014$, $r = 0.506$) and the left pars orbitalis volume ($p = 0.032$, $r = 0.525$). Furthermore, there was a positive correlation between hinting scores and surface area in a cluster within the left superior temporal sulcus surface area, extending to supra-marginal, middle, and inferior temporal regions ($p = 0.014$, $r = 0.473$). However, in the T1-weighted MRI analysis, no significant correlations were observed in HCs or in subcortical structures. Similarly, the DTI analysis did not reveal any significant correlations in mental state reasoning for both the schizophrenia group and HCs.

Discussion: In conclusion, this multimodal brain imaging study revealed significant differences in theory of mind and neuroimaging measures between patients with schizophrenia and HCs. This research also presented findings supporting the role of cortical volume and surface areas in distinct brain regions concerning the mental state reasoning components of theory of mind in individuals with schizophrenia.

F187. ALTERATION OF GRAY MATTER MICROSTRUCTURES IN PATIENTS WITH TREATMENT RESISTANT SCHIZOPHRENIA AFTER COMMENCING CLOZAPINE TREATMENT

Wonik Jo^{*1}, HyeJin Sim¹, Min Jeong Kwon¹, Seoyeong Kim², Ki Woong Kim², Euitae Kim²

¹Seoul National University College of Brain and Cognitive Science, ²Seoul National University Hospital

Background: To elucidate neurobiological mechanisms behind clozapine and treatment-resistant schizophrenia (TRS), neuroimaging studies have found structural alterations in different regions of the brain. However, these conventional imaging techniques lack the capability to detect microstructural alterations. This study aimed to investigate microstructural alteration in the brains of TRS patients after commencing clozapine treatment via texture analysis using a three-dimensional gray-level co-occurrence matrix (GLCM).

Methods: 30 patients with TRS and 18 with treatment response (NTRS) were recruited. T-1 weighted magnetic resonance imaging (MRI) was obtained twice within eighteen weeks of the interval. Texture features were calculated using GLCM from sixteen regions of interest (ROIs). A paired sample T-test and Wilcoxon signed-rank test were performed to figure out texture features that have changed significantly after adjusting the significance with the Bonferroni method. Features were eliminated via correlation analysis to reduce the dimension and intercorrelation between features from each ROIs. Differences in texture features between groups from each time point and the alteration of texture features were tested using the T-test and Mann-Whitney U-test. The association of these significant features and the symptom scores were evaluated with partial correlation while controlling the effect of antipsychotic equivalent dose, duration of illness, and age.

Results: Patients with TRS showed significant alterations in the texture features from the posterior corpus callosum, frontal cortex, and thalamus (p -Bonferroni LESS THAN 0.05). Patients with NTRS showed no significant alterations among features from ROIs. When comparing the significant texture features of TRS and NTRS patients from each time point, only uniformity from the frontal cortex after treatment ($t = -2.18$, $p = 0.036$) but none showed a difference between groups. However, there was a significant difference in the correlation

changes in the posterior corpus callosum (p LESS THAN 0.05). While there was a significant volume decrease in the thalamus and frontal cortex of TRS patients, there was no alteration in the volume of the corpus callosum besides the mid-posterior region. The alteration of correlation (T6), which has increased significantly after treatment with clozapine, had a positive correlation with the improvement of visual learning amongst TRS patients ($r = 0.59$, p -Bonferroni LESS THAN 0.05).

Discussion: Our finding suggests that there exists a microstructural alteration in the corpus callosum which has an association with improvement of cognitive function among patients with TRS. It is important to note that there was no significant change in the corpus callosum volume, while the texture feature has altered significantly after treatment. This may suggest that there could be a different mechanism of clozapine that induces subtle changes in the brain region and drives a positive outcome for patients.

F188. FACIAL AFFECT PROCESSING IN PERSONS WITH VARIED LEVELS OF SCHIZOTYPY: AN ERP STUDY

Jaime Morales*¹, Brooke Bonta¹, Mason Richards¹, Brian F. O'Donnell¹, William P. Hetrick¹

¹*Indiana University*

Background: Persons with schizophrenia present with facial affect recognition deficits early in the development and throughout the course of the disorder. Efforts have been made to pinpoint when, how, and where facial affect recognition deficits go awry before the onset of the disorder to help alleviate the impact of deficits as psychosis develops. Assessment of persons with elevated levels of schizotypy has been used to probe if facial affect recognition is a trait-like vulnerability for schizophrenia. Indeed, behavioral facial affect recognition is an area of deficit in persons with elevated schizotypy. Persons with higher schizotypy present with similar, yet attenuated levels of deficit as persons with schizophrenia. It is not well known whether there are underlying neuronal correlates of facial processing that can help determine if, when, and how facial affect recognition is impacted in schizotypy. We used event-related potentials (ERPs) to determine if facial affect recognition deficits arise from early visual processing and/or the encoding of facial features.

Methods: The present study examined the P1 early visual processing and N170 facial recognition ERPs during an emotion recognition task in young adults without a history of serious mental illness ($N=50$) within the Bloomington, Indiana community. Schizotypy was assessed utilizing the Schizotypal Personality Questionnaire Brief-Revised (SPQ-BR). During the EEG recordings, participants viewed pictures of faces expressing happy, angry, and neutral emotions. Participants were asked to assess which emotion was being presented. Amplitudes for both the P1 and N170 were examined from electrodes O1/O2 and P7/P8, respectively. Analyses focused on ERPs elicited to each emotion individually and then with all emotions combined.

Results: Correlation analyses revealed that participants with higher SPQ total scores associated with reduced N170 amplitudes to angry faces. No correlations between SPQ-total scores and other ERP amplitudes were found.

Discussion: This study shows that although persons with schizotypy typically have reduced behavioral emotion recognition, their neuronal responses (as measured by the P1 and N170) do not show similar abnormalities of both visual processing and facial recognition as observed in persons with schizophrenia for neutral and happy emotions. Yet, those with higher schizotypy tend to allocate fewer resources to facial recognition as indicated by reduced N170 amplitudes when viewing and assessing angry facial expressions; an avenue of exploration that

should be further examined to better understand if negatively valenced emotions are of importance when emotion recognition is impacted in schizotypy.

F189. BRAIN STRUCTURE AND FUNCTION IN ADULT SURVIVORS OF DEVELOPMENTAL TRAUMA WITH PSYCHOSIS: A SYSTEMATIC REVIEW

Alexander Noar*¹, Michael Bloomfield², Mustapha Modaffar¹, Camilla Walker³, Ting-Yun Chang¹

¹University College London, ²University College London and MRC Clinical Sciences Centre,

³Camden and Islington Foundation Trust

Background: Developmental trauma increases psychosis risk in adulthood, and is associated with poor prognosis and treatment response. It has been proposed that developmental trauma may give rise to a distinct alterations in brain structure and function. Our aim was to test this hypothesis by systematically reviewing neuroimaging studies of brain structure and function in adults with psychosis diagnoses, according to whether or not they had survived developmental trauma. We registered our search protocol in PROSPERO (CRD42018105021).

Methods: We systematically searched literature databases for relevant studies published before June 2023. We identified thirty-one imaging studies (n = 1,761 psychosis patients, n = 1,775 healthy controls or healthy siblings).

Results: Developmental trauma was associated with global and regional differences in grey matter; corticolimbic structural dysconnectivity; a potentiated threat detection system; dysfunction in regions associated with mentalization; and elevated striatal dopamine synthesis capacity.

Discussion: Trauma-induced changes in brain structure and function may induce vulnerability to psychosis. This would be consistent with findings from other studies that developmental trauma exposure is associated with changes in structure and function in circuits that are implicated in psychosis. Accumulated trauma-induced changes may have an additive effect on brain volume reductions that are known to occur in schizophrenia. Whilst the majority of studies were cross-sectional, there was high-quality prospective evidence of putative trauma-related effects alongside dose-effects of trauma severity on changes in brain structure which would support causation. These findings warrant further research to elucidate vulnerability and resilience mechanisms for psychosis in developmental trauma survivors.

F190. ALTERED TOPOLOGY OF THE FUNCTIONAL CONNECTOME IN PSYCHOSIS RISK AND MODULATION BY OXYTOCIN

Cathy Davies*¹, Daniel Martins¹, Ottavia Dipasquale¹, Rob McCutcheon², Andrea De Micheli³, Valentina Ramella-Cravaro³, Umberto Provenzano³, Grazia Rutigliano³, Marco Cappucciati³, Dominic Oliver², Steven CR Williams¹, Paul Allen¹, David Taylor⁴, Sukhi Shergill¹, Paul Morrison¹, Philip McGuire², Yannis Paloyelis¹, Paolo Fusar-Poli³

¹Institute of Psychiatry, Psychology and Neuroscience, King's College London, ²University of Oxford, ³EPIC Lab, , Institute of Psychiatry Psychology and Neuroscience (IoPPN), King's College London, ⁴Maudsley Hospital and Institute of Pharmaceutical Science, King's College London

Background: Functional brain network abnormalities are increasingly implicated in psychotic disorders. Aberrant connectome organisation is also present prior to the onset of psychosis in patients at Clinical High Risk (CHR) and is associated with disease onset and symptomatology. Previous research suggests that the neuropeptide oxytocin, a potential novel treatment, modulates network dynamics in healthy individuals but its effects in CHR patients remain unknown.

Methods: In two parallel randomised, double-blind, 40IU intranasal oxytocin vs placebo challenge studies with a crossover design, 47 males (30 CHR and 17 healthy controls) each participated in two resting-state fMRI scans: once following oxytocin and once following placebo. Using a graph theoretical approach, topological differences in the functional connectome were examined for group effects (CHR vs healthy control), treatment effects (oxytocin vs placebo) and group x treatment interactions.

Results: Group effects were observed predominantly in frontoparietal network regions and treatment effects in ventral attention network regions (all pFDR LESS THAN .05). Moreover, we found that many effects of oxytocin on network topology differ across CHR and healthy individuals, with significant interactions observed in numerous regions strongly implicated in psychosis onset, such as the thalamus, pallidum, entorhinal cortex and nucleus accumbens, and cortical regions localising primarily to the default mode network (all pFDR LESS THAN .05).

Discussion: Our findings provide novel evidence of functional brain network disorganisation associated with psychosis risk and demonstrate that oxytocin modulates network topology in regions implicated in the pathophysiology of psychosis in a clinical status/psychosis risk-specific manner. Given the current lack of effective pharmacotherapies for CHR patients, a deeper understanding of how connectomic alterations contribute to psychosis risk, and the potential ameliorative effects of experimental treatments such as oxytocin, remain important avenues for future research.

F191. TOPOLOGICAL ABNORMALITIES OF THE MORPHOMETRIC SIMILARITY NETWORK OF THE CEREBRAL CORTEX IN SCHIZOPHRENIA

Sung Woo Joo^{*1}, Young Tak Jo², Sun Min Kim¹, Daegeun Kim¹, Jinah Kim¹, So Young Yoo³, Soohyun Joe⁴, Jungsun Lee¹

¹Asan Medical Center, ²Kangdong Sacred Heart Hospital, ³SMG-SNU Boramae Medical Center, ⁴University of California San Diego

Background: The morphometric similarity (MS) network is constructed using multiple MRI parameters of each cortical region and similarity between cortical regions. Although the MS network can detect microstructural alterations of cortical regions and capture the connections between histologically similar cortical areas, it is uncertain how topological characteristics of the MS network are affected by schizophrenia.

Methods: We obtained T1- and diffusion-weighted images of 239 healthy controls and 190 patients with schizophrenia to construct the MS network. Group comparisons of the mean MS of the cortical regions and subnetworks were performed. The strengths of the connections between the cortical regions and the global and nodal network indices were compared between the groups. Clinical associations with the network indices were tested using Spearman's rho.

Results: Compared with healthy controls, patients with schizophrenia had significant group differences in the mean MS of several cortical regions and subnetworks. Patients with schizophrenia had both superior and inferior strength of connections between the cortical regions compared with healthy controls. We observed regional abnormalities of the MS

network in patients with schizophrenia in terms of lower centrality values of the pars opercularis, superior frontal, and superior temporal areas. Certain nodal network measures of the right pars opercularis and left superior temporal areas were associated with illness duration in patients with schizophrenia.

Discussion: We identified regional abnormalities of the MS network in schizophrenia and observed that the left superior temporal area may be a key region in the topological organization and connections between cortical regions.

F192. A LIVING SYNTHESIS AND TRIANGULATION OF THE EVIDENCE FROM CLINICAL TRIALS AND PRECLINICAL ANIMAL EXPERIMENTS INVESTIGATING TRACE AMINE-ASSOCIATED RECEPTOR 1 (TAAR1) AGONISTS FOR PSYCHOSIS

Spyridon Sifakis^{*1}, Robert R. McCutcheon², Virginia Chiochia³, Edoardo G. Ostinelli⁴, Charlotte Austin⁴, Claire Friedrich⁴, Jaycee Kennett⁴, Francesca Tinsdeall⁵, Fiona Ramage⁵, Nobuyuki Nomura¹, Grazia Rutigliano⁶, Luke Vano⁷, Simonne Wright⁸, Claire Stansfield⁹, Damian Omari Juma¹⁰, Ioannis Mantas¹¹, Oliver D. Howes¹², Lea Milligan¹³, Carmen Moreno¹⁴, Julian H. Elliott¹⁵, James Thomas⁹, Malcolm R. MacLeod⁵, Emily Sena⁵, Soraya Seedat¹⁶, Georgia Salanti¹⁷, Jennifer Potts⁴, Andrea Cipriani¹⁸, Stefan Leucht¹, for the GALENOS project¹⁹

¹Technical University of Munich, ²Institute of Psychiatry, Psychology and Neuroscience, King's College London, University of Oxford, ³Institute of Social and Preventive Medicine, University of Bern, ⁴University of Oxford, ⁵Centre for Clinical Brain Sciences, The University of Edinburgh, ⁶King's College London, Institute of Psychiatry Psychology and Neuroscience (IoPPN), ⁷King's College London, Institute of Psychiatry, ⁸Stellenbosch University, Stellenbosch, ⁹EPPI Centre, Social Research Institute, University College London, ¹⁰My Mind Our Humanity, ¹¹Karolinska Institutet, ¹²King's College London, Institute of Psychiatry; Medical Research Council Clinical Sciences Centre, Hammersmith Hospital, Imperial College London, ¹³MQ Mental Health Research, ¹⁴Hospital General Universitario Gregorio Marañón, School of Medicine, Universidad Complutense, IiSGM. CIBERSAM. ¹⁵Cochrane Australia, School of Public Health and Preventive Medicine, Monash University, ¹⁶Stellenbosch University, ¹⁷Institute of Social and Preventive Medicine (ISPM), University of Bern, ¹⁸University of Oxford, ¹⁹<https://galenos.org.uk>

Background: Trace amine-associated receptor 1 (TAAR1) agonism offers a potentially emerging novel approach for treating psychosis, proposed to be efficacious and associated with a more favorable side-effect profile compared to current antipsychotics acting as dopamine D2 receptor antagonists. However, recent clinical trials have shown inconsistent findings regarding the efficacy of the TAAR1 agonists under clinical development (i.e., ulotaront and ralmitaront). Nonetheless, the volume of data is increasing, and additional compounds are undergoing preclinical development. Therefore, our aim was to facilitate bridging preclinical and clinical research through a living systematic review by synthesizing and triangulating evidence from human and non-human data.

Methods: The living systematic and meta-analysis is co-produced by multiple stakeholders within the GALENOS project (Cipriani et al., 2023), and its protocol was published (Sifakis et al., 2023) and registered with PROSPERO (ID: CRD42023451628). For the first iteration of the review, we searched in multiple electronic databases (last search in November 2023) for

randomized controlled trials (RCTs) and preclinical in vivo studies comparing TAAR1 agonists with antipsychotics, placebo or other control conditions in individuals with psychosis or animal models for psychosis, respectively. At least two independent reviewers screened the records found in the search, extracted data, and evaluated the risk of bias using appropriate tools. Our primary outcomes were overall symptoms measured by validated rating scales in RCTs and relevant behavioral proxies in animal studies, such as model-induced hyperlocomotion. We synthesized data from clinical and animal studies separately using random-effects meta-analyses and examined potential sources of heterogeneity. We evaluated the confidence in the evidence using the GRADE approach and organized a triangulation interdisciplinary meeting with independent experts to draw an overall conclusion from the evidence from human and non-human data.

Results: We found that TAAR1 agonists may have on average little to no effect compared to placebo on overall symptoms in adults with acute schizophrenia (k=4 studies, 3 examining ulotaront and 1 examining ralmitaront; n=1296 participants; SMD=0.14, 95%CI: -0.17, 0.46); however, the evidence is very uncertain. Conversely, TAAR1 agonists appeared to reduce model-induced hyperlocomotion in animal models of psychosis with a large effect size based on data from over 100 experiments but with notable heterogeneity (potential sources of heterogeneity under examination). The analyses and the triangulation meeting are ongoing, and the final results of the initial review iteration will be presented at the congress.

Discussion: We identified a discrepancy between the findings of preclinical animal experiments and RCTs examining TAAR1 agonists for psychosis. This living systematic review aims to understand this discrepancy and facilitate the bridging of the translational gap, potentially providing insights for the future development of novel antipsychotics.

Grant Information: We are funded by Wellcome, a global charitable foundation. The funders had no role in study design, data collection and analysis, decision to publish, or preparation of the manuscript.

F193. ARIPIPRAZOLE 2-MONTH READY-TO-USE: A NOVEL LONG-ACTING INJECTABLE ANTIPSYCHOTIC FORMULATION FOR ADMINISTRATION ONCE EVERY 2 MONTHS

Matthew Harlin¹, Daiki Kaneko¹, Murat Yildirim ^{*2}, Pedro Such², Jessica Madera-McDonough¹, Frank Larsen²

¹*Otsuka Pharmaceutical Development and Commercialization, Inc.*, ²*H. Lundbeck A/S*

Background: Schizophrenia and bipolar I disorder (BP-I) are chronic mental health conditions that require maintenance pharmacological treatment to ensure symptom control. Despite this, suboptimal adherence with daily oral antipsychotic treatment is common. Long-acting injectable (LAI) antipsychotics have been developed to increase adherence versus oral medication; currently available LAIs offer dosing intervals that range from 2 weeks to 6 months. Data have shown a beneficial effect of LAIs versus oral antipsychotics in terms of reducing the risk of hospitalization and relapse. Aripiprazole exhibits partial agonist activity at dopamine D2 receptors and serotonin 5-HT1A receptors, full agonist activity at dopamine D3 receptors, and antagonist activity at serotonin 5-HT2A receptors. Until recently, aripiprazole has been available in a daily oral formulation and as an extended-release, once-monthly formulation for intramuscular (IM) injection (aripiprazole once-monthly 400 mg [AOM 400]).

Methods: Aripiprazole 2-month ready-to-use (Ari 2MRTU) has been developed as a novel LAI formulation of aripiprazole monohydrate for gluteal IM administration once every 2 months, for the treatment of schizophrenia or BP-I. Ari 2MRTU offers extended exposure to aripiprazole concentrations within the therapeutic window to 2 months.

Results: Ari 2MRTU has been shown to be generally well tolerated; investigators' assessments of the injection site reflected minimal reactions in adults with schizophrenia or BP-I. Ari 2MRTU is a prolonged-release suspension for injection in a single-use pre-filled syringe; it is provided in its final container, with no dilution or reconstitution required prior to administration. Each Ari 2MRTU pre-filled syringe contains 960 mg of aripiprazole monohydrate (total volume 3.2 mL) for administration once every 2 months, providing a dose of aripiprazole that is comparable with a monthly dose of AOM 400. In case of any tolerability issues, a 720-mg dose of Ari 2MRTU (total volume 2.4 mL) for administration once every 2 months is available, providing a dose of aripiprazole that is comparable with a monthly dose of AOM 300 mg. The suspension is a white to off-white color, with a neutral pH (approximately 7.0); Ari 2MRTU should be stored at controlled room temperature. Ari 2MRTU should be injected slowly as a single IM injection in the gluteal muscle. For patients who have never taken aripiprazole, tolerability to aripiprazole must be established prior to initiating treatment with Ari 2MRTU. Overlapping treatment with oral aripiprazole is required for patients initiating Ari 2MRTU, unless they have been stabilized on AOM. The recommended maintenance dose of Ari 2MRTU is 960 mg. A maintenance dose of 720 mg should be considered in the event of adverse reactions with the 960 mg dose and is recommended in patients who are poor metabolizers of CYP2D6 or who are taking strong inhibitors of CYP2D6 or CYP3A4. Following an initial dose, Ari 2MRTU should be administered once every 2 months (56 days after the previous injection).

Discussion: Ari 2MRTU is a novel LAI formulation of aripiprazole monohydrate for gluteal IM administration that comes in a ready-to-use syringe and does not require reconstitution. Increasing the dosing interval to 2 months has the potential to reduce the treatment burden for patients and clinicians.

F194. PREDICTIVE VALIDITY OF BEHAVIORAL ASSAYS RELEVANT TO SCHIZOPHRENIA IN ZEBRAFISH

Leonardo Bastos¹, Sofia Z. Becker¹, Matheus Gallas-Lopes¹, Carlos G. Reis¹, Thailana Stahlhofer-Buss¹, Elaine Elisabetsky¹, Angelo Piatto¹, Ana P. Herrmann¹, Ana Herrmann*¹

¹*Universidade Federal do Rio Grande do Sul*

Background: While the precise mechanisms that underlie schizophrenia remain elusive, there is mounting evidence that it is associated with abnormalities in glutamate receptor signaling and hyperactivity in mesolimbic dopaminergic pathways. MK-801 is a noncompetitive NMDA receptor antagonist used as a pharmacological strategy to mimic behavioral phenotypes related to schizophrenia symptoms in laboratory animals. In rodents, the administration of MK-801 leads to hyperlocomotion (relevant to positive symptoms), and social withdrawal (relevant to negative symptoms). However, there are few studies evaluating the effect of antipsychotics on behavioral changes induced by MK-801 in zebrafish. The aim of this study was to evaluate whether the antipsychotics olanzapine (atypical) and sulpiride (typical) counteract the effects induced by acute exposure to MK-801 on the social preference and open tank tests in adult zebrafish. Results are expected to inform on the predictive validity of these behavioral assays.

Methods: We used 240 male and female adult zebrafish (3-4 months old, 300-500 mg). The animals were randomly allocated to the experimental groups (n=15), and individually exposed

for 20 minutes to control solution or three different concentrations of olanzapine (experiment 1: 7.5, 15, and 30 mg/L) or sulpiride (experiment 2: 42.5, 85, 170 mg/L), followed by 5 μ M MK-801 or control solution for another 20 minutes. After exposure, the animals were subjected to the social preference test (5 minutes, after 2-minute habituation) to analyze time spent in the interaction zone, distance traveled, immobility time, and crossings, which was immediately followed by the open tank test (5 minutes) to analyze distance traveled, absolute turn angle, clockwise rotations, and immobility time. The videos were analyzed by blinded researchers using the ANY-Maze® software. Data were analyzed by two-way ANOVA/Bonferroni.

Results: In the social preference test, the only parameters consistently altered by MK-801 in experiments 1 and 2 was the number of crossings. MK-801 also reduced the time in the interaction zone (experiment 1) and increased the distance traveled (experiment 1) and the immobility time (experiment 2). In the open tank test, MK-801 decreased distance traveled, absolute turn angle, and clockwise rotations, while increased immobility time; these results were observed in both experiments. Olanzapine nonspecifically reduced the time in the interaction zone at the highest concentration, increased the distance traveled at the lowest concentration, and potentiated MK-801 effect on the number of crossings at the lowest and intermediate concentrations. In the open tank test, all olanzapine concentrations prevented the increase in immobility time induced by MK-801 and nonspecifically increased the distance traveled and the number of clockwise rotations (opposite effects to MK-801). Sulpiride had no significant effects on any of the parameters analyzed.

Discussion: MK-801 effects in the open tank test were more robust than in the social preference test, which may be more sensitive to unknown environmental variations and/or interindividual variability. Although olanzapine demonstrated opposite effects to those of MK-801 in the open tank test, the contrary was observed in the social preference test. More studies are needed to establish the predictive validity of these behavioral assays in zebrafish. The prospects of this work are to test other antipsychotics, expand the range of concentrations, change the order and duration of treatments, and evaluate the outcomes of interest in behavioral phenotypes more robustly altered by MK-801 (e.g., shoal cohesion test).

Jaguar Health Inc. provided financial support for this work.

F195. PSYCHIATRIST CONCERNS REGARDING POTENCIAL SIDE EFFECTS OF CLOZAPINE: AN ARGENTINEAN STUDY

Alejo Corrales*¹, Pedron Damian Gargoloff², Manuel Vilapriño³, Federico Rebok⁴

¹Argentine National University UNT, ²Hospital Alejandro Korn, Psychiatric department, La Plata, Argentina., ³Universidad Nacional de Cuyo, Departamento de Neurociencias de la Facultad de Ciencias Médicas, Mendoza, Argentina., ⁴Hospital "Dr. Braulio A. Moyano", Servicio de Emergencia, Buenos Aires, Argentina.

Background: Clozapine, the first atypical antipsychotic developed, is uniquely effective in its ability to improve clinical outcomes in patients with treatment-resistant schizophrenia (TRS). The clinical indications of clozapine are not limited to the two FDA indications (TRS and suicidality in patients with psychosis), patients who are sensitive to extrapyramidal symptoms are an important third group of patients who may benefit from clozapine. Accurate clozapine information is crucial for the clinician because adverse effects impose balancing its risk/benefits. Even though clozapine-induced agranulocytosis is the most well-known side effect, the use of clozapine is associated with several side effects such as myocarditis,

gastrointestinal hypomotility, seizures, substantial weight gain, and sedation so, for these reasons, clozapine is not considered as a first-line antipsychotic. However, there have been only a few studies shedding light on the clinician concerns regarding the potential side effects of clozapine, in Argentina. The aims of this study are: 1- To explore clinician concerns on clozapine-induced side effects, before starting clozapine treatment 2- to identify variables associated with these concerns.

Methods: This was an Argentinean study using an online survey that was carried out between May to August 2021. The online questionnaire was administrated through the google drive platform, and more than 3000 Argentinean psychiatrists were invited to participate in this study. The questionnaire included items concerning professional practice characteristics (such as years practicing as a psychiatrist, the modal work setting -inpatient/outpatient/partial hospitalisation, context in which the psychiatrists provide their service -public/private-, number of patients they are currently prescribing clozapine), and 8 common side effects related to clozapine (such as neutropenia, hypersalivation, gastrointestinal hypomotility, myocarditis, pulmonary embolism, seizures, metabolic syndrome). The concerns about side effects were evaluated on a five-point Liker scale (1= not at all concerned, 2 = sightly concerned, 3 = somewhat concerned, 4 = moderately concerned, 5 = extremely concerned). Statistical analysis was performed using the Chi-Square test.

Results: A total of 304 clinicians answered the survey. According to the data stemming from the drug company, our sample represents 35% of clozapine prescribers in Argentina. Conforming to the Liker scale rating, the level of concern was rated as follow; Neutropenia as moderately concerned (26%, n = 79), hypersalivation as moderately concerned (28%, n=85), gastrointestinal hypomotility/ileus as somewhat concerned (33%, n=99), myocarditis as moderately concerned (30%, n=85), pulmonary embolism as somewhat concerned (31%, n=95), seizures as moderately concerned (30%, n=91), metabolic syndrome as moderately concerned (34%, n=104). Statistical associations between the variables were not found (Chi Square=1.2, df=1, p GREATER THAN .05).

Discussion: This study shows that psychiatry concerns about clozapine-induced side effects are an important issue within the clinical setting, regardless of frequency and type of clozapine-induced side effects. The clinicians are aware of potential side effects before prescribing clozapine. Despite gastrointestinal hypomotility is a potentially dangerous side effect, the level of concern is similar among the side effects including agranulocytosis. The concerns on clozapine side effects could influence the decision-making in treatment-resistant schizophrenia.

F196. BEYOND DOPAMINE D2 RECEPTOR ANTAGONISM FOR THE TREATMENT OF POSITIVE SYMPTOMATOLOGY OF SCHIZOPHRENIA – MYTH OR REALITY?

Idil Mitsadali*¹, Haneul Choi², Ines Jimenez-Pulido³, Patricia Radu⁴, Jennifer Fletcher¹, Ben Grayson¹, John Gigg¹, Michael Harte¹

¹University of Manchester, ²University of Bath, ³University of Edinburgh, ⁴University of Nottingham

Background: Sub-chronic administration of phencyclidine (scPCP) has been shown to be a well-validated rodent model for schizophrenia, which induces relevant cognitive deficits and negative symptoms. Positive symptoms are usually studied by acute amphetamine injection followed by measuring locomotor activity (LMA) in otherwise healthy rodents. Utilisation of the scPCP model for positive symptomatology is uncommon thus striatal neurotransmission is

not well-studied in this model. This study investigated the relevance of scPCP rat model for the positive symptoms of schizophrenia, looking at 1) sensitisation to repeated amphetamine, 2) the effects of haloperidol, clozapine on amphetamine induced LMA and 3) the effect of xanomeline on acute amphetamine- or PCP-induced hyperlocomotion in scPCP and scVehicle (scVeh) treated rats.

Methods: 200 adult female Lister-Hooded rats either received scVeh (saline solution) or scPCP (2 mg/kg, bidaily i.p. injections for 7 days), followed by a 7-day washout. In experiment one, rats (n=20, 10 per group) received an acute amphetamine injection (0.75 mg/kg, i.p.) once a week for 3 weeks, and LMA was measured for 90 mins. In experiment two, rats (n=60, 30 per group) received haloperidol (0.05 mg/kg, s.c.), clozapine (5mg/kg, s.c.) or saline 30 mins prior to acute amphetamine (0.75 mg/kg, i.p.) or saline, and LMA was measured for 90 mins. In experiment 3, rats (n=120, 60 per group) received either saline or xanomeline (1, 3 or 10 mg/kg) prior to acute amphetamine (0.75 mg/kg, i.p.), PCP (2 mg/kg, i.p.) or saline, and LMA was measured for 90 mins. A haloperidol dose response (0.025, 0.05 and 0.075 mg/kg, s.c.) was also conducted in 60 scPCP rats using the same LMA test regimen as described above. Area under the curve was calculated from the ambulatory counts recorded in 5-min bins. Data was analysed using a two- or one-way ANOVA followed by Tukey's or Šídák's test.

Results: Both scVeh- and scPCP-treated rats showed sensitisation to amphetamine, measured as an augmented hyperlocomotion from week 1 to 2 (p LESS THAN 0.001; p LESS THAN 0.05 respectively). Only scPCP-treated rats showed further sensitisation from week 2 to week 3 (p LESS THAN 0.05). Both haloperidol (0.05 mg/kg) and clozapine (5 mg/kg) prevented amphetamine-induced hyperlocomotion in the scVeh group. Haloperidol at 0.025 and 0.05 mg/kg did not prevent amphetamine-induced hyperlocomotion in the scPCP group. Haloperidol at 0.075mg/kg and clozapine (5 mg/kg) prevented amphetamine-induced hyperlocomotion in the scPCP group. Xanomeline at 10 mg/kg prevented the amphetamine-induced hyperlocomotion in scVeh rats, but it did not prevent neither the amphetamine- nor acute PCP-induced hyperlocomotion in scPCP rats.

Discussion: These findings indicate the presence of a pathophysiology in the scPCP model that renders the model very relevant to the positive symptomatology in schizophrenia. The differential response following haloperidol and xanomeline highlight the importance of assessing symptomatology in relevant preclinical models and may hold importance for clinical translation. Future studies are underway to investigate striatal neurotransmission in the scPCP rat model and its relationship to clinical studies.

F197. THE INFLUENCE OF SEX AND MENOPAUSE ON ANTIPSYCHOTIC SERUM CONCENTRATIONS

Franciska de Beer*¹, Bodyl Brand¹, Iris Sommer¹, Marieke Begemann¹, Clementine Stuijt¹, Daan Touw¹

¹*University Medical Center Groningen*

Background: Most antipsychotics used today are prescribed using a one-size-fits-all approach, based on male-dominated clinical trials. At the same time, women are more likely to report antipsychotic side effects, and side effects in women are predicted by sex differences in drug pharmacokinetics. On average, sex differences in pharmacokinetics, with estrogen playing a significant role, cause the drug to stay longer in the female body. This is hypothesized to lead to higher serum concentrations in women when a one-size-fits-all approach is used. After menopause, estrogen levels remain low, which is hypothesized to affect antipsychotic serum

concentrations. We sought to explore sex differences in serum concentrations of 8 commonly used antipsychotics and examined how these sex differences change after the age of 45.

Methods: Antipsychotic concentrations of 14227 plasma samples were analyzed, which were drawn between January 2017 and December 2022 in the Netherlands in 5477 unique adult men and women, with a median of 2 samples per person (IQR=3). The dataset consisted of concentrations of olanzapine (n=1910, 41% female), clozapine (n=6410, 32% female), aripiprazole (n=1967, 41% female), and quetiapine (n=764, 62% female). To investigate the effect of sex on antipsychotic serum concentrations, we employed linear mixed-effects models (LMEMs) using R v4.0.3, accounting for age (fixed effect), time, measured as the number of months since the first measurement as fixed effect and a random intercept for participants. Next, we examined the effect of reaching the age of 45 (i.e., mean age of menopause in women), by dividing the samples according to sex and age (LESS THAN 45 vs. ≥ 45 years), using LMEMs with a random effect for patient and a fixed effect for time. When applicable, FDR-corrected post hoc comparisons were employed to compare men LESS THAN 45 with the other groups and to compare women LESS THAN 45 with women ≥ 45 .

Results: Preliminary analyses indicated a significant effect of sex on serum concentrations for 4 antipsychotics, with women having on average higher levels of serum concentrations of olanzapine, clozapine, and aripiprazole. Sex/age-group analyses revealed significant effects for clozapine, aripiprazole, and quetiapine. Pairwise post hoc comparisons revealed that that serum concentrations of clozapine were highest in women LESS THAN 45 compared to men, and compared to women ≥ 45 . Serum concentrations of aripiprazole were highest in women ≥ 45 , as compared to men LESS THAN 45. Conversely, serum concentrations of quetiapine were lower in women LESS THAN 45, women ≥ 45 , and men ≥ 45 .

Discussion: In sum, we found pronounced sex differences in serum concentrations, which differ per antipsychotic and may evolve with advancing age. Our findings suggest that the one-size-fits-all approach for prescribing antipsychotics may not serve both sexes equally, and stresses the need for further research into the sex and hormone-dependent pharmacokinetic mechanisms of antipsychotics.

F198. LIVING SYSTEMATIC REVIEW AND META-ANALYSIS OF PHARMACOKINETIC DRUG-GENE INTERACTIONS IN SCHIZOPHRENIA PHARMACOTHERAPY: THE IMPORTANCE OF CYP450 GENETIC POLYMORPHISM

Filip Milosavljevic*¹, Stefan Leucht¹

¹*Klinikum Rechts der Isar, Technical University of Munich*

Background: While there is a great need for effective schizophrenia treatment options, pharmacotherapy in schizophrenia is often very challenging. Reasons include treatment resistance, frequent need for treatment adjustments and the risk of serious adverse reactions; while the development of new, superior drugs remains slow. In such a landscape, approaches such as pharmacogenomics hold a great potential to maximise the effectiveness of currently available psychiatric drugs by predicting and mitigating harmful pharmacokinetic drug-gene interactions. Our recent meta-analysis contributed to this research by precisely quantifying several such drug-gene interactions: +51% and +47% increase in aripiprazole plasma levels in CYP2D6 intermediate and poor metabolizers, respectively; and +40% and +31% increase in risperidone plasma levels in CYP2D6 intermediate and poor metabolizers, respectively; all compared to CYP2D6 normal metabolizers. Nevertheless, it is a major challenge to implement pharmacogenomics into everyday clinical practice, as clinical guidelines are unclear and often

have to rely on limited evidence and individual clinical trials with low statistical power. Here, we propose the protocol for the living systematic review and meta-analysis aimed to build on our previous work and overcome these shortcomings of pharmacogenomic clinical data in schizophrenia.

Methods: Living meta-analysis is an innovative, emerging type of scientific reporting that is continuously updated, which is especially important for the rapidly evolving research topics such as pharmacogenomics. Living meta-analysis can potentially accelerate the implementation of pharmacogenomics for antipsychotic drugs by summarizing, and subsequently increasing the statistical power of available evidence; and by rapidly implementing new data as it emerges. This project will start by transforming the data on Aripiprazole-CYP2D6, Risperidone-CYP2D6, Clozapine-CYP2C19, Haloperidol-CYP2D6 and Quetiapine-CYP2D6 drug-gene interactions into a format suitable for the continuous update and live online display. Next, the data on drug-gene interactions not encompassed in our previous work due to pragmatic reasons, will be systematically searched, extracted and analysed. This will include interactions of: Aripiprazole with CYP3A4/5; Asenapine with CYP1A2 and UGT1A4; Clozapine with CYP2D6, CYP1A2 and CYP3A4/5; Iloperidone with CYP3A4/5 and CYP2D6; Olanzapine with UGT1A4 and CYP1A2; Quetiapine with CYP3A4/5; Risperidone with CYP3A4/5; Zotepine with CYP3A4/5 and CYP1A2; Haloperidol with CYP3A4/5, UGT2B7 and CYP1A2; Chlorpromazine with CYP1A2, CYP3A4 or CYP2D6; and Zuclopenthixol with CYP3A4/5 and CYP2D6. For each drug-gene pair of interest, drug plasma concentration data and genomic data will be extracted regardless of the study design. Based on the CYP450 or UGT genotypes, patients will be classified into metabolizer groups (phenotypes) according to the current consensus guidelines (Clinical Pharmacogenetic Implementation Consortium - CPIC), or pragmatically analysed separately for every mutation of interest where such consensus is not achieved. Then, dose-corrected plasma concentration for the given drug will be compared between the reference phenotype and variant phenotypes with ratio-of-means meta-analysis method. If new genotype-phenotype classification consensus is to emerge during the life of this living systematic review, data will be reclassified accordingly. After the baseline for all of the mentioned data is established; automatic systematic search re-runs will be established and the team for the selection and extraction of those data will be designated, ensuring at least one monthly update. At the same time, openly available website will be assigned for the reporting of current magnitude of pharmacokinetic drug-gene interactions, as well as the strength of this evidence.

Results: As this abstract describes the proposed protocol for the living systematic review and meta-analysis, no results are available at the time.

Discussion: This living systematic review and meta-analysis will aim to encompass all clinically relevant antipsychotic drugs that are metabolized by at least one liver enzyme that is coded by the polymorphic gene. This way, the comprehensive database of pharmacokinetic drug-gene interactions relevant for the schizophrenia therapy will be created. Even though the importance of CYP450 and UGT polymorphism is often speculated to influence the efficacy, tolerability and the drug switching in antipsychotics, interventional clinical trials attempting to mitigate these effects have to rely on in-vitro data or on assumptions that are not evidence-based. This living meta-analysis will provide evidence-based and precisely estimated data on the extent of these pharmacokinetic drug-gene interactions that may inform future interventional pharmacogenomic clinical trials. Also, for the antipsychotic drugs where therapeutic drug monitoring is indicated, results of this living meta-analysis will be immediately useful to the clinicians by informing the expected drug plasma level changes based on a patient's genotype without the need to wait for the steady-state drug plasma concentrations to be achieved.

F199. EVIDENCE ON ANTIPSYCHOTIC DRUG TREATMENT FOR SCHIZOPHRENIA FROM WESTERN AND CHINESE TRIALS – IDENTIFYING TRIALS USING APPROPRIATE METHODS AND CONDUCTING JOINT NETWORK-META-ANALYSES

Johannes Schneider-Thoma*¹, Yikang Zhu², Mengchang Qin¹, Yu Dong², Shiwei Guan², Spyridon Sifakis¹, Chunbo Li², Stefan Leucht¹

¹*School of Medicine, Technical University of Munich*, ²*Shanghai Mental Health Center, Shanghai Jiao Tong University School of Medicine*

Background: About one third of all conducted trials in schizophrenia in the past years comes from China. The majority of them are published in local Chinese journals only indexed in Chinese literature databases. Unfortunately, there are concerns about the methodological quality of these trials particularly in terms of methods of randomisation and allocation concealment. We aim to identify studies on antipsychotic drugs, request details about study methods from authors and include appropriately-conducted studies in joint meta-analyses together with studies identified in international databases (called “Western trials” because the majority comes from the USA and Europe).

Methods: This systematic review is funded by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation – Project number 468853597) and the National Natural Science Foundation of China (NSFC – Project number 8211101161) and conducted in collaboration of the department of psychiatry of the Technical University of Munich, German and the Shanghai Mental Health Center, China. We search multiple international and Chinese electronic literature databases for randomized-controlled trials (RCTs) comparing antipsychotics (all second-generation antipsychotics; selected first generation antipsychotics) with each other or placebo for efficacy in schizophrenia. We contact authors of trials by telephone, email and letters to request additional information about the study methods used to allocate participants to treatment groups, to conceal allocation before participants’ inclusion and to blind treatment during the trial. Therefore, to facilitate answering and evaluation, we also created an online survey.

Of trials with appropriate methods we will extract multiple outcomes and conduct network meta-analyses to synthesize the evidence on comparative efficacy and tolerability between different antipsychotics.

Results: Concerning Chinese-trials, we screened more than 10 000 references in Chinese databases and found ca. 4500 studies described as using “randomisation” for group allocation. Ca. 200 of them mentioned that treatment was blinded, ca. 100 stated that treatment was open-label, the remaining more than 4000 studies did not mention blinding. In general, details about trial methods were often only briefly reported. Currently, the contacting of study authors to request additional information about study methods is ongoing.

Concerning Western-trials, we updated our database of studies based on previous systematic reviews. It comprises ca. 730 studies, of which the majority (ca. 630) are described as double-blind. Currently, we prepare for contacting the study authors. Results of the contacting, including the number of authors contacted and reached, reasons for unavailability as well as the received information about study methods and their evaluation will be presented on the poster at the congress.

Discussion: On the poster, we will discuss our experiences with contacting study authors and the challenges and limitations involved. Moreover, we will discuss the results of how many studies were identified as using appropriate or suboptimal/inappropriate methods and how this

information can guide other systematic reviewers who are faced with the question of whether to include studies from China.

F200. DYSGLYCEMIA ASSOCIATED WITH ANTIPSYCHOTIC USE: A SYSTEMATIC REVIEW AND META-ANALYSIS

Emily Smith^{*1}, Kristoffer Panganiban¹, Kateryna Maksyutynska¹, Jiwon Lee², Femim Prasad², Sandra Pereira¹, Jonathan Monteiro³, Vedansh Kaushik², Kaitlin Fuller⁴, Michael McCarthy⁵, Jacob Ballon⁶, Tyler Prestwood⁶, Christoph Correll⁷, Sri Mahavir Agarwal⁸, Zachary Freyberg⁹, Margaret Hahn⁸

¹Centre for Addiction and Mental Health, University of Toronto, ²University of Toronto, ³McMaster University, ⁴St. Francis Xavier University, ⁵University of California San Diego, ⁶Stanford University, ⁷Zucker School of Medicine, ⁸Centre for Addiction and Mental Health, Banting and Best Diabetes Centre, University of Toronto, ⁹University of Pittsburgh

Background: Antipsychotics (APs) are the cornerstone of treatment for schizophrenia spectrum disorders (SSDs) and are approved for the treatment of affective disorders including bipolar disorder (BD). However, AP use is associated with severe metabolic consequences including weight gain, dyslipidemia, and dysglycemia. Although studies indicate that glucose dysfunction can occur independently of weight gain, AP-induced glycemic changes are usually considered to be a consequence of AP-induced weight gain. Therefore, the aims of this review are to: 1) specifically clarify the effect of APs on glucose homeostasis independently of weight gain and 2) determine whether APs similarly impact glycemic control independently of drug class and treatment duration.

Methods: We searched MEDLINE, EMBASE, PsychINFO, CENTRAL, CINAHL, and Web of Science from inception to August 2023 to identify all randomized controlled trials (RCTs) that compared the effect of APs on glucose metabolism to placebo (PBO), with no restriction on psychiatric diagnosis. Random effects meta-analyses examined glucose dysfunction as both continuous and dichotomous outcomes, with subgroup analyses conducted for study length, AP type, and age (child/adolescent vs. adult). Where possible, meta-regression analyses were conducted to explore the effects of weight gain, study length, and AP dose on change in glucose.

Results: Of 20954 references identified in our search, 70 RCTs in patients with SSDs (N=40 studies) and BD (N=30 studies) met our inclusion criteria. In both populations, AP use was associated with a significantly greater increase in blood glucose compared to placebo (mean difference (MD) SSD = 0.05 mmol/L [0.01, 0.09], p=0.01, I²=0%, n=8535 AP vs. n=3389 PBO; MD BD = 0.10 mmol/L [0.05, 0.15], p LESS THAN 0.0001, I²=46%, n=6018 AP vs. n=4137 PBO). Sub-group analyses revealed that neither study length nor AP type altered this finding. Nevertheless, in patients with BD, age significantly impacted AP-induced alterations in blood glucose, with adults showing a greater increase (p=0.03, I²=79%). Plasma insulin was also significantly increased by AP exposure (MD SSD = 13.97 pmol/L [6.42, 21.51], p=0.0003, I²=0%, n=3678 AP vs. n=1169 PBO; MD BD = 12.85 pmol/L [1.14, 24.56], p=0.03, I²=55%, n=2111 AP vs. n=1676 PBO), with a significant subgroup difference according to AP type in both groups (SCZ: p=0.02, I²=62.1%; BD p=0.0001, I²=85.6%). There was an additional effect of study length on plasma insulin in individuals with SSDs (p=0.03, I²=79.8%). Importantly, the strength of the effect of different APs on blood glucose did not appear to follow the established hierarchy of weight gain liabilities outlined in the literature. Specifically,

so-called ‘weight neutral APs’ such as ziprasidone and lurasidone produced comparable dysglycemia to APs traditionally associated with significant weight gain like olanzapine (SSD: $p=0.45$, $I^2=0\%$; BD: $p=0.46$, $I^2=0\%$). Subsequent meta-regression analyses found that AP-associated hyperglycemia may be independent of study length and AP dose in patients with SCZ (p GREATER THAN 0.05) and independent of study length and baseline-to-endpoint weight gain in patients with BD (p GREATER THAN 0.05). AP use did not appear to have a significant effect on HOMA-IR or treatment-emergent hyperglycemia (dichotomous outcome) in either patient group.

Discussion: Our review demonstrates that both short- and long-term exposure to APs are associated with a significant increase in dysglycemia risk as indicated by AP-induced elevations in glucose and insulin. Furthermore, all APs cause some degree of glucose dysregulation regardless of exposure time and established propensities for AP-induced weight gain. Further studies are required to better understand how AP use contributes to dysglycemia, including temporal changes throughout the treatment course, and how these effects could potentially be mitigated using metabolic interventions.

F201. COMPARATIVE EFFECTIVENESS OF LONG-ACTING INJECTABLE PALIPERIDONE WITH OTHER LONG-ACTING INJECTABLE AND ORAL ANTIPSYCHOTIC DRUGS IN SCHIZOPHRENIA

Dae Geun Kim^{*1}, Sun Min Kim¹, Jinah Kim¹, Sung Woo Joo¹, Jungsun Lee¹

¹*University of Ulsan College of Medicine, Asan Medical Center*

Background: Even after several years since the introduction of long-acting injectable (LAI) antipsychotics, there is scarce evidence on the comparative effectiveness of LAI antipsychotics on clinical outcomes in schizophrenia. A low utilization rate of LAI antipsychotics in clinical practice limits the investigation of this issue through the traditional randomized clinical trial design. A nationwide health insurance database in South Korea has a notable strength of including information on the utilization of medical services by the entire population in South Korea. Here, we used the nationwide population database to investigate the comparative effectiveness of two LAI antipsychotics (paliperidone and aripiprazole), which are mostly used in South Korea, on the risk of treatment discontinuation and psychiatric admission.

Methods: We used the Health Insurance Review Agency database between July 2009 and July 2021 in South Korea. The prevalent cohort of schizophrenia patients was obtained based on operational conditions following our previous studies, which resulted in a total of 288,547 patients with schizophrenia. Treatment discontinuation was defined as a lapse of 28 days from the expected date of the next antipsychotic prescription. We compared the risk of treatment discontinuation and psychiatric admission among LAI paliperidone, LAI aripiprazole, and oral antipsychotics using a within-individual Cox regression model.

Results: For the risk of psychiatric admission, the LAI aripiprazole and oral antipsychotics had lower (0.90, 0.85-0.95) and higher (1.34, 1.31-1.38) risks compared with the LAI paliperidone, respectively. With a reference of the LAI paliperidone, oral antipsychotics were associated with a higher risk of treatment discontinuation (1.68, 1.61-1.74). The LAI aripiprazole had no significant difference in the risk of treatment discontinuation compared with the LAI paliperidone (0.99, 0.92-1.08).

Discussion: Our results show that the LAI paliperidone was inferior in lowering the risk of psychiatric admission than the LAI aripiprazole. However, no significant differences were observed in the risk of treatment discontinuation between the LAI paliperidone and LAI aripiprazole.

F202. CLOZAPINE-INDUCED RETROGRADE EJACULATION TREATED WITH IMIPRAMINE: A CASE REPORT AND LITERATURE REVIEW

Alexandra Cerulli-Kanellopoulos*¹, Alexandra Arruda¹

¹*Hôpital Sacré-Coeur de Montréal*

Background: Sexual adverse effects are commonly reported with antipsychotics, especially those with strong dopaminergic antagonism, and this can impair quality of life and lead to medication non-compliance. Retrograde ejaculation is a rare sexual side effect found with the use of typical and atypical antipsychotics, including clozapine. Management of this condition is largely based on observational data. Imipramine, a tricyclic antidepressant, has been suggested as a potential treatment strategy for antipsychotic-induced retrograde ejaculation. This could prove particularly useful for patients on clozapine, where reducing the dose or switching antipsychotics is not always feasible as it is considered the only effective medication for treatment-resistant schizophrenia. This study aims to present a case of improved retrograde ejaculation induced by clozapine with the use of imipramine.

Methods: We present a case of a 27-year-old Guinean man with resistant schizophrenia, hospitalized on a psychiatric unit, who developed retrograde ejaculation after recently being initiated on clozapine. A review of the literature was conducted in the MEDLINE, EMBASE and Pubmed databases to identify studies of retrograde ejaculation secondary to antipsychotic use and its management. After achieving a dose of clozapine 425 mg daily, the patient expressed concerns of producing little to no semen after ejaculation. Specific laboratory tests were ordered to rule out any physiological causes. A post-ejaculation urinary analysis was performed to objectively identify the presence of spermatozoa in the urine.

Results: Seventeen studies were retained for the literature review. Conference abstracts and research titles without any abstracts or full articles were excluded. Many of the included studies were case reports, with relatively few reports on clozapine. Treatment strategies used to reverse the retrograde ejaculation mostly included either reducing the antipsychotic dose or changing the antipsychotic agent. Imipramine was the only pharmacological agent used in four different studies of retrograde ejaculation secondary to thioridazine, iloperidone, risperidone and quetiapine. Physiological tests, including glycated hemoglobin, prolactin, luteinizing and follicle-stimulating hormones, total testosterone and thyroid-stimulating hormone returned normal. A post-ejaculation midstream urinary analysis identified very low levels of spermatozoa. As such, it was concluded that the retrograde ejaculation was secondary to clozapine use. As the dose of clozapine could not be reduced or the agent changed for another antipsychotic agent due to the severity of the patients' symptoms, imipramine was initiated and gradually increased to a dose of 75 mg daily. At follow-up eight months later, the patient reported a notable decrease in retrograde ejaculation.

Discussion: To our knowledge, this is the first case report of improved clozapine-induced retrograde ejaculation with imipramine. This is also the first study to assess the long-term efficacy of imipramine to treat this sexual side effect. It highlights the importance of identifying and addressing sexual dysfunction secondary to antipsychotic use, particularly with a drug like clozapine, the only effective medication for treatment-resistant schizophrenia. The onset of sexual dysfunction following the initiation of clozapine, and the exclusion of alternative causes, suggests a probable link to clozapine-induced retrograde ejaculation, as indicated by a Naranjo score of 7. While sexual side effects induced by certain antipsychotics, such as risperidone, typically result from dopaminergic antagonism in the tuberoinfundibular pathway, retrograde ejaculation seems to occur through antagonism at the $\alpha 1$ -adrenoreceptors in the bladder neck.

Other treatments have demonstrated effectiveness in alleviating retrograde ejaculation, but their use has not been documented in cases of antipsychotic-induced retrograde ejaculation. However, while limited data exists on its use, imipramine may show promise as a treatment strategy through its actions as an $\alpha 1$ -adrenergic receptor agonist. As clozapine is associated with fewer sexual adverse effects owing to minimal dopaminergic blockade, it is essential to address potential sexual side effects with clozapine to improve quality of life and to ensure medication adherence.

F203. THE EFFECTS OF CLOZAPINE ON BEHAVIOURAL AND PSYCHOLOGICAL SYMPTOMS OF DEMENTIA: A RETROSPECTIVE CHART REVIEW

Kateryna Maksyutynska*¹, Abdul Ahad², Zaineb Hamza³, Ashnie Sukhu¹, Sanjeev Kumar¹, Sri Mahavir Agarwal¹

¹*Centre for Addiction and Mental Health, University of Toronto*, ²*Centre for Addiction and Mental Health, University of Waterloo*, ³*Centre for Addiction and Mental Health, McMaster University*

Background: Behavioural and psychological symptoms of dementia (BPSD) are prevalent in individuals with neurocognitive disorders. Antipsychotic medications are frequently prescribed for severe BPSD, but have only modest benefit with significant treatment resistance. Limited research has been conducted on the effectiveness of clozapine (CLZ) in this population. Therefore, this study aims to explore the effectiveness of CLZ treatment for BPSD.

Methods: A retrospective chart review was conducted for inpatients diagnosed with neurocognitive disorder and initiated on CLZ. PRN medication administration was collected daily from 2 weeks prior to 12 weeks post CLZ initiation. Clinical assessments were drawn from the quarterly Resident Assessment Instrument-Mental Health (RAI-MH) conducted a minimum of 4 weeks pre and 4 weeks post CLZ initiation (on average, at the 9-week pre- and post-CLZ time points). Weight and complete blood count were recorded from baseline, every 4 weeks (+/- 2 weeks), to 12 weeks post CLZ initiation. Wilcoxon test was used to compare paired outcomes across time points.

Results: Nine patients (mean age 66.2 years, 66.7% males) were included; 7 had a comorbid diagnosis of a mood (n=1) or schizophrenia spectrum disorder (n=6). The highest stable mean CLZ dose attained was 206.9 mg. There was a significant decrease in the number of psychotropic PRN medications administered for BPSD at the 2-4 (M:5 [IQR:10.5]; p=0.035), 4-6 (M:0 [IQR:9]; p=0.017), and 8-10 (M:0 [IQR:12.5]; p=0.027) week time points post CLZ initiation, as compared to pre CLZ initiation (M:11 [IQR:10]). The total number of PRNs (psychotropic and non-psychotropic) also showed a similar pattern across time. Furthermore, patients were required to be observed by staff for fewer days (M:3 [IQR:6.5]; p=0.042) post CLZ initiation (M:2 [IQR:3]) as compared to before CLZ. No significant changes in other clinical assessments were noted post CLZ initiation. There were no significant changes in the use of PRNs administered for constipation, neutrophil count, or weight, up to 12 weeks post CLZ initiation.

Discussion: A significant decrease in PRN use and requirement for observations by staff was observed among inpatients with BPSD after CLZ initiation, without any significant increase in rates of adverse events. These findings highlight the need for further research to explore the effectiveness of CLZ in this population.

F204. DIFFERENTIAL EFFECTS OF D2/D3 ANTAGONISM AND D2/D3 PARTIAL AGONISM ON NEGATIVE SYMPTOMS AND REWARD PROCESSING IN HEALTHY HUMANS: A PLACEBO-CONTROLLED, DOUBLE-BLIND CROSSOVER STUDY

Martin Osugo^{*1}, Pierluigi Selvaggi¹, Uzma Zahid¹, Matthew Wall², Valeria Finelli¹, George Chapman³, Thomas Whitehurst³, Ellis Chika Onwordi³, Ben Statton⁴, Rob McCutcheon⁵, Tiago Reis Marques⁶, Mitul Mehta⁷, Robin Murray¹, Oliver Howes⁸

¹King's College London, Institute of Psychiatry, ²Imanova Ltd, Hammersmith Hospital, ³Psychiatric Imaging Group, MRC London Institute of Medical Sciences, Hammersmith Hospital, London, UK, ⁴Imperial College London, ⁵University of Oxford, ⁶Imperial College School of Medicine, ⁷Center for Neuroimaging Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, ⁸King's College London, Institute of Psychiatry; Medical Research Council Clinical Sciences Centre, Hammersmith Hospital, Imperial College London

Background: Negative symptoms are core features of schizophrenia. There are no licenced treatments as the underlying neurobiology is unclear, however dopaminergic dysfunction is implicated. A putative mechanism for antipsychotic (AP) induced negative symptoms is that antagonism of dopamine receptors leads to the blunted striatal reward response seen in AP treated schizophrenia patients. These reward deficits correlate with negative symptom severity, however drawing clear inferences on causation is challenging as the effects of the disease and AP use are difficult to disentangle. To address this, several studies in healthy volunteers have demonstrated reductions in striatal reward response following AP administration. However, all studies so far have used single doses and none have assessed the relationship between AP induced reward dysfunction and AP induced negative symptoms. We aimed to demonstrate a causal relationship between dopaminergic antagonism, reward dysfunction and negative symptoms by administering amisulpride (AMI; selective D2/D3 antagonist) and aripiprazole (ARI; D2/D3 partial agonist) to healthy humans.

Methods: A randomised, double-blind, placebo-controlled crossover study design was used. Two independent samples of healthy volunteers received AMI and placebo, or ARI and placebo, for seven days each. A washout period of at least 5 half-lives (drug and active metabolites) was used in between. AMI doses were: Day 1:200mg, Day 2:300mg, Days 3-7: 400mg. ARI doses were Days 1-2:5mg, Days 3-7:10mg. fMRI and negative symptoms were assessed at baseline and following administration of AP and placebo. Negative symptoms were assessed using validated scales (CAINS, BNSS, PANSS negative) and analysed using a mixed model, with pairwise comparisons corrected for multiple comparisons. Neural reward was assessed using the monetary incentive delay task. fMRI data were analysed in FSL, utilising standard pre-processing procedures, a whole brain paired t-test (cluster-based correction for multiple comparisons, Z GREATER THAN 2.3, p LESS THAN 0.05) comparing the AP and placebo conditions, and prespecified ROI analysis.

Results: 86 healthy volunteers were enrolled in total (39 AMI, 37 ARI). 50 completed the study (25 AMI, 25 ARI). Mean age was 26.6 ± 8.2 , 59% were female. There were no significant demographic differences between the AMI and ARI groups. For AMI (all three scales), the overall mixed effects models were significant (BNSS: $n=29$, $p=0.0004^*$) and corrected pairwise comparisons revealed significantly greater negative symptoms following

AMI administration compared to both placebo (BNSS: $n=29$, $p=0.028^*$), and baseline assessment (BNSS: $n=29$, $p=0.0003^*$). There were no significant differences between baseline assessment and placebo (BNSS: $n=29$, $p=0.32$). On AMI, we also found reduced BOLD activation during reward outcome in the prefrontal cortex, anterior cingulate, paracingulate, caudate and insula compared to placebo in both whole brain and ROI analyses, with medium-large effect sizes (-0.47 to -0.81). The reduction in caudate activation on AMI during reward outcome was correlated with AMI induced negative symptoms ($n=21$, $\rho = -0.492$, $p=0.024^*$). Compared to placebo, ARI had no effect on negative symptoms or reward processing.

Discussion: Subchronic D2/D3 antagonism induces negative symptoms in healthy volunteers, and this is correlated with drug induced reductions of reward response in the caudate. These findings provide causal evidence linking striatal dopaminergic dysfunction to negative symptoms. However, subchronic D2/D3 partial agonism has no effect on reward function or negative symptoms. Our findings confirm dopamine's central role in reward processing and have implications for the treatment of negative symptoms in schizophrenia.

F205. EFFECTS OF THE EARLY TREATMENT WITH THE POSITIVE ALLOSTERIC MODULATOR OF THE MGLU2 RECEPTOR JNJ-46356479 ON THE BCL-2 LEVELS IN A POSTNATAL KETAMINE MOUSE MODEL

David Olivares Berjaga^{*1}, Albert Martínez-Pinteño¹, Natalia Rodríguez¹, Santiago Madero², Alex González-Segura¹, Lluçia Prohens¹, Irene Martínez-Serrano², Sergi Mas¹, Constanza Morén¹, Eduard Parellada², Patricia Gassó¹

¹University of Barcelona, ²Hospital Clínic Barcelona

Background: Schizophrenia (SZ) glutamatergic dysfunction hypothesis proposes the presence of excessive Glutamate (Glu) levels, known as the Glu storm, leading to excitotoxicity during the disorder development. Evidence demonstrates excitotoxic events during the early stages of the disease could lead to excessive synaptic pruning due to increased apoptosis of the dendritic spines in critical brain areas (Parellada et al., 2021). Accordingly, dysregulation of the apoptotic protein levels has been observed in SZ patients and in SZ-like animal models. Consequently, it has been proposed that targeting the Glu-induced excitotoxicity and high apoptotic levels it would be possible to ameliorate patient's deterioration. New therapies targeting the glutamatergic system has been proposed. Positive allosteric modulators (PAM) of the metabotropic GLU receptor 2 (mGluR2), such as JNJ-46356479 (JNJ), inhibit the presynaptic release of GLU. In animal models, JNJ has previously shown the capacity of ameliorating the cognitive and negative deficits present in a postnatal ketamine (KET) mice model (Martínez-Pinteño et al., 2020) and partially attenuate the dysregulation of the apoptotic protein levels induced by KET (Olivares-Berjaga et al., under review). Additionally, early JNJ treatment during adolescence also improved cognitive and negative symptoms in the same model (Martínez-Pinteño et al., 2023). At cellular level, JNJ attenuated apoptosis, particularly the Caspase-3 activation, induced by dopamine and GLU in human neuroblastoma cell cultures (Gassó et al., 2023). We aimed to evaluate the effects of the early treatment with JNJ on the antiapoptotic protein Bcl-2 levels in prefrontal cortex (PFC) and hippocampus (HPC) tissues, studied in a SZ-like mice model postnatally exposed to KET. Also, we aimed to assess if treatment with the current antipsychotic drug clozapine (CLZ) promote the same effects.

Methods: SZ-like mice model was generated by the administration of KET (30mg/Kg) to the pups on postnatal days (PND) 7, 9 and 11. From PND 35 to 60, animals were treated with JNJ (10mg/Kg), CLZ (10 mg/Kg) or vehicle (VEH). Six experimental groups were generated

(VEH, VEH+JNJ, VEH+CLZ, KET+VEH, KET+JNJ, KET+CLZ). At adulthood (PND 120), mice were euthanized and perfused with PBS 1X followed by 4% paraformaldehyde. 30- μ m coronal sections of PFC and HPC tissues were obtained and prepared for immunofluorescent labelling with antibodies for Bcl2. Confocal images were automatically analysed using ImageJ software to quantify the fluorescence intensity of the protein. Significant differences between the groups were studied through Two-Way ANOVA, setting as factors the experimental group and the animal sex.

Results: Bcl-2 protein levels showed significant differences between the study groups in HPC. Protein expression was measured in CA1, CA2, CA3 and DG separately. Significant differences between the treatment groups were observed on CA1, CA3 and DG. After Bonferroni post hoc comparisons the three areas of the HPC demonstrated reduced Bcl-2 levels in the KET+VEH and KET+CLZ groups compared to the VEH+JNJ group. No significant reduction in Bcl-2 levels were seen in those animals exposed to KET treated with JNJ. No significant differences were observed in PFC or CA2.

Discussion: These evidenced early pharmacological treatment with JNJ could be able to attenuate brain apoptosis in the adult animal, as previously described in cell cultures (Gassó et al., 2023) and after treating the animals during the animal adulthood (Olivares-Berjaga et al., under review). Consequently, modulation of the glutamatergic system could be a useful target to alleviate the exacerbated apoptotic brain state observed in SZ patient or during the early stages of the disorder.

F206. SEXUAL SIDE EFFECTS OF ANTIPSYCHOTIC DRUGS: A SYSTEMATIC REVIEW WITH SINGLE-ARM, PAIRWISE AND NETWORK META-ANALYSIS OF RANDOMIZED CONTROLLED TRIALS AND NON-RANDOMIZED STUDIES

Shimeng Dong^{*1}, Johannes Schneider-Thoma¹, Spyridon Sifakis¹, Orestis Efthimiou², Stefan Leucht¹

¹*Technical University of Munich*, ²*Institute of Social and Preventive Medicine, University of Bern*

Background: Schizophrenia is a frequent, severe, and mostly chronic mental disorder, which typically starts in early adulthood. Antipsychotic drugs are the mainstay of acute treatment of schizophrenic psychosis and of recurrence prophylaxis. However, antipsychotics can disrupt normal sexual functioning by causing disorders of sexual desire, erection and ejaculation, vaginal lubrication, orgasm, as well as disorders of the breasts (growth, milk production) and the menstrual cycle. Such sexual side effects are very important for afflicted individuals, as they strongly reduce their quality of life. Subsequently, these side effects are a frequent cause for stopping antipsychotic treatment, which may lead to increased risk of persistent symptoms and relapses, with dire consequences for patients, relatives, and society in general. As the various licensed antipsychotics differ in their pharmacological mechanisms (receptor binding profiles), it is likely that they cause different sexual side effects, and to varying degrees. However, and despite the high clinical relevance, there has been no systematic comparison of the different antipsychotics in terms of sexual side effects. This systematic review aims to address this gap and provide evidence-based information, to facilitate the individual choice of medication.

Methods: To identify eligible studies, we will search the register of the Cochrane Schizophrenia group for randomized controlled trials (RCTs) and multiple electronic databases for non-randomised studies (NRSs) on antipsychotic drugs in schizophrenia. Both searches have no date/time, language, document type, and publication status restrictions. Patients with

schizophrenia or related disorders will be included. We will include all second-generation; first-generation antipsychotics as well as placebo will also be included when they were used as comparators. We will extract all adverse events related to sexual functioning. The primary outcome will be “any sexual side effect”: the number of patients with at least one event, as reported by the original authors. Secondary outcomes will be any sexual adverse event in men and women separately, and any adverse events related to the three phases of sexual response cycle i) “desire” (related terms are, e.g., libido, sexual thoughts), ii) “arousal” (e.g. erection, lubrication) and iii) “orgasm (e.g. ejaculation, anorgasmia)”, as well as any adverse related to iv) breast dysfunction (e.g. gynecomastia, galactorrhea) and v) menstruation irregularities (e.g. amenorrhea, dysmenorrhea). We are conducting separate single-arm and pairwise meta-analyses of RCTs and NRSs, and proceed to network meta-analysis of RCTs. Subsequently, we proceed with combined network meta-analysis of RCTs and NRSs if requirements in heterogeneity, transitivity, and consistency within and across designs are met.

Results: We will present the aims of the project and our methods in detail on the poster together with preliminary results of the systematic search.

Discussion: Potential strength and limitations of the review will be present and discussed on the poster.

F207. CASE REPORT: CLOZAPINE INDUCED AGRANULOCYTOSIS IN A PATIENT WITH TREATMENT-RESISTANT SCHIZOPHRENIA PREVIOUSLY STABLE ON CLOZAPINE

Sangeetha Elango¹, Nicholas Abraham*¹, Arvind Rajagopalan¹, Enquan Cheow¹

¹*Institute of Mental Health*

Background: Clozapine is an effective antipsychotic medication commonly used for treatment-resistant schizophrenia. Those who respond to Clozapine experience a significant increase in quality of life [1]. Approximately 1% of patients on Clozapine experience the potentially life-threatening side effect of Clozapine-induced agranulocytosis (CIA) [1], which is characterized by an absolute neutrophil count (ANC) less than 100 neutrophils per microlitre of blood. Peak incidence and mortality are noted to occur within the first 3 months of treatment [2]. Notably, CIA is an idiosyncratic adverse drug reaction, that occurs independent of dosing and at any time during treatment, with the majority of dyscrasias occurring within the first 18 weeks of treatment [2].

Methods: This is a case report of a 46-year-old Chinese male, a non-smoker with treatment resistant Schizophrenia, stable on Clozapine 150 mg every morning and 250 mg every night, for more than 20 years. He had previously experienced neutropenia (ANC 1.3x10⁹/L) whilst on Clozapine in August 2013 and Clozapine was stopped. The decision was made to rechallenge with Clozapine in February 2014 due to lack of treatment response. He again developed neutropenia over 9 days in March-April 2016 (lowest ANC 1.15 x10⁹/L), however Clozapine was not stopped during this time. He was on frequent full blood count (FBC) monitoring and his ANC eventually normalized.

Results: In October 2023 he had an unrelated medical issue that required transfer of care to another institution, following which Clozapine was stopped for 3 days. His ANC prior to stopping Clozapine was 4.01x10⁹/L. Upon readmission, Clozapine was restarted at 12.5mg twice daily and slowly titrated, as per our local guidelines. He underwent weekly FBC monitoring during titration, which was stable. Clozapine was titrated up to 75mg every morning

and 150mg every night by the 18th day post re-initiation. On the 19th day, he developed neutropenia (ANC $1.28 \times 10^9/L$) and agranulocytosis (ANC $0.47 \times 10^9/L$) on the 20th day. He was referred for specialist review, and the cause of the agranulocytosis was determined to be Clozapine, with no other medical causes established. Clozapine was stopped and he was switched onto Olanzapine. His ANC levels subsequently improved, and normalized 2 days later.

Discussion: When Clozapine treatment is started in an inpatient setting, it is recommended to start at 12.5mg once or twice daily on day one, followed by daily incrementations by 25–50mg [3]. A large study found that the risk of CIA in Asian individuals is 2.4-fold higher than in Caucasians [4]. It is reported that Caucasians, who are average Clozapine metabolisers, may need doses ranging from 300-600 mg per day to hit therapeutic concentrations (350 ng/ml). However, in Asian populations, average therapeutic Clozapine doses are below 300mg/day [5]. Additionally, approximately 10% of Asians are genetically poor metabolisers requiring even lower doses of 50-150mg per day for therapeutic effect. Some known risk factors of CIA include advanced age and CYP1A2 inhibiting medications such as Fluvoxamine and Sodium Valproate [6]. A possible factor to consider is that our patient was also on Sodium Valproate long-term, which could have contributed to the initial neutropenia. This is an unusual case of agranulocytosis noted on stopping and restarting Clozapine after 3 days, in a patient previously stable on Clozapine for more than 10 years. This case demonstrates the importance of close monitoring and slow titration of Clozapine when re-introducing it even in patients who had previously tolerated it well, reinforcing what is advised in most guidelines. It also underscores the fact that CIA is an idiosyncratic reaction [7], which is still poorly understood.

F208. SHORT-TERM WEIGHT AND METABOLIC OUTCOMES AFTER SWITCHING TO ARIPIPRAZOLE LAI IN SCHIZOPHRENIA

Seoyoung Kim^{*1}, Euitae Kim², Sung-Wan Kim³, Beomwoo Nam⁴, Kyoung-Uk Lee⁵, Bong Ju Lee⁶, Seung-Hee Won⁷, Chang Hwa Lee⁸, JUN SOO KWON⁹, the MAESTRO study group¹⁰

¹Seoul National University Bundang Hospital, ²Seoul National University College of Medicine, ³Chonnam National University Medical School, Gwangju Bukgu Community Mental Health Center, ⁴School of Medicine, Konkuk University, ⁵Uijeongbu St. Mary's Hospital, The Catholic University of Korea, College of Medicine, ⁶Lee Bong Ju Psychiatric Clinic, ⁷Kyungpook National University School of Medicine, ⁸Eulji University School of Medicine, Eulji University Hospital, Seoul National University College of Medicine, ¹⁰the MAESTRO study group

Background: Weight gain and metabolic disturbance is a major concern regarding antipsychotic treatment, associated with excess mortality in patients with schizophrenia compared to general population. It is well-known that the risk for weight gain differs among various antipsychotic drugs and aripiprazole has been demonstrated to have lower risk for weight gain and metabolic disturbance. While the mechanism underlying weight gain and metabolic disturbance is largely unknown, it has been suggested that both central satiety system and peripheral metabolic process is affected from antipsychotic drugs. Aripiprazole has a receptor profile as a dopamine partial agonist, and this unique feature might have a role in less weight gain and metabolic side effects. In this study, we aimed to monitor the change in weight and metabolic profile short-term after switching to LAI aripiprazole and to compare the outcomes based on previously prescribed antipsychotic drugs.

Methods: The study was based on an open-label, parallel-group study design. Patients diagnosed with schizophrenia who were clinically stable under oral antipsychotic drugs were enrolled. PANSS and CGI-S were used for clinical assessments. Weight and fasting blood metabolic profile were monitored before and after 4, 8, 12 and 16 weeks after switching to LAI aripiprazole. Patients who were previously treated with oral aripiprazole (Group I) and patients who were previously treated with oral antipsychotic drugs other than aripiprazole (Group II) were compared.

Results: At 16 weeks after switching to LAI aripiprazole, Group II resulted in weight loss and decreased waist circumference, while Group I showed almost no change. Significant decrease in serum LDL cholesterol level were observed in both Group II.

Discussion: Switching to LAI aripiprazole resulted in weight decrease and improved metabolic profile in patients treated with antipsychotics other than oral aripiprazole. This suggest that LAI aripiprazole can be an option for patients having weight gain side effects under antipsychotic drugs other than aripiprazole, but further research with longer follow-up is needed.

F209. OPTIMIZING PHARMACOLOGICAL TREATMENT FOR ADHD IN INDIVIDUALS WITH COMORBID PSYCHOTIC DISORDERS: CHALLENGES AND STRATEGIES

Olivier Corbeil^{*1}, Sébastien Brodeur², Laurent Béchar³, Maxime Huot-Lavoie², Charles Desmeules⁴, Elizabeth Anderson⁴, Josiane Courteau⁵, Marco Solmi⁶, Ridha Joobar⁷, Marc-André Roy², Marie-France Demers³

¹Laval University, ²Faculty of Medicine, Université Laval, ³Faculty of Pharmacy, Université Laval, ⁴School of Psychology, Université Laval, ⁵Sherbrooke University, PRIMUS Research Group, ⁶Department of Psychiatry, University of Ottawa, ⁷McGill University, Douglas Mental Health University Institute

Background: Attention-deficit hyperactivity disorder (ADHD) frequently coexists with schizophrenia spectrum and other psychotic disorders (SZSPD), contributing to poorer overall outcomes. The treatment of ADHD using psychostimulants, the first-line medications for managing ADHD, has been constrained due to concerns regarding an elevated risk of psychotic events. Existing evidence on this matter remains limited and inconclusive. Further data are crucial to gain a comprehensive understanding of this potential risk and to advance strategies promoting recovery in individuals facing these complex comorbidities.

Methods: A retrospective cohort study utilizing administrative health registries to assess the risk of hospitalization for psychosis subsequent to the initiation of psychostimulants among individuals diagnosed with SZSPD was conducted. Additionally, a narrative review of existing data will facilitate the proposal of optimized pharmacological approaches for managing ADHD within this specific population. The aim is to address prevailing challenges and provide potential strategies to enhance treatment efficacy in individuals facing these two comorbidities.

Results: Among 2219 individuals diagnosed with SZSPD and receiving combined treatment with antipsychotics, the initiation of psychostimulants did not show an increased risk of hospitalization for psychosis (adjusted HR = 0.36, 95% CI 0.24 - 0.54, p LESS THAN 0.0001). These outcomes corroborate an earlier observational study, albeit conducted with a smaller sample size. While general population data indicate a potential elevated risk of psychotic events with amphetamine use compared to methylphenidate, such evidence is yet to be established for

individuals with SZSPD. Concerns regarding psychotic events linked to psychostimulants primarily stem from experimental symptom provocation studies.

Discussion: Although recent observational studies suggest that using psychostimulants in individuals with SZSPD might be safer than traditionally perceived, several caveats remain regarding patient selection for this strategy, determining optimal psychostimulant doses, and defining the minimum duration of SZSPD remission for safe administration. Arguments can be presented to support favoring methylphenidate over amphetamines, restricting their use to individuals in remission adhering to adequate antipsychotic treatment, prioritizing long-acting formulations, and employing minimal effective doses. However, more robust evidence from randomized controlled trials is crucial to comprehensively evaluate the efficacy and safety of this approach. Meanwhile, judiciously selecting patients may allow for beneficial ADHD treatment alongside SZSPD, contributing to enhanced recovery.

F210. REPRODUCIBILITY OF BEHAVIORAL PHENOTYPES WITH RELEVANCE TO SCHIZOPHRENIA: A SINGLE-LABORATORY MULTI-BATCH STUDY ON THE EFFECTS OF MK-801 IN ZEBRAFISH

Matheus Gallas Lopes^{*1}, Elaine Elisabetsky¹, Angelo Piatto¹, Ana Paula Herrmann¹

¹*Universidade Federal do Rio Grande do Sul*

Background: Pharmacological blockade of NMDA receptors with antagonists such as MK-801 is the underpinning of popular animal models of schizophrenia that attempt to recapitulate the hypofunction of GABAergic interneurons. Most of these models also present face validity since they induce behavioral phenotypes relevant to the positive, negative, and cognitive symptoms of schizophrenia. Considering the recent failures in translating preclinical findings into new antipsychotic drugs, investigating the reliability of animal models is of great relevance to avoid research waste and further setbacks. The aim of this study was to employ a single-laboratory multi-batch design, followed by a random-effects meta-analysis, to evaluate the reproducibility of MK-801-induced behavioral phenotypes in the Social Preference (SPT) and Open Tank (OTT) tests in zebrafish.

Methods: We used 360 4-month-old wild-type zebrafish (*Danio rerio*), with an equal distribution of males and females (ethics committee 43858/2023). Following block randomization procedures, animals were allocated to one of two experimental groups: control or 5 μ M MK-801 ($n = 15$). Subjects were individually exposed to water or MK-801 for 20 min, and sequentially subjected to the SPT and OTT tests for 7 and 5 minutes, respectively. This experiment was repeated 12 times by the same research team at the same laboratory under consistent conditions, varying only the batch of animals. Social preference (as measured by the time spent near a stimulus shoal) and locomotor parameters were automatically scored using the software ANY-Maze. Data were analyzed by a random-effects meta-analysis to assess the combined effect of the intervention on each behavioral outcome across the experiments.

Results: In the SPT, significant effects of MK-801 in reducing social preference were observed in only 2 out of the 12 experiments. However, the meta-analysis yielded a significant overall effect of MK-801 in reducing social preference, with a pooled effect size of -0.45 [95%-CI -0.69; -0.21] and individual effect sizes ranging from 0.22 to -1.27 across experiments. This pattern was observed across most of the outcomes in the SPT. Conversely, in the OTT, a robust and significant effect of MK-801 was observed for its outcomes. For instance, reduction of the absolute turn angle was observed in all experiments, with a pooled effect size of -1.55 [95%-CI -1.97; -1.12] and individual effect sizes ranging from -3.01 to -0.86. This pattern was consistent for the other outcomes in the OTT.

Discussion: Two different behavioral assays were conducted to evaluate a range of phenotypes induced by the same intervention following the same protocol. Surprisingly, two distinct sets of results were obtained depending on the assay: while in the OTT we observed robust and significant effects across all experiments, in the SPT individual effect sizes were less consistent. Such intriguing divergence suggests that, apart from internal and external validity problems, reproducibility issues may also be correlated with factors intrinsically tied to the nature of the behavioral assays or the outcomes under examination. Further studies are needed to investigate which aspects of the behavioral assays may explain this phenomenon. Our findings also provide indirect evidence supporting within-study heterogenization as a method to improve the reproducibility of preclinical research, and underscore the importance of establishing sound foundational principles for experimental trials before continuing to replicate protocols that have consigned numerous drug candidates to the depths of the "valley of death" of translational science.

F211. MAKING MEANING OF MULTIMORBIDITY FOR PEOPLE WITH SCHIZOPHRENIA

Sean Halstead¹, Dan Siskind², Nicola Warren¹, Dan Siskind*³

¹*The University of Queensland*, ²*School of Medicine, The University of Queensland, MIRT, Woolloongabba Community Health Centre, Addiction and Mental Health Services and MIRT*, ³*Metro South Addiction and Mental Health Service*

Background: People living with schizophrenia and other severe mental illness (SMI), experience a multitude of poorer health outcomes compared to those without mental illness, such as shortened life expectancy of 10-20 years. This is thought to be largely driven by the accumulation of multiple chronic diseases. The notion of additional disease outside of the SMI of interest has primarily been studied through the lens of comorbidity, a framework which emphasises the presence of a 'secondary' condition in relation to an index condition: (e.g., diabetes mellitus is a recognised comorbidity of schizophrenia). Conversely, multimorbidity, defined as the coexistence of two or more chronic conditions, has been proposed as a more useful framework for characterising the chronic disease burden faced by those with SMI, with respect the number and types of other physical and psychiatric conditions that people with SMI experience. Our aim was to describe the utility of applying a multimorbidity framework to assess and measure the chronic health burden of those with schizophrenia and other SMI, and understand how the combination of poor physical and mental health interact as a risk factor for adverse health outcomes.

Methods: The research presented here is a synthesis of a narrative literature review we undertook to contextualise how multimorbidity has been studied to date amongst those with SMI. We will present our synthesis of the literature for the following questions:

- 1) How is multimorbidity defined, both in- and outside of psychiatric contexts?
- 2) How does multimorbidity manifest in people with SMI with respect to the number and types of chronic conditions they experience?
- 3) How does multimorbidity mediate poor health outcomes as a risk factor?

4) How can multimorbidity be measured and applied in a clinically meaningful framework for those with severe mental illness?

Results: Multimorbidity is a term that has emerged in the literature relatively recently, particularly within psychiatric research. Narrative review highlighted that those with and without SMI experience similar clusters of physical multimorbidity with respect to the types of co-occurring conditions, however, those with SMI appear to experience a greater burden of multimorbidity at comparatively younger ages. Multimorbidity has been demonstrated to be a mediator of a variety of adverse health outcomes, specifically premature mortality, increased disability, and increased health-economic resource utilisation. We have also sought to summarise the existing models of how multimorbidity is measured, with respect to disease counts and existing indices such as the Charlson Comorbidity Index.

Discussion: Upon synthesising the existing literature, we proposed the utility in framing multimorbidity as a cumulative risk exposure variable that takes into account both quantity and duration of chronic illnesses. With this approach, we hypothesise that (i) people with SMI experience a greater cumulative exposure to chronic illness as part of multimorbidity during their lifetime, and (ii) this greater exposure is a significant mediator of adverse health outcomes such as premature mortality. For those with SMI, it is speculated that this exposure to chronic disease is exacerbated by diagnostic overshadowing, marked by increased under-diagnosis and under-treatment of physical health conditions in those with SMI. Ultimately, multimorbidity appears to be an emerging epidemiological concept that is integral to understanding the chronic disease burden faced by those living with SMI. We envision that a multimorbidity model of care that comprises a multidisciplinary team of various health disciplines will enable more holistic and integrated treatment of physical and mental health. This will be critical in mitigating the health inequities faced by those with schizophrenia and other SMI.

This research has previously been published as a Viewpoint in the Australian and New Zealand Journal of Psychiatry.

Halstead, S., Siskind, D., and Warren, N. (2023). Making meaning of multimorbidity and severe mental illness: A viewpoint. Australian and New Zealand Journal of Psychiatry, (Published Online First). <https://doi.org/10.1177/00048674231195560>

F212. EVALUATING THE EPIDEMIOLOGY OF CLOZAPINE-ASSOCIATED NEUTROPENIA AMONG PEOPLE ON CLOZAPINE ACROSS AUSTRALIA AND AOTEAROA NEW ZEALAND: A RETROSPECTIVE COHORT STUDY

Korinne Northwood¹, Nicholas Myles², Scott Clark³, Susanna Every-Palmer⁴, Hannah Myles⁵, Steve Kisely¹, Nicola Warren¹, Dan Siskind^{*6}

¹*The University of Queensland*, ²*Royal Adelaide Hospital*, ³*The University of Adelaide*, ⁴*University of Otago, Wellington*, ⁵*Northern Adelaide Health Network*, ⁶*Metro South Addiction and Mental Health Service*

Background: Clozapine is associated with the risk of serious neutropenia. However, this may decrease over time, meaning that indefinite absolute neutrophil count (ANC) monitoring may be unnecessary. This study aims to determine the epidemiology and timing of clozapine-associated neutropenia outcomes, investigate variables that may contribute to the odds of neutropenia, and determine risk of competing neutropenic events during clozapine treatment.

Methods: We performed retrospective analysis of the Australian and New Zealand Viatrix Pharmacovigilance system, one of two monitoring databases for these two countries, between

06 June 1990 and 25 October 2022. Patients were excluded from further analysis if they commenced clozapine prior to 1990 (when data recording reliably commenced), did not have a haematology test within two weeks of commencement date, or had zero-week follow-up. All other patients were included. Rates of minor ($\text{ANC} \geq 1.0 \times 10^9/\text{L}$) and severe ($\text{ANC} \text{ LESS THAN } 1.0 \times 10^9/\text{L}$) neutropenia, were determined, with time to event used to calculate rolling weekly average, and to perform competing risk analysis of outcomes using Cox proportional and Fine-Gray sub-distribution hazard calculation.

Results: 26,630 patients, with 2.6 million absolute neutrophil count (ANC) values were included. The total cohort was predominantly male ($n = 17585$, 66%) and young (mean age 36.1 years, $\text{SD}=13.7$). Rates for minor neutropenia ($\text{ANC} \geq 1.0 \times 10^9/\text{L}$), serious neutropenia ($\text{ANC} \text{ LESS THAN } 1.0 \times 10^9/\text{L}$) leading to cessation and serious neutropenia, unrelated to clozapine without cessation were 4.3%, 1.2% and 0.84% respectively. In clozapine naïve patients ($n=15,973$), serious neutropenia leading to cessation peaked in the first 18-weeks with a rolling averaged weekly incidence of 0.05%, stabilising at 0.001% weekly by 2-years. Minor neutropenia and serious neutropenia unrelated to clozapine rates remained constant at 0.02% and 0.002% per-week, respectively. The median time to a serious neutropenic event leading to cessation was 17-weeks (IQR 9.96–102). Prior clozapine exposure reduced the risk of serious neutropenia leading to cessation (OR 0.19, 95% CI 0.12 – 0.31, $p \text{ LESS THAN } 0.0001$).

Discussion: The majority of serious neutropenia leading to clozapine cessation occurs within 18 weeks of treatment and becomes negligible after two years. Weekly haematological monitoring for the first 18 weeks, may be safely reduced to four-weekly and ceased after two years unless clinically indicated. Clozapine retreatment after interruption with 2 cumulative years of unremarkable testing may not require further haematological monitoring. A serious neutropenia ANC threshold of $\leq 1.0 \times 10^9/\text{L}$ could be used in more jurisdictions.

F213. NO IMMEDIATE STRUCTURAL CHANGES INCURRED BY TMS TREATMENT IN SCHIZOPHRENIA

Peter Van Dyken^{*1}, Nadia Zeramdini², Hani Abdelhafiz², Jessica Ahrens², Farida Zaher², Marcelo Berlim², David Bloom², Ridha Joobar², Alkomiet Hassan³, Frank Padberg³, Nikolas Koutsouleris³, Emmanuel Schwarz³, Lena Palaniyappan²

¹University of Western Ontario, ²Douglas Mental Health University Institute, ³Ludwig-Maximilians-University

Background: Transcranial Magnetic Stimulation (TMS) is a promising treatment approach for patients with intractable symptoms of schizophrenia, with its noninvasive administration and minimal side-effect profile. Recent reviews (Patel et al., 2023; Poorganji et al., 2023; Soltani et al., 2022) have reported low-grade evidence of treatment efficacy for negative symptoms. The exact mechanism of TMS remain unclear, but it appears to modulate functional and structural plasticity (Jannati et al., 2023) and brain connectivity (Hernandez-Pavon et al., 2023). Schizophrenia is a malady of synaptic plasticity and dysconnectivity, accompanied by widespread cortical thinning (Banaj et al., 2023) and increases in white matter diffusivity. Long-term, stable improvement in persistent features such as negative symptoms after TMS may require the reversal of these structural changes (Hasan et al., 2017; Kozel et al., 2011). We investigated the extent to which a 3-week course of high frequency left DLPFC TMS affects brain structure in patients with high negative symptom burden in schizophrenia.

Methods: $N=11$ schizophrenia patients were recruited from a cohort in Montreal, Quebec, Canada. Participants were scanned before and after treatment with TMS following the RESIS

study protocol (10-Hz rTMS, 15 sessions, 1000 stimuli per session) (Hasan et al., 2016). Data was acquired with 3T MRI using diffusion-weighted (b=0,1000,2000; 95 directions; 1.6mm res) and T1-weighted (MPRAGE; 1mm res) protocols. Diffusion data was preprocessed with and FSL pipeline (degibbs, susceptibility distortion correction with topup, motion and eddy current correction with eddy). Anatomical surface meshes and cortical thickness was calculated with fastsurfer and ciftfy. Fractional anisotropy (FA) and mean, radial, and axial diffusivity (MD, RD, AD) were fit to the diffusion data in the grey matter and projected onto the cortical midsurface. Changes in cortical thickness and diffusivity between scans, as well as the interaction between thickness and PANSS30, using a mixed linear model, with subjects as random effects. Multiple comparisons were corrected using random field theory.

Results: No significant differences were found across scanning sessions for structural thickness, FA, MD, RD, or AD. There was no interaction between thickness and PANSS30 or any of the PANSS subscores. We are currently expanding our analysis across a larger sample size and exploring if region-specific changes restricted to the site of stimulation alone is more likely in this context.

Discussion: Detectable, global structural changes in the cortical grey matter are not found in the immediate wake of 10-Hz, 15-session, left DLPFC TMS in schizophrenia. Although this does not prove TMS is structurally inert, it does demonstrate a lack of immediate, easily visible, distributed change. Importantly, the cortex has a complex microenvironment not easily characterized by the simple diffusion tensor metrics reported above. More sophisticated diffusion models, such as NODDI, may provide a more subtle picture of structural change.

F214. HOW CAN WE BETTER MANAGE ANTIPSYCHOTIC-INDUCED WEIGHT GAIN IN PEOPLE LIVING WITH SEVERE MENTAL ILLNESS: A REALIST SYNTHESIS

Ian Maidment¹, Sheri Oduola*²

¹Aston University, ²University of East Anglia

Background: People with severe mental illnesses (SMI) such as schizophrenia, bipolar disorder die on average 15 to 20 years earlier than everyone else. Two thirds of these deaths are from preventable physical illnesses such as hypertension, cardiovascular disease, and diabetes, which are worsened by weight gain. Antipsychotics are associated with significant weight gain. The aim of the study was to use develop a framework and guidance for non-pharmacological approaches to manage antipsychotic-induced weight gain in people with severe mental illness (SMI). We present preliminary findings from the RESOLVE study.

Methods: We are conducting a realist review and realist evaluation. Two stakeholder groups, a lived experience group and a practitioner group input into the trajectory of the research. We developed initial programme theories currently being tested and refined. Our literature search identified 773 documents across seven bibliographic databases, of which 60 full text documents are included. The realist evaluation will incorporate up to 60 qualitative interviews with healthcare professionals, carers, and service users.

Results: the realist review indicate there are a range of service-level and individual-level approaches/interventions for managing antipsychotic-induced weight gain in mental healthcare. Our review shows that interventions need to be tailored to the individual, multimodal, flexible and commence as quickly as possible after prescription. Further, continuous support from various sources (e.g., family, peer, digital) is key to the success of the interventions, as this facilitates motivation and engagement.

Preliminary results from the realist evaluation (38 interviews) stress the importance of locating interventions within mental health services. However, the current configuration and dichotomous split between physical and mental health services results in unmet physical health needs for SMI patients. SMI and obesity are both long term conditions, mental health staff do not have the appropriate skills, knowledge, confidence, or experience to provide care for SMI patients with physical health needs such as weight gain. Small pockets of good practice exist in mental health services e.g., early intervention services but access to weight management support in mental healthcare is poor.

Discussion: An innovative systems wide approach to the management of antipsychotic medication related weight gain is required to improve the lives of people living with SMI. However, current mental healthcare systems in the UK are not effectively configured to manage antipsychotic weight gain.

F215. THE EFFECT OF METACOGNITIVE EDUCATION TREATMENT ON THOUGHT DISORDER AND COGNITIVE IMPAIRMENT IN SCHIZOPHRENIA PATIENTS

Selis Koyuncuoglu¹, Emine Ilgın Hosgelen*¹, Bilge Targıtay Öztürk¹, Tolga Binbay¹, Berna Binnur Akdede¹, Köksal Alptekin¹

¹*Dokuz Eylül University,*

Background: Schizophrenia impairs psychosocial functionality, accompanied by delusions, hallucinations and disorganized behaviors, and impairments in language, thought and affect. Thought disorder includes disorders in the production and organization of thoughts. In recent years, in addition to antipsychotic treatment, various psychotherapies have been applied in schizophrenia to improve these clinical symptoms. Metacognitive treatment program aims to change the cognitive substructure of erroneous and distorted thoughts in patients and make them aware of their own mental processes. The aim of this study was to investigate the effect of Metacognitive Training on thought disorder and cognitive impairment in schizophrenia patients.

Methods: In this study, 61 patients diagnosed with schizophrenia according to DSM-V criteria who applied to Dokuz Eylül University school of Medicine, Department of Psychiatry, Schizophrenia and Other Psychotic Disorders Outpatient Unit were included. Twenty-one patients were included into the Metacognitive Training Group (MCT) and 40 patients were in the control group. Metacognitive Training Program was applied for 8 weeks, 1 day a week by face-to-face sessions with the MCT group patients. Thought disorders were evaluated by the Formal Thought Disorder Scale (FTD) and cognitive tests included the Dokuz Eylül Theory of Mind Scale (DEZİKÖ), Reading the Mind from the Eyes (RMET) test, Digit Span and Category Fluency (CFT) test. Severity of schizophrenia symptoms were evaluated by using PANSS (Positive and Negative Syndrome Scale). Depression level of the patients was measured by the Calgary Schizophrenia Depression Scale. All tests were applied to MCT group and control group at the beginning and at the end of 8 weeks.

Results: We found no statistically significant difference between the pre-test and post-test FTD scores of the MCT group and the control group. However, there was a statistically significant difference pre-test and post-test DEZİKÖ scores of MCT group and control group. DEZİKÖ scores of the MCT group significantly increased after the metacognitive therapy compared to control group ($z = -2.317$; $p=.021$). Also, depression scores of the MCT group significantly decreased after metacognitive therapy compared to control group ($t(1,20) = 2.496$; $p=.021$).

There were no statistically significant differences between MCT and control groups regarding PANSS positive, PANSS negative, PANSS psychopathology, PANSS total and RMET scores, and the neuropsychological tests Digit Span and CFT scores.

Discussion: In this study, we found metacognitive training program could be an effective program to increase social cognition skills in schizophrenia patients. In addition, there was a decrease in the severity of depression in schizophrenia patients who received MCT. First of all, it is thought that not being able to reach the targeted sample in the experimental group in this study had a detrimental effect on the meaningfulness of the data evaluation. Theory of mind skills occupy a large place in MCT. In the MCT program, it was observed that the skills were improved in patients in a manner consistent with the literature due to the fact that the skills were worked with modules in a repetitive manner. Considering this curative effect, it is seen that the skills targeted to be given to patients with MCT overlap with ToM skills.

F216. TREATMENT OF SMOKING CESSATION BY VIRTUAL REALITY IN SCHIZOPHRENIA

Köksal Alptekin¹, Emine Ilgın Hosgelen^{*2}, Faik Kartelli¹, Markus Berger¹, Oğuz Kılınc³, Gonca Ercegil⁴, Berna Yalınçetin², Özge Akgül⁵, Görsev Yener⁵, Berna Binnur Akdede¹

¹*Dokuz Eylul University*, ²*Dokuz Eylul University, Institute of Health Science*, ³*Dokuz Eylul University School of Medicine*, ⁴*Psychotherapist in Private Practice*, ⁵*Izmir Democracy University*,

Background: Patients with schizophrenia live twenty years less than normal people. Smoking cigarettes is one of the leading causes of early death and 60-80 % of patients with schizophrenia smoke. Their daily number of smoking cigarettes is high. Moreover, different from healthy people, patients with schizophrenia are consecutive smokers and they inhale cigarettes more deeply. There are Both behavioral and drug treatments aim to decrease smoking or achieve smoking cessation in schizophrenia patients; however, they are not successful. Virtual reality (VR) is composed of imitated real environments on computers. VR in the treatment of schizophrenia is new to science and offers promising VR application on normal people is effective in smoke addiction. Therefore, VR therapy may be an effective way of quitting smoking in patients with schizophrenia. However, there has not been any VR treatment of smoking cessation for schizophrenia patients. This research will be the first study in the world investigating the effect of Virtual Reality Treatment on smoking cessation in schizophrenia patients.

Methods: The participants who were smoking and diagnosed as Schizophrenia according to DSM-IV criteria were categorized into four groups: two experimental groups undergoing VR sessions, namely VR-Sch (n=26) for patients with schizophrenia, and VR-Healthy Controls (VR-HC, n=22). Additionally, two control groups were established, with one being the Sch group (non-VR-Sch, n=23) and the other the HC group (non-VR-HC, n=21), both without receiving VR interventions. VR sessions included ten individual virtual reality (VR) sessions, administered on a weekly basis, focused on smoking cessation. In order to evaluate smoking addiction level, we assessed the Fagerstrom Test for Nicotine Dependence (FTND). Also, participants were assessed in terms of quality of life by using the WHOQOL-Bref (WHO Quality of Life Scale), neuropsychological performance by using a neuropsychological test battery, theory of mind by using the Dokuz Eylul Theory of Mind Index (DEZİKÖ), psychosocial functioning by using Personal and Social Performance Scale (PSP). These tests were applied as pre (T0) and post-tests (T1) at the beginning of the intervention and 10 weeks

later, at the end of the intervention. Multi-factorial repeated measures ANOVA was performed to test the difference within and between groups in SPSS.

Results: Age and total education years were not significantly different between VR-Sch (43.20 ± 1.74 ; 10.52 ± 5.37), VR-HC (39.1 ± 1.9 ; 12.14 ± 3.18), non-VR-Sch (40.65 ± 1.85 ; 11.83 ± 3.07) and non-VR-HC (42.1 ± 1.9 ; 13.52 ± 4.52) ($p=0.42$, $p=0.19$, respectively). The main effect of time was significant [$F(1,88)=19.74$, p LESS THAN .001]. The main effect of time x group interaction was significant [$F(1,88)=4.26$, $p=.042$] indicating that the FTND score of VR groups showed a significant decrease compared to non-VR groups. The main effect of time x group interaction was not significant for VR-Sch and Non-VR-Sch groups [$F(1,88)=67.53$, $p=.007$]. The mean scores of FTND decreased over time in VR-Sch (T0: 6.31 ± 1.91 , T1: 4.27 ± 2.34) and VR-HC (T0: 4.68 ± 2.1 , T1: 2.86 ± 2.36) groups. However, the main effect of time was not significantly different between VR-Sch and VR-HC [$F(1,88)=.47$, $p=.49$].

Discussion: This study indicates that VR intervention programs designed for smoking cessation effectively reduce dependence levels in individuals who smoke. The findings suggest that the “VR Smoking Cessation Program” might be beneficial not only for those with schizophrenia but also for the general smoking population. It may also serve as a supplementary therapeutic approach, alongside pharmacotherapy, for individuals who are motivated to quit smoking.

F217. NETWORK META-ANALYSIS ABOUT THE EFFECTS OF NON-INVASIVE BRAIN STIMULATION TECHNIQUES FOR TREATMENT RESISTANT SCHIZOPHRENIA

Stefan Leucht^{*1}, Carolin Lorenz², Shimeng Dong², Nobuyuki Nomura³, Spyridon Sifakis²

¹Technical University of Munich, ²Klinikum rechts der Isar, School of Medicine and Health, Technische Universität München, ³School of Medicine and Health, Technical University of Munich

Background: Antipsychotics are the cornerstone of treatment, but around 40% of patients do not respond adequately to antipsychotics, and up to a third do not respond to two adequate antipsychotic trials, meeting the criteria for 'treatment-resistant' schizophrenia according to international guidelines. Effective interventions for treatment-resistant schizophrenia are of great importance and a top priority for research, according to a consensus of patients and clinicians published in Nature. Clozapine is the only antipsychotic indicated for treatment-resistant schizophrenia as it has high efficacy, however the non-response rate is up to 60%. Among the limited treatment options for non-response to antipsychotics, adjunctive treatment with non-invasive brain stimulation (NIBS) may be promising. Several techniques have been investigated in clinical trials, and two of them, electroconvulsive therapy (ECT) and repetitive transcranial magnetic stimulation (rTMS), are currently recommended in international guidelines for treatment-resistant schizophrenia. However, these recommendations are based on mixed and outdated evidence, which is also reflected in inconsistencies between expert groups. In addition, all currently available reviews performed a pairwise meta-analysis, where studies comparing two interventions can be analyzed simultaneously. Most NIBS techniques have not been directly compared in single studies and therefore it is still unclear which are the most effective, acceptable and tolerable. To close this knowledge gap, a network meta-analysis (NMA) is required.

Methods: We plan to conduct a network meta-analysis (NMA) on the comparative efficacy and safety of NIBS. First, we will conduct a series of pairwise meta-analyses. If the conditions for an NMA are met (see below), we will perform the NMA in a frequentist framework using

netmeta in R. We will use a random-effects model as heterogeneity is likely, and a fixed-effects Mantel-Haenszel method in the case of rare dichotomous outcomes (96), such as mortality. The certainty of the evidence for the primary outcome (i.e. overall symptoms) and for discontinuations for any reason will be assessed using the Confidence in Network Meta-Analysis (CINeMA) approach, taking into account within-study bias, reporting bias, indirectness, impression, heterogeneity and incoherence. Alpha is set at two-sided 5%, except for heterogeneity/incoherence tests at 10%. We will examine inconsistency and publication bias with appropriate measures.

Results: Study selection and data extraction have been completed. Analysis is currently ongoing. First results will be ready and presented at the conference.

Discussion: Treatment-resistance remains an extremely important problem in the treatment of schizophrenia. With the current network meta-analysis we will identify the most effective non-invasive brain stimulation techniques for this condition. Moreover, substantial information for the design of studies in this area will be obtained.

F218. A SYSTEMATIC REVIEW ON THE IMPACT OF VIRTUAL REALITY INTERVENTIONS ON PSYCHOSOCIAL OUTCOMES IN PSYCHOSIS

Emine Ilgin Hosgelen¹, Sinem Güneri*¹, Burak Erdeniz², Berna Akdede¹, Köksal Alptekin¹

¹Dokuz Eylül University, ²İzmir University of Economics,

Background: Decrease in social and vocational skills is common in individuals with psychotic disorders, leading to an increased risk of social isolation (Dziwota et al., 2018), impacting roughly 80% of those with psychotic disorders (Suman et al., 2023). This heightened social isolation has

severe consequences, negatively impacting the overall quality of life, daily life functioning, functional outcome, and motivation levels, and increasing the risk of relapse. Virtual reality (VR) integrated intervention programs have a promising method for psychosocial intervention by providing a controlled environment for individuals to practice social skills under the supervision of mental health professionals. This study aims to conduct a systematic review in terms of the effectiveness of VR interventions that aim to improve social skills in psychotic disorders.

Methods: PRISMA guideline was followed in the current systematic review. Literature search was performed twice on 1 March 2023 and on 20 August 2023 in two academic databases, Web of Science (WoS) and PubMed by two independent researchers (EIH and SG). The reason for performing the literature search twice was to include the latest articles during the last six months. For the review, we included studies if they (1) included social situations in VR intervention programs, (2) focused on social functioning and/or social cognition, (3) evaluated patients before and after the VR intervention (4) included patients diagnosed with psychosis or schizophrenia according to DSM-IV-TR, DSM-5 or ICD-10 criteria, (5) were research article, (6) were in English. Quality assessment was conducted by using the manual of The Effective Public Health Practice Project (EPHPP, 2010).

Results: From two databases, a total of 331 articles were obtained. Duplicate records (n=89) and ineligible articles were removed after evaluation. In the final review, fifteen studies that met the inclusion criteria were included into the study. The studies primarily focused on three key areas: psychosocial functioning (n=5), social cognitive skills (n=7), and vocational training (n=3). Out of 8 studies, 7 were cohort studies with a single-group pre and post-treatment evaluation while only one study included a control group. In addition, 1 controlled trial and 6

randomized controlled trials were included in the review. In particular, 6 of these studies conducted follow-up evaluations. Session duration of the studies ranged from 10 hours to 16 weeks and intervention frequency ranged from twice a week to a weekly basis. Few studies (single-group n=2; with a control group n=4) reported significant improvements while others (single-group n=4; with a control group n=3) observed no change after the intervention.

Discussion: The use of VR in interventions for psychosocial functioning for individuals diagnosed with psychosis represents a significant advancement in therapeutic approaches. However, studies aiming to improve psychosocial functioning used different methodologies including session scenarios, duration, and frequency of the sessions. They enable researchers to create social and vocational environments that cannot be replicated in real-life settings during therapy sessions. However, not all studies indicated effective or sufficient results. There is a need for conducting additional research and developing new VR designs to comprehensively understand the effectiveness of VR in enhancing psychosocial functioning in individuals diagnosed with psychosis.

F219. EFFECTIVENESS OF ECT AMONG THE PATIENTS WITH SCHIZOPHRENIA, SCHIZOAFFECTIVE DISORDER, AND CATATONIC SYMPTOMS

Veonho Joo^{*1}, Imyel Kim², Jiyoung Kim¹, Jina Kim¹

¹Asan Medical Center, University of Ulsan College of Medicine, ²Maumchan Psychiatric Clinic

Background: Electroconvulsive therapy has long been used in the treatment of schizophrenia and its related disorders. Its relative effectiveness among schizophrenia and its related disorders has not been clarified yet. We were trying to investigate the relative effectiveness of ECT among schizophrenia, schizoaffective disorder, delusional disorder, and patients with psychotic and catatonic symptoms.

Methods: All the patients with schizophrenia, schizoaffective disorder, and delusional disorder at our department who were admitted and received ECT since 2003, and were included in the study. Among the 46 patients, 32 were patients with schizophrenia, 11 were patients with schizoaffective disorder, and 3 were patients with delusional disorder. Using retrospective chart review, two authors at our department independently assessed the effectiveness of ECT at the time of discharge of patients. The criteria for being improved were clinically significant reduction of psychotic symptoms including delusions and /or hallucinations and reduction of aggressive behaviors toward self or others. The consensus decisions for the improvement were made between the two authors.

Results: The proportion of patients that responded to ECT were 65.6% in schizophrenia, 72.7% in schizoaffective disorder, and 33.3% in delusional disorder. The 77.8% among patients with catatonic symptoms (7/9) responded to ECT. Our results showed that the patients with catatonic symptoms responded to ECT better than patients without catatonic symptoms. The patients with schizoaffective disorder responded relatively better than patients with schizophrenia.

Discussion: The reason for superior effectiveness of ECT among the patients with schizoaffective disorder compared to schizophrenia was speculated. It is well known that the effect of ECT on severe depression and bipolar disorder is more superior than on schizophrenia. In that sense, schizoaffective disorder which has mood symptoms could have better response to ECT than schizophrenia.

F220. PROMOTING INTIMATE RELATIONSHIPS IN MENTAL ILLNESS: A SYSTEMATIC REVIEW OF INTERVENTIONS

Meryl Caiada*¹, Simon Felix¹, Sarah Guionnet¹, Kevin-Marc Valery¹, Julien Bonilla-Guerrero², Jean-Marc Destailats², Antoinette Prouteau³

¹University of Bordeaux, ²Hospital of Jonzac, ³University of Bordeaux and Hospital of Jonzac

Background: The following abstract is based on the original article, published in the Community and Mental Health Journal (Caiada et al., 2023, DOI: 10.1007/s10597-023-01204-z). Persons with Serious Mental Illness (SMI) express unmet needs in the intimate relationship domain and suffer from a severe lack of social participation. Indeed, they are more single and less married than the general population (Thornicroft et al., 2004; White et al., 2021). However, these unmet needs have received little attention until recently. This study reviews interventions that aim to facilitate the development and the maintenance of intimate relationships (IR) of persons with schizophrenia, bipolar disorder and major depression.

Methods: A systematic review following PRISMA guidelines was conducted. Studies published in Scopus, PubMed, EBSCO (Psych INFO, Psych ARTICLES, Psychology and Behavioral Sciences Collection) from January 1, 2000, to December 2021, were screened. Interventions focusing on sexual health only were excluded.

Results: The search using terms referring to “schizophrenia”, “bipolar disorder”, “major depression”, “IR” and “interventions” revealed 11 studies. Among them, ten reported interventions for persons with depression and nine were couple therapy. Most interventions targeted satisfaction with couple relationships as the main therapeutic objective. Heterogeneity in study design precludes any firm conclusions about their efficacy. Interestingly, only one intervention focused on single persons interested in developing IR and only one were designed for persons with psychosis disorder.

Discussion: The results highlight the lack of interventions: (i) aimed at promoting IR, (ii) designed for single persons, and (iii) targeting persons with psychotic disorders. This result may reflect the persisting stigmatization of persons with psychotic disorders, and the taboo associated with the IR and sexuality of persons with mental illness. Further studies are needed to develop inclusive interventions promoting the development of IR in persons with mental illness.

F221. ENHANCING PATIENT-CENTERED CARE IN SCHIZOPHRENIA TREATMENT: DEVELOPMENT AND EVALUATION OF THE PROTECTS-SE APPLICATION

Alessandro Rodolico¹, Pierfelice Cutrufelli*², Antonio Di Francesco², Davide Conti², Irene Bighelli¹, Pasquale Caponnetto², Carmen Concerto², Rosaria Furnari², Gabriele Leotta³, Ludovico Mineo², Katharina Müller¹, Spyridon Sifas¹, Antonino Petralia², Stefan Leucht¹, Maria Salvina Signorelli²

¹Technical University of Munich, ²University of Catania, ³Darwin Technologies

Background: The importance of patient-centered care and shared decision-making in treating schizophrenia spectrum disorders is widely recognized, yet its effective implementation continues to be a significant challenge, particularly regarding the management of side effects. To address this issue, we developed the Patients Reported Outcomes Technological Evidence-Centered Tool for Schizophrenia - Side Effects (PROTECTS-SE), a novel tool with an

interactive user interface, designed for clinicians and patients. This tool provides access to evidence-validated information regarding side effects management and advanced decision-support algorithms, thereby streamlining the process of making and understanding medical decisions. The platform incorporates the GASS scale to systematically collect data on experienced side effects from the patient. Based on this data and following medical guidelines, the platform generates evidence-based solution proposals for subsequent psychiatrist-patient discussion. The application functions on a secure HIPAA-compliant platform to ensure the confidentiality and safety of patient information.

Methods: This study used a qualitative research design, analyzing semi-structured interviews with patients and healthcare providers. Themes were extracted, systematically analyzed, and organized in a framework to evaluate the impact of the PROTECTS-SE application on crucial usability issues: ease of use, clarity of data presentation, fulfillment of user needs, enhancement of patient-physician collaboration, improvement in adherence to treatment, patient sense of empowerment, and utility for the clinician.

Results: The preliminary findings indicate that PROTECTS-SE may facilitate shared decision-making process between clinicians and patients, effectively addressing multiple intrinsic barriers to patient empowerment. This includes perceived improvements in patient-clinician communication, trust, and overall patient engagement in their healthcare. Efficiency in the clinical process decision for the physician and increasing patients' sense of participation in their care were highlighted as strengths during the interviews. However, some areas require further development, specifically regarding data representation, which is potentially overloaded and complex for some users.

Discussion: The results highlight the potential utility of PROTECTS-SE in enhancing patient-centered care in schizophrenia spectrum disorders. The application integrates real-time data analytics, evidence-based guidelines, and a user-friendly interface, offering a comprehensive solution to the difficulties involved in shared decision-making and helping to address the complexities of antipsychotics side-effects management. Integrating evidence-based medicine with a patient-focused approach, tools like PROTECTS-SE could improve patient empowerment and clinician proficiency. Future studies should focus on assessing this application's real-world performance and efficacy.

F222. ENHANCING EVERYDAY FUNCTIONING IN LONG-TERM PSYCHIATRIC CLINICAL CARE: A PRAGMATIC RANDOMIZED CONTROLLED PILOT TRIAL INTO THE ACCEPTABILITY AND FEASIBILITY OF COGNITIVE REMEDIATION AND TDCS FOR PEOPLE WITH SEVERE MENTAL ILLNESS

Anika Poppe¹, Leonie Bais², Nienke Buist^{*1}, Daniëlle van Duin³, Branislava Curčić-Blake⁴, Marieke (Gerdina) Pijnenborg¹, Lisette van der Meer¹

¹University of Groningen, ²Lentis Center for Mental Health Care, ³Phrenos Center of Expertise, ⁴BSCS Cognitive Neuroscience, University Medical Center Groningen,

Background: Cognitive impairments are commonly experienced by individuals with severe mental illness (SMI) and predict problems in everyday life. This pragmatic, randomized, controlled, pilot trial explored the acceptability, feasibility, and preliminary effects of cognitive remediation (CR) combined with transcranial direct current stimulation (tDCS) for cognitive and everyday functioning in individuals with SMI in long-term psychiatric clinical care.

Methods: Twenty-four individuals with SMI were randomized to either CR+active tDCS (n = 13) or CR+sham tDCS (n = 13) over 32 sessions (16 weeks). Acceptability was evaluated in

semi-structured interviews. Cognitive and everyday functioning were evaluated at baseline, post-16 week waiting period, post-intervention, and 6-months post-intervention.

Results: Overall, participants were positive about the training. Over 60% of participants completed at least 20 sessions, exceeding predefined feasibility criteria. CR appeared to yield personal benefits to participants, significant improvements in cognitive tests post-intervention and at follow-up and improved self-reported negative symptoms at follow-up. Observed everyday functioning and cognition, and subjective cognitive complaints did not change following CR.

Discussion: This study concludes that CR is an acceptable and feasible intervention for individuals with SMI in long-term psychiatric clinical care. The addition of tDCS requires further investigation to ascertain its potential benefits. Currently, a larger randomized controlled trial following this pilot trial is set up.

F223. DON'T STOP ME NOW: A SPORT-BASED INTERVENTION TO PROMOTE SOCIAL INTEGRATION IN EARLY PSYCHOSIS – A STUDY PROTOCOL

Akke-Marij Ariesen*¹, Laura Steenhuis², Susanne Spoelman³, Nynke Boonstra⁴, Claudia Emck⁵, Clement Waarheid³, Jooske van Busschbach⁶, Marieke Pijnenborg²

¹University of Groningen, ²University of Groningen /Mental Health Institution GGZ Drenthe, ³Mental Health Institution GGZ Drenthe, ⁴Mental Health Institution KieN-VIP / NHL Stenden University of Applied Sciences/University Medical Center Utrecht, ⁵Vrije Universiteit Amsterdam, ⁶Windesheim University of Applied Sciences /University of Groningen, University Medical Center Groningen

Background: Already in the early phase of psychosis, individuals often experience problems with participating in society. After having experienced a psychotic episode, people frequently stop working or studying, participate less in leisure activities, and lose contact with their peers. Several factors, including negative symptoms, (self)stigma, and social exclusion, may contribute to this reduced social participation. Additionally, physical health problems, such as metabolic risk factors, are often already present in the early phase of psychosis, and may increase due to inactive behaviour. In order to prevent a progressive worsening of social isolation it is essential to timely intervene. This study presents the protocol of a research project that aims to examine the effectiveness of a sport-based intervention developed to promote the social (re)integration of individuals in the early phase of psychosis.

Methods: 24 individuals, between 18-65 years of age, within the first five years of diagnosis of a psychotic disorder, and currently in care at one of four participating mental health facilities in the Netherlands will be included. In terms of content and design, the intervention was partly based on the outcomes of a qualitative needs and barriers study conducted in the target population, and was improved on the basis of a feasibility study. The intervention includes a minimum of 22 sessions, in a 24-26 week time-frame, and consists of three phases: phase 1 – individual psychomotor therapy (focused on goal setting and regaining trust in one's physical capabilities); phase 2 – group sessions combining psychomotor therapy and sports (focused on social connectedness); phase 3 – joining a self-selected sports club or activity in the local community, under guidance of a community sport coach (focused on social integration). The intervention is tailored to an individual's personal needs and goals. The effectiveness of the intervention will be tested by means of a multiple baseline single-case design (n = 1). Measurement instruments include interviews, questionnaires, accelerometers (ActiGraphs), and experience sampling.

Results: The primary outcome is the level of social integration as determined by 1) self-reported daily and overall changes in the social network, level of social functioning, and experienced social inclusion, and 2) whether participants have successfully commenced and continued sports activities in their local community. Additionally, changes in daily and overall levels of self-stigma, physical activity, self-esteem, and negative symptoms are assessed. Improvements in these outcome measures post-intervention and at 6-month follow-up mark the (expected) effectiveness of the intervention. At follow-up, the secondary outcome is to explore the lived experiences of social participation after partaking in the intervention in terms of employment, studies, leisure activities, and the fulfilment of social roles.

Discussion: By building a bridge between sport-related activities in a mental health care setting, and sport activities in the local community, the proposed intervention aims to contribute to the social participation and social (re)integration of individuals in the early phase of psychosis.

F224. INTEGRATING A MOBILE APP FOR SHARED DECISION-MAKING IN TREATMENT FOR PSYCHOTIC DISORDERS: PRELIMINARY FINDINGS AND IMPLICATIONS

Mari Skoge*¹, Sofie Ragnhild Aminoff¹, Gina Engen Bryhni², Elizabeth Ann Barrett¹, Erlend Mork¹, Kristine Kling¹, Kari Jorunn Kværner³, Ingrid Melle⁴, Carmen Elisabeth Simonsen¹, Linn Nathalie Støme³, Tor Gunnar Værnes¹, Kristin Lie Romm¹

¹Early Intervention in Psychosis Advisory Unit for South East Norway, Clinic of Mental Health and Addiction, Oslo University Hospital, ²Sanderud Hospital, Psychiatric Health Services Division, Innlandet Hospital Trust, Norway, ³Centre for Connected Care, Clinic of Mental Health and Addiction, Oslo University Hospital, ⁴Institute of Clinical Medicine, University of Oslo,

Background: Strengthening shared decision-making (SDM) in mental healthcare can improve the precision and quality of treatment. Patients with psychotic disorders may have problems expressing their needs, due to symptomatology and contextual factors. Digital tools, such as mobile applications (apps), may act as facilitators for SDM. While the literature is promising, there is a need for a deeper understanding about the integration of apps into treatment as usual for psychotic disorders, from both patient and clinician perspectives. The aim of this study is to investigate feasibility and acceptability of integrating an app for SDM, iTandem, in treatment for psychotic disorders. iTandem is designed to be flexible, with a personalized interface. It contains eight modules: sleep, medication, recovery, mood, psychosis, activity, substance use, and feedback on therapy. This paper comprises an iteration in the development and investigation of iTandem, and the preliminary findings guide the future work on clinical applications of digital tools.

Methods: Eight clinicians and nine patients from inpatient and outpatient units at Innlandet Hospital Trust, a mainly rural area of Norway, were recruited. Patients were recruited consecutively, were above 18 years old and currently undergoing treatment for psychotic disorders. Patients and clinicians jointly selected app modules to focus the treatment during a six-week pilot trial. Data from the app were securely transferred to a report accessed by clinicians, and discussed during sessions. The report was used to monitor symptoms and recovery process, and to guide interventions according to the input. A mixed methods approach was used for data analysis. Quantitative data was collected with pre- and post-intervention questionnaires, including items on patient demographics (age, gender, time in treatment,

distance to hospital), and the System Usability Scale (SUS). Data were analysed in SPSS Statistics 29. Qualitative data were collected from individual in-depth semi-structured post-intervention interviews and analysed in NVivo 14, using systematic text condensation.

Results: Preliminary findings suggest positive user experiences. Mean SUS scores for patients and clinicians were 75 and 82, respectively. Some of the preliminary themes emerging from the qualitative analysis were shared by both groups as iTandem: 1) enabled an overview of problem areas and their connections, 2) served as an aid for memory and structure, and 3) facilitated broader discussions of the patients' needs. Patients underlined the importance of clinician engagement, and some experienced the need of social support to be able to actively take part in the intervention. Clinicians found it challenging to introduce and implement a digital tool into treatment as usual, as it felt unfamiliar. Furthermore, they expressed concerns about patient vulnerability, as well as organisational factors, as barriers to implementation.

Discussion: Patients and clinicians recognize the potential of a digital tool for SDM, emphasizing how it increased involvement and personalization according to individual needs. However, clinicians seem to have concerns regarding this patient group's level of functioning, which might act as a barrier to offer such tools. The findings indicate that there are stronger predictors for successful integration than symptom severity. Variables such as tech-savviness, digital habits and motivation may be of great impact. In addition, clinicians experienced organisational factors as obstacles. Implementing digital tools in mental healthcare, needs to be followed by careful considerations to service design and integration into the routines of consultation.

F225. METACOGNITIVE TRAINING FOR AUDITORY HALLUCINATIONS: EFFICACY OF AN ONLINE-BASED SELF-HELP INTERVENTION

Laura Fässler*¹, Steffen Moritz², Malek Bajbouj³, Christine Knaevelsrud⁴, Kerem Boege³

¹Charité, University Medicine Berlin, ²University Medical Center Hamburg, ³Charité, Universitätsmedizin Berlin, Campus Benjamin Franklin, ⁴Freie Universität Berlin, Institute for Psychology

Background: Auditory hallucinations (AH) are considered as a hallmark characteristic of schizophrenia spectrum disorders (SSD). However, AH can be assumed on a continuum from ordinary to pathological perceptions. A broad range of affected persons with mental disorders and SSD experience their AH as severely distressing and functionally restrictive. In recent years, psychotherapeutic approaches have been established as complementary to pharmacological interventions for SSD. Previous research highlights the empirical evidence for the effectiveness of metacognitive approaches for positive symptoms in SSD. However, there remains insufficient evidence for effective, cost-efficient, and accepted interventions for AH that needs to be investigated further. Moreover, there is still an incisive lack in the psychological care of SSD, primarily caused by several structural flaws and shortcomings in treatment accessibility. To minimize the research and care gap in the psychotherapeutic treatment of persons with SSD and AH, we aimed to investigate the efficacy of an online-based self-help intervention for AH that is primarily based on metacognitive training (MCT) according to Moritz and Woodward (2007).

Methods: For the first time worldwide, we intended to examine an adaptive and particularly low-threshold self-help manual for distressing AH based on MCT. The recruitment took place at the Department of Psychiatry and Psychotherapy of the University Medical Centre Hamburg-Eppendorf (UKE) in cooperation with the Department of Psychiatry and Psychotherapy at

Charité – University Medicine Berlin, Campus Benjamin Franklin, and various support groups and online platforms. The project is implemented as a randomized controlled trial (RCT) with self-reported assessments at baseline (T0) and post-intervention (T1) after six weeks. Participants were randomly allocated to the intervention or waitlist-control group. The intervention is carried out online (PDF file) with various worksheets and interactive elements that are primarily based on MCT. To date, we randomized N = 74 persons with AH. The data collection process will end in December 2023.

Results: As the primary outcome, we will analyze the frequency and distress of AH measured by the hallucination subscale of the Psychotic Symptom Rating Scale (PSYRATS). The primary analysis will be calculated using an analysis of covariance (ANCOVA) model with group differences from T0 to T1 as the dependent variable. We will include the baseline data of AH and the medication dosage as covariates to increase the power of the results. Furthermore, we will conduct an intention-to-treat (ITT) analysis with multiple imputation methods by chained equations to consider missing data. Additionally, we will only include complete cases with baseline and post data in a per-protocol (PP) analysis. To examine the subjective satisfaction with the intervention, we will report descriptive results to analyze satisfaction. Since the data collection will end in December 2023, we will present new and unpublished data. Preliminary analyses revealed no significant differences between the intervention and control group ($F(3, 39) = 4.67, p = .29, \eta^2_{\text{partial}} = .03$). However, the satisfaction with the intervention indicated high subjective reported rates that need to be further evaluated.

Discussion: Due to still existing and tremendous shortcomings in the psychotherapeutic supply of SSD, it is crucial to investigate low-threshold complementary interventions to conventional approaches further. The proposed study aims to examine a particular straightforward treatment for AH within a self-help manual based on MCT. Due to its low threshold and cost-effective implementation, the intervention is suitable for conduct in low- and middle-income countries, independent of language or residence. In this regard, we aspire to reveal relevant insights into a novel psychotherapeutic approach that addresses a clinical population that frequently experiences personal and structural marginalization and stigmatization.

F226. COMPARISON OF FEASIBILITY, SAFETY, AND EFFICACY OF TELEHEALTH-BASED VS. IN-PERSON AEROBIC EXERCISE TO IMPROVE NEUROCOGNITION AND DAILY FUNCTIONING IN INDIVIDUALS WITH SCHIZOPHRENIA

David Kimhy*¹, Luz H. Ospina¹, Melanie Wall², Dan Altshuler², L. Fredrik Jarskog³, Jacob Ballon⁴, Joseph McEvoy⁵, Matthew Bartels⁶, Marianne Goodman¹, Sloane Miller¹, T. Scott Stroup²

¹*Icahn School of Medicine at Mount Sinai*, ²*Vagelos College of Physicians and Surgeons, Columbia University*, ³*University of North Carolina, Chapel Hill*, ⁴*Stanford University*, ⁵*Augusta University Health*, ⁶*Albert Einstein College of Medicine*

Background: People with schizophrenia display significant deficits in neurocognition that have been identified as key predictors of poor daily functioning and disability. Previous reports have indicated that aerobic exercise (AE) training can enhance neurocognitive functioning in this population, with training traditionally having been administered via in-person AE sessions. However, following the advent of the COVID-19 pandemic and the subsequent shelter-in-place orders, many clinics transitioned their clinical services to telehealth-based delivery. Yet, there

is scarce information about the feasibility, safety, and efficacy of telehealth-based AE in people with schizophrenia.

Methods: Here we describe outcomes from a single-blind, randomized clinical trial examining the impact of 12-week AE vs. a stretching-and-toning control intervention on neurocognition and daily functioning in people with schizophrenia. Following the onset of the COVID-19 pandemic, the trial transitioned from in-person format to remote AE intervention via telehealth, with training frequency and duration, along with research procedures, remaining identical. The in-person AE involved trainer-led use of AE equipment (e.g., treadmill, elliptical machine, stationary bikes) and active-play video games (e.g., Xbox Kinect). Participants in the telehealth-based AE exercised at home (e.g., jumping jacks, jogging in place) via a 2-way video link with a trainer using iPads. We compared the feasibility, safety, and efficacy of trainer-led AE training among participants in the in-person (pre-COVID-19) vs. telehealth AE phases (post-COVID-19 onset).

Results: Compared to in-person AE, telehealth-based AE was associated with significantly lower drop-out rate (7/23 vs. 0/14, respectively), though also lower number of sessions attended, total time spent exercising, and proportion of session-time exercising at or above target intensity. There were no serious adverse events associated with either AE formats. Similarly, there were no significant group differences in the proportion of patients with any AE-related minor or moderate adverse events (e.g., joint pain, muscle strain, blisters, dyspnea). Employing longitudinal mixed-effect analyses, there were no significant differences between the in-person vs. telehealth groups regarding changes in aerobic fitness (VO₂max), neurocognition (MATRICS Consensus Cognitive Battery; MCCB), and functioning (Schizophrenia Cognition Rating Scale (SCoRS) and Specific Levels of Functioning Scale (SLOF)). However, the in-person AE group displayed significantly greater improvement in the SLOF Interpersonal domain (ES=.79, p=.03).

Discussion: Our preliminary findings suggest telehealth-based delivery of AE is feasible, safe, and results in comparable cognitive and functional benefits, except for aspects of social functioning. We discuss the implications of these findings, along with a review of the challenges associated with delivery of telehealth-based AE.

F227. NEURAL CORRELATES AND NEURAL STIMULATION OF SENSORIMOTOR TEMPORAL RECALIBRATION MECHANISMS IN SCHIZOPHRENIA SPECTRUM DISORDERS AND HEALTHY SUBJECTS

Christina Schmitter^{*1}, Konstantin Kufer¹, Olaf Steinsträter¹, Jens Sommer¹, Tilo Kircher¹, Benjamin Straube¹

¹Philipps-University

Christina Schmitter

Background: Core symptoms in patients with schizophrenia spectrum disorders (SSD), such as hallucinations or ego-disturbances, have been associated with a failure of internal forward models to adequately predict the sensory outcomes of self-generated actions. Importantly, due to dynamically changing environmental conditions, forward models must also be capable of flexibly recalibrating their predictions, for example, to account for additional delays between action and outcome. This mechanism is known as sensorimotor temporal recalibration.

Methods: In two studies with healthy subjects, we investigated (1) the neural correlates of sensorimotor temporal recalibration using fMRI (N = 25), and whether (2) transcranial direct current stimulation (tDCS) can be used to facilitate behavioral recalibration effects (N = 22).

In a third study, we assessed whether (3) sensorimotor temporal recalibration effects are reduced in patients with SSD (N = 22) compared to matched healthy controls (N = 20), and whether tDCS can facilitate recalibration in both groups. In all studies, subjects were repeatedly exposed to delays between actively elicited or passively performed button press movements and auditory or visual sensory outcomes. The effects of this procedure on temporal perception were assessed with a delay detection task.

Results: Results showed that (1) recalibration was related to clusters of activation in left hippocampus [$t = 4.28$, nr. voxels = 120, peak: $x = -36$, $y = -10$, $z = -18$] and in the bilateral cerebellum [$t = 4.35$, nr. voxels = 1716, peak: $x = -10$, $y = -46$, $z = -16$]. (3) Patients with SSD exhibited no difference in behavioral temporal recalibration effects compared to healthy controls [$F(1,40) = .267$, $p = .608$, $\eta^2 = .007$], and, compared to sham stimulation, anodal tDCS of the cerebellum facilitated temporal recalibration (2) in healthy subjects [$t(21) = 3.090$, $p = .006$, $d = .659$] and (3) across both patients and healthy controls [$t(41) = 2.472$, $p = .009$, $d = .381$].

Discussion: These findings show for the first time that the hippocampus plays an important role in temporal recalibration, presumably related to the updating and encoding of the newly learned temporal relationship between movements and their sensory outcomes. They further indicate that sensorimotor temporal recalibration mechanisms may be preserved in SSD and highlight the importance of the cerebellum in both patients and healthy subjects for this process. Additionally, the results suggest that cerebellar tDCS could be a promising tool for addressing deficits in action-outcome monitoring and related adaptive sensorimotor functions in SSD.

F228. EFFECTS OF VIRTUAL REALITY BASED SOCIAL SKILLS TRAINING ON SOCIAL COGNITION AND SELF-DISTURBANCES IN INDIVIDUALS WITH SCHIZOPHRENIA

Hyeon-Seung Lee^{*1}, Michael Sangimino¹, Catherine Chang¹, Nilanjan Sarkar¹, Sohee Park¹

¹*Vanderbilt University*

Background: Social impairment and self-disturbances are core features of schizophrenia that contribute to long-term disability and poor outcome. Although there is good evidence to link self-disturbance and social impairments, they are not typically targeted together for intervention. Importantly, the potential impact of social skills training on bodily self-disturbance has not been studied. We implemented a simulation-based social skills game, which focuses on rehearsing interpersonal interactions that might unfold under familiar scenarios in VR rather than explicitly teaching social cognitive skills. We expected to observe improvements in clinical symptoms, social impairments and self-disturbance in individuals with schizophrenia (SZ).

Methods: In a cross-over design, SZ participated in 8 sessions of novel social skills training program and 8 sessions of a control condition in which they played a non-social VR game. The order of the two conditions was counterbalanced across participants. The social skills training game in VR involved achieving interpersonal ‘missions’ with an avatar under multiple familiar scenarios (e.g. bus stop, shop). They worked through these social missions of varying difficulty levels while receiving feedback. The control condition consisted of 8 sessions of commercial, nonsocial games. Clinical symptoms assessment, social cognitive tests, computerized mapping of embodied emotion (self disturbance assessment) and resting state functional brain scans were conducted pre- and post- training and also at pre- and post - control condition.

Results: After VR training, there were significant improvements in positive and negative symptoms, social functioning and self-disturbance. Across a range of emotions, awareness and

localization of bodily sensations improved after training. Awareness of embodied emotions was associated with the integrity of the frontoparietal social brain networks. In addition, participants reported gaining confidence in social interactions.

Discussion: Simulating and rehearsing interpersonal interactions in VR improved clinical symptoms, social functioning, emotion embodiment and the integrity of the frontoparietal network of SZ. These results indicate the importance of targeting self-disturbance and social impairment in concert in the context of intervention. Note that there was no explicit training or teaching of specific social skills or rules. These results suggest that simulation and rehearsal of making small talk with a stranger in a low-stakes scenario may be an effective strategy for improving social functioning.

F229. MODERATING EFFECTS OF CLINICAL AND DEMOGRAPHIC CHARACTERISTICS ON VIRTUAL REALITY CBT FOR PARANOIA: FOR WHOM DOES IT WORK?

Maureen Berkhof¹, Elise van der Stouwe¹, Roos Pot-Kolder², Mark Van der Gaag³, Wim Veling¹, Chris Geraets*¹

¹University Medical Center Groningen, ²The University of Melbourne, ³VU University Amsterdam Clinical Psychology

Background: VR-CBT can be effective in treating paranoia and anxiety in people with a psychotic disorder. However, it is unknown who benefits most from VR-CBT. The aim of this study is to investigate moderating factors that may influence the effectiveness of VR-CBT.

Methods: In total, 95 patients with a psychotic disorder and paranoid ideations were included from a multicenter RCT. Participants were assigned to VR-CBT or treatment as usual (TAU). The VR-CBT group received 16 sessions of individual treatment. Moderator analyses were performed to explore the influence of demographic (age, gender, and education) and clinical characteristics (illness duration, paranoia, anxiety, depression, safety behaviour, self-esteem, and social functioning) on post-treatment effects of paranoia and anxiety as measured with questionnaires as well as the experience sampling method (ESM).

Results: Higher levels of safety behaviour before the treatment resulted in greater benefits of VR-CBT on paranoid ideation and ESM paranoia. Higher age was associated with greater benefits of VR-CBT on social anxiety, but not paranoia outcomes. There was no consistent evidence of moderation by any of the other sociodemographic or clinical variables for paranoid ideation and social anxiety.

Discussion: The findings suggest that a diverse spectrum of patients, with different backgrounds and symptom severity can benefit from VR-CBT. VR-CBT can be recommended to a broad spectrum of patients with a psychotic disorder, and particularly those with high levels of safety behaviors, including severe avoidance.

F230. METABOLIC SYNDROME IN PEOPLE TREATED WITH ANTIPSYCHOTICS (RISKMET): A MULTIMETHOD STUDY PROTOCOL INVESTIGATING GENETIC, BEHAVIOURAL, AND ENVIRONMENTAL RISK FACTORS

Giovanni de Girolamo*¹, RISKMET Consortium¹

¹IRCCS St. John of God Clinical Research Centre

Background: Many individuals who suffer from mental disorders in both childhood and adulthood (1) and are undergoing antipsychotic (AP) treatment are at significant risk of physical comorbidities. Second-generation antipsychotics (SGAs) are commonly prescribed to manage symptoms primarily linked with schizophrenia spectrum disorders (SSD), bipolar disorder (BD) and other mental health conditions in paediatric populations, such as disruptive behaviour disorders and irritability or aggression in the context of neurodevelopmental disorders. The rise in the number of associated medical conditions in these patients can be attributed to several factors: (a) pathogenetic and biological factors (e.g., metabolic or immune system disorders, genetic susceptibility); (b) unhealthy behaviours, including poor diet, smoking, sleep disturbances and low levels of physical activity; (c) low utilisation of healthcare services, often due to stigma; and (d) negative consequences of common medications (e.g., side effects). The most frequent medical comorbidities in psychiatric patients include type-2 diabetes, cardiovascular disease (CVD), and endocrine disorders, such as metabolic syndrome (MetS). MetS is indicative of a preclinical state characterised by a cluster of risk factors for CVD and type-2 diabetes mellitus, which tend to cooccur in individuals with MetS. To meet MetS diagnostic criteria individuals have to satisfy at least three of the following five diagnostic criteria: (1) waist circumference GREATER THAN 102 cm (M); GREATER THAN 88 cm (F); (2) fasting glucose GREATER THAN 100 mg/dL (or antidiabetic treatment); (3) blood pressure GREATER THAN 130/85 mmHg (or treatment with antihypertensive agents); (4) triglycerides GREATER THAN 150 mg/dL; and (5) HDL cholesterol LESS THAN 40 mg/dL (M); LESS THAN 50 mg/dL (F). The prevalence of MetS is markedly high among patients with SSD, BD and NDD: notably, many of those patients underwent prolonged treatment with APs, often in combination.

Methods: The RISKMet project has three objectives, each with distinct research phases.

1.The first objective is to ascertain risk factors for MetS in patients treated with APs, particularly SGAs. The study will utilize a case–control design, with two subject groups recruited from both adult and paediatric populations: patients diagnosed with MetS (cases, MetS+) and patients without MetS (controls, MetS-), who will be matched for sex, age group, disease severity, using Clinical Global Impression (CGI) (30), diagnosis and AP treatment. To identify risk factors for MetS, a thorough assessment of familiarity with MetS will be carried out, together with an assessment of psychological and functional risk factors (e.g., behavioural characteristics, disability, quality of life, diet, sleep quality).

2.The second objective is to thoroughly assess the present health status of patients who have been given SGAs and either have or do not have symptoms of MetS. A large set of biomarkers will be investigated, notably: Ab-Tg, Ab-TPO, Adiponectin, ALT, Apo A1, Apo B, AST, C-Peptide, Fetuin-A , Glycoprotein, Ft4, GGT, Glycemia, HbA1c, HDL, Insulin, LDL, Leptin, Lp (a), Oral Glucose Tolerance Test (OGTT), Protein Glycation Derangements, P-Selectin Glycoprotein, Total cholesterol, Triglycerides, TSH, Vitamin D, Zinc-Alpha2-Glycoprotein, Zonulin.

3.The third objective is to prospectively investigate behavioural patterns linked to MetS, including PA, sleep, and dietary habits. PA and sleep will be tracked with a wrist-worn accelerometer, while eating behaviours (such as daily caloric intake, binge eating episodes, night-time eating, cravings, fast food consumption, and satiety) will be monitored through a mobile-based ESM.

Results: The objectives of the RISKMet project are multipronged, aiming to explore MetS from clinical, biological, and behavioural perspectives. This multifaceted approach is crucial for comprehensively understanding the risk factors, characteristics, and behavioural patterns

associated with MetS in AP-treated patients. By focusing on high-risk populations, the project seeks not only to identify risk factors but also to intervene and prevent the progression of this condition, which is a significant contributor to morbidity and mortality in this population. The project is a two-year multicentre, multiphase study that will recruit diverse patient populations from different locations and age groups, including adults and children. This comprehensive approach will have 2 evaluation time points (T0 and T3) and will involve multiple study sites to enhance robustness and generalizability. The study will include individuals with MetS (MetS+), control groups of individuals without MetS (MetS-), and, in the paediatric population, their parents. This comprehensive approach will explore familial genetic susceptibility for MetS and consider potential confounding factors by recruiting healthy controls, thereby enabling investigation of horizontal familial liability for MetS.

Discussion: There is growing attention being paid to devising preventive measures that reduce the risk of comorbidities associated with SGA usage. This study will provide helpful information to improve the clinical use of SGA, modifying the risk/benefit ratio in the direction of more benefits and fewer risks.

F231. ECOLOGICAL MONITORING OF PHYSICAL ACTIVITY, EMOTIONS AND DAILY LIFE ACTIVITIES IN SCHIZOPHRENIA: THE DIAPASON STUDY

Giovanni de Girolamo*¹, DIAPASON Consortium²

¹*IRCCS St. John of God Clinical Research Centre*, ²*DIAPASON Consortium Italy*

Giovanni de Girolamo

Background: Patients with schizophrenia spectrum disorders (SSD) often show marked impairments in daily time functioning, with adverse consequences for prognosis, number of medical comorbidities and mortality rates. However, despite the importance assigned to the daily time use of patients with SSD, most studies have mainly collected self-reported retrospective data. The use of retrospective self-reports in patients with severe mental disorders is prone to errors related to recall bias and to potentially impaired cognitive capacities. The integration of innovative methodologies (eg, ecological momentary assessment (EMA)) and wearable devices like accelerometer-based biosensors in research and clinical practice with individuals with SSD is promising. These tools reduce biases, provide longitudinal, objective and time-resolved ecologically valid data (ie, a fine-grained picture of patients' experiences in their natural contexts) and capture the variability over time and the dynamic patterns of reactivity to the environment. We performed a cohort study aimed at investigating: (1) the differences in PA, daily activities and emotions between patients with SSD and healthy controls (HC); (2) the strength of the association between these variables and clinical features among patients with SSD.

Methods: Ninety-nine patients with SSD (53 residential patients, 46 outpatients) and 111 matched HC were assessed for several clinical variables, and levels of functioning by means of standardised clinical measures. Self-reported daily activities and emotions were assessed with a smartphone application for ecological momentary assessment (EMA), and PA levels were assessed with a wearable accelerometer for 7 consecutive days. Sociodemographic, physical and clinical assessments. The 24-item Brief Psychiatric Rating Scale (BPRS) was used to assess psychopathology. Negative symptoms severity was assessed with the Brief Negative Symptom Scale (BNSS). The 43-item Specific Levels of Functioning Scale (SLOF) was used for the assessment of levels of functioning. The WHO Disability Assessment Schedule 2.0

(WHODAS 2.0) was used for the assessment of disability level. Self-reported daily time use (i.e., daily activities) and emotions were prospectively assessed with a brief questionnaire on a smartphone-based application for EMA, developed ad hoc for the project. The mobile application included three sections: current activities, social contacts and emotions. Notifications occurred 8 times a day, from 08:00 a.m. to 12:00 p.m., for seven consecutive days. PA was monitored using the wearable accelerometer-based biosensor ActiGraph GT9X Link worn on the non-dominant wrist for seven consecutive days (the same days for the EMA monitoring). Data were summarised using mean and SD, median and IQR for quantitative variables, counts and percentages for qualitative ones. Comparisons of sociodemographic and clinical variables across residential patients, outpatients and control participants were carried out through the χ^2 test for categorical variables and the analysis of variance test for continuous variables.

Results: Patients with SSD, especially those living in residential facilities, spent more time being sedentary, and self-reported more sedentary and self-care activities, experiencing higher levels of negative emotions compared with HC. Moreover, higher functioning levels among patients were associated with more time spent in moderate-to-vigorous activity. The three groups significantly differed for all activity levels (both min/day and %), with healthy controls showing higher PA levels than the two patient groups, even controlling for daily % of wearing time, the number of cigarettes per day and season. Time spent in different PA levels are expressed in mean min/day. Sedentary time was significantly higher in residential patients compared with both outpatients and healthy controls (respectively RR 1.16 (95% CI 1.10 to 1.23); $p < 0.001$; RR 1.15 (95% CI 1.15 to 1.28); $p < 0.001$). Outpatients and healthy controls did not differ from each other for time spent sedentary (RR 1.04 (95% CI 0.99 to 1.10); $p=0.10$). When expressed in relative terms, the sedentary time represented 48% 51% of total wake time in patient groups, which was also a significantly larger fraction compared with healthy controls (i.e., 40%). MVPA was significantly higher in healthy controls (91.3 mean min/day) than in both outpatients (64.1 mean min/day) and residential patients (44.6 mean min/day). Outpatients spent a significantly larger fraction of time doing MVPA per day compared with residential patients (RR 0.70 (95% CI 0.53 to 0.92); $p=0.01$) and lower time when compared with healthy controls (RR 0.70 (95% CI 0.55 to 0.90); $p=0.004$).

Discussion: Sedentary behaviour and negative emotions are particularly critical among patients with SSD and are associated with more impaired clinical outcomes. Mobile-EMA and wearable sensors are useful for monitoring the daily life of patients with SSD and the level of PA. This population needs to be targeted with specific rehabilitative programmes aimed at improving their commitment to structured daily activities.

F232. SCHIZOTYPY EFFECTS ON (ANTERIOR) HIPPOCAMPUS VOLUME AND BLOOD FLOW IN HEALTHY SUBJECTS ARE MODULATED BY AUTISTIC TRAITS

Ahmad Abu-Akel^{*1}, Tina Meller², Ulrika Evermann³, Julia-Katharina Pfarr², Andrea Federspiel⁴, Sebastian Walther⁵, Sarah Grezellschak², Igor Nenadić²

¹University of Haifa, ²University of Marburg, ³Philipps-University Marburg, ⁴University Hospital of Psychiatry, ⁵University Hospital of Psychiatry and Psychotherapy Bern,

Background: Recent studies in schizotypy (a well-validated psychosis risk phenotype), clinical high-risk, and first episode schizophrenia have reported changes in anterior

hippocampus volumes, with putative progression to posterior hippocampus areas during disease progression. This has led to the hypothesis that the anterior hippocampus might be an “epicenter” in developing schizophrenia. However, there is also substantial overlap with other pathologies for this brain structure and accounting for this overlap or co-morbidities (e.g., autism spectrum disorders, affective disorders) is mostly lacking. Given the limitations of classical case-control designs, new approaches are needed to identify biological underpinnings of disease spectra and their interaction.

Methods: They study assessed autistic and schizotypal traits—as models of subclinical expressions of disease phenotypes—and examined their association with volumes and regional cerebral blood flow (rCBF) of bilateral anterior, mid- and posterior hippocampus segments from structural MRI scans in 318 and arterial spin labelling (ASL) in 346 nonclinical subjects, which overlapped with the structural imaging sample (N = 298). The association of hippocampal volume and rCBF with AQ, schizotypy and their interaction were performed using MANCOVA, while accounting for age, sex, IQ, depressive symptoms, and total intracranial volume. Response surface methodology was used to estimate the response surface pattern of the association of interacting autistic and schizotypal dimensions with level of hippocampal volume/rCBF.

Results: Analyses reveal that the association of positive schizotypy (a proxy of psychosis proneness) with hippocampal subfield volume variation is modulated by both AQ social skills (anterior, mid- and posterior bilaterally) as well as AQ imagination difficulties (anterior bilaterally). Moreover, results show that AQ attention switching (increased focus of attention) is associated with right hippocampal head (anterior) rCBF, and that the association of positive schizotypy with hippocampal tail (posterior) rCBF is associated with AQ attention to detail, bilaterally.

Discussion: The study’s findings provide empirical evidence for the modulation of hippocampal subfield structure and function through the interaction of subclinical schizotypal and autistic traits. Intriguingly, while positive schizotypy is associated with variation in both hippocampal volume and rCBF, its association with volume is modulated by autistic socio-cognitive traits, while its association with rCBF is with autistic attentional traits. Taken together, these results make the case for considering the synergistic impact of different (subclinical) disease spectra on transdiagnostic biological parameters in psychiatry.

F233. PSYCHOMETRIC PROPERTIES OF RADAR (RETROSPECTIVE ASSESSMENT FOR DEFINITIVE ANTIPSYCHOTIC RESPONSE) SCALE

Pavithra Jayasankar*¹, Vanteemar Sreeraj¹, Suhas Satish¹, Ranjitha R¹, Logesh K¹, Debanjan Bhattacharjee², Naren Rao³, Vijay Kumar¹, Shivarama Varambally¹, Ganesan Venkatasubramanian¹

¹National Institute of Mental Health and Neurosciences, ²Consultant Psychiatrist, ³Manoshanti Clinic,

Background: The anti-psychotic drugs are the main stay of treatment in psychotic disorders including schizophrenia. The response to anti-psychotics is heterogenous as is the symptom manifestation, course, and outcome of schizophrenia. Predicting the factors determining the response to an antipsychotic is an important step in ahead in personalizing the treatment. Most often, course of the illness is not considered while assessing the anti-psychotic response. There are no standard tools that can evaluate the long-term response to a given antipsychotic. Hence

a scale for assessment of definitive response to antipsychotic was developed. Development of the scale:

Based on literature review and expert group discussions RADAR was developed to assess response to antipsychotic over a longitudinal course of illness considering multiple factors that influence clinical improvement. It has two parts with a total of 15 items. Higher score represents the strength of definitive response to a given anti-psychotic.

Methods: This study aims to assess the concurrent validity, inter rater reliability and internal consistency of RADAR scale. Two out of three raters assessed the antipsychotic response using RADAR scale separately for 36 anti-psychotic trials. Spearman correlation was used to assess concurrent validity. Intra-class coefficient and Cronbach's alpha was calculated to measure inter-rater reliability and internal consistency respectively.

Results: There was a significant negative correlation between RADAR total score and Clinical Global Impression - Improvement (CGI – I) ($r = 0.68$, $p < 0.001$). Intra-class correlation coefficient among the two raters was 0.95 ($p < 0.001$). The Cronbach's alpha among items was 0.45.

Discussion: RADAR has good concurrent validity with CGI – I. A high inter-rater reliability is encouraging for its utility in clinical research. Future studies with higher sample would assist in standardising the tool.

F234. EXPERIENCING SCHIZOPHRENIA SYMPTOMS THROUGH AUGMENTED REALITY: FROM ASSESSING STUDENTS' NEEDS TO PROTOTYPING A SIMULATION

Emma Tison^{*1}, Solène Delsuc¹, Claudia Krogmeier², Arnaud Prouzeau², Martin Hachet², Antoinette Prouteau¹

¹University of Bordeaux, ²Centre Inria de l'université de Bordeaux

Background: The stigma of schizophrenia, in addition to being present among mental health professionals (for a review see Valery and Prouteau, 2020), is already present among students (Sideli et al., 2021) and even associated with the level of clinical experience (Fernandes, 2022). There are a whole host of technological interventions to train professionals: they have shown contradictory results, particularly in terms of impact on stigma (for a review see Rodriguez-Rivas et al., 2022 ; Tay et al., 2023). Some have actually proven counterproductive, increasing the desire of subjects for social distance from those with schizophrenia (Brown, 2020 ; Morgan et al., 2018 ; Rodriguez-Rivas et al., 2022 ; Silva et al., 2017). Rodriguez-Rivas et al. (2022) argue that these negative outcomes may be explained by the focus of the interventions on symptoms rather than the recovery process, which may increase stereotypes and prejudice. Moreover, it has been suggested that they should be used with caution and ideally in combination with educational or contact interventions (Ando et al., 2011). We aim at developing an augmented reality (AR) intervention for training mental health students. Nonetheless, there is no data on French mental health students' training needs. Our objectives were i) to explore the training needs of mental health students for an AR instrument and ii) to use this data to prototype a unique AR simulation of schizophrenia symptoms for training purposes.

Methods: A mixed participatory approach (qualitative and quantitative) was used to analyze students' needs and comprised two stages.

Following Traynor (2015) methodology, a focus group of N=6 psychology students was organized to identify i) the relevance of a survey on the training needs of health students and

ii) create the survey content. A thematic analysis of the transcript was then carried out using QDA Miner Lite. Finally, items for a survey were generated with the focus group on the basis of the thematic analysis results. The resulting questionnaire comprised 20 questions divided into 5 categories: "satisfaction with mental health training and the role of clinical practice", "legitimacy", "satisfaction with schizophrenia training", "AR tool" and "suggestions and information". It was distributed via LimeSurvey to health and social work students at University of Bordeaux. We received and analyzed 288 responses.

Results: Almost 70% (69.4%) of the sample were moderately or not at all satisfied with the information they received on schizophrenia during their initial training course. Almost 90% (88.5%) of the sample were interested in an AR simulation of the positive and negative symptoms of schizophrenia. Participants also described how they thought the simulation should be implemented: preferably in small groups (80.2%), preceded by theoretical course and a post-intervention debriefing (86.8%), with third- and first-person symptom's visualization (73.3%) and retracing different moments in the life of a person with schizophrenia (49.7%). This, with the basis of the scientific literature, enabled us to develop the AR prototype. It is a simulation of different symptoms of schizophrenia (auditory hallucinations, anhedonia, delusions, etc.) in different life contexts (schoolwork, telephone conversations, etc.). The poster will contain images and concrete examples of the content of the simulation.

Discussion: This study enabled us to obtain, create and design an AR prototype to simulate the symptoms of schizophrenia. This prototype was built not only on the basis of the scientific literature, i.e. what works best to educate and destigmatize, but also on the basis of the actual needs of the students who will be involved in this training. Future research will focus on testing the simulation in terms of training and destigmatizing efficacy.

F235. DEVELOPMENT AND VALIDITY OF LIFESTYLE SCALE FOR PSYCHIATRIC PATIENTS WITH METABOLIC SYNDROME

Bo-Hyun Yoon^{*1}, Won-Myong Bahk², Young-Joon Kwon³, Kwanghun Lee⁴, Moon-Doo Kim⁵, Haran Jeong¹, Kyungmin Kim¹

¹Naju National Hospital, ²Yeouido St. Mary's Hospital, The Catholic University of Korea, ³Soonchunhyang University, ⁴College of Medicine, Dongguk University, , ⁵Jeju National University Hospital

Background: This study examines the applicability of the 'Lifestyle Evaluation Tool for Patients with Metabolic Syndrome (LET-PMS) questionnaire' to psychiatric patients with metabolic syndrome which was originally developed for general population.

Methods: A cohort of 320 patients diagnosed with schizophrenia spectrum disorder (N=190), bipolar spectrum disorder (N=65), and depressive disorder (N=65) participated in this study. They underwent assessment using 36 items from the LET-PMS questionnaire and various established scales. The evaluation encompassed psychometric properties, including reliability analysis, exploratory factor analysis, and confirmatory factor analysis.

Results: We refined the LET-PMS questionnaire by eliminating six items through a reliability test. The resultant questionnaire exhibited 6 factors. The overall Cronbach's alpha value was 0.896, with factor-specific reliability coefficients ranging from 0.730 to 0.859. Confirmatory factor analysis of the adapted LET-PMS yielded a 0.069 (between 0.05 and 1.1) root mean square error of approximation, Goodness of fit and comparative fit indexes were 0.815 and 0.821, respectively. Consequently, all 30 items met the criteria for suitable configuration.

Discussion: 'Lifestyle Evaluation Tool for Psychiatric Patients with Metabolic Syndrome (LET-PPMS)' questionnaire demonstrated suitability for psychiatric patients with metabolic syndrome, exhibiting robust internal consistency and sound structural validity.

F236. THE ROLE OF HYPOESTROGENIC CONDITIONS IN WOMEN WITH PSYCHOSIS

Maria Antonietta Nettis^{*1}, Khalida Ismail², Robin Murray², Kathy Greenwood⁴, Zerrin Atakan², Shubulade Smith², Fiona Gaughran²

¹*South London and Maudsley NHS Foundation Trust*, ²*Institute of Psychiatry, Psychology and Neuroscience (IoPPN), King's College London*, ⁴*School of Psychology, University of Sussex and Sussex Partnership NHS Foundation Trust*,

Background: Increasing evidence suggests that oestrogen levels in women with psychosis may affect the severity and course of psychiatric symptoms, as well as response to medications. Indeed, oestrogens not only have shown neuroprotective effects, but also the ability to increase D2 receptor sensitivity to antipsychotic medications (González-Rodríguez et al. 2022) (Brand et al. 2021). However, such a protective factor in women may be lost in conditions associated with reduced circulating oestrogens, such as the menopause or iatrogenic hyperprolactinemia. In fact, antipsychotic-induced hyperprolactinaemia is associated with ovulatory dysfunction and gonadal suppression. However, the relationship between hyperprolactinemia, women's age (and related hormonal phase) and clinical symptoms of psychosis is still unclear. This work aimed at:

1. investigating how psychiatric symptoms presentation differs according to women's specific age ranges (corresponding to different oestrogenic status)
2. investigating the relationship between hyperprolactinemia and psychiatric symptoms in women with psychosis with both a cross sectional and longitudinal approach and according to different age ranges.

Methods: We analysed data on 176 women aged 18-65, from the IMPaCT study ("Improving physical health and reducing substance using in psychosis") (Gaughran et al., 2017).

We analyzed data on i) mental health status with the Positive And Negative Syndrome Scale (PANSS), and Montgomery Asberg Depression Rating Scale (MADRS); ii) current medications; iii) period frequency, with the Liverpool University Neuroleptic Side Effect Rating Scale (LUNSERS) and iv) prolactin levels, at baseline and 15-month follow-up.

We used tMann-Witney and Kruskal-Wallis tests to explore differences in clinical symptoms across different ages. We used Spearman rho correlations to investigate the association between prolactin changes and symptoms changes over time in the different age groups.

Results: We found that women aged above 40 (N=102) (when perimenopause usually starts) had higher PANSS total scores than their younger counterparts (N=63) (Mann-Whitney U=-2506.5, p=0.018). Similar results were found for PANSS General symptoms (Mann-Whitney U=2666.5, p=0.036). In women above 40, hyperprolactinemia seemed to be associated with worse positive symptoms. In particular, those with baseline hyperprolactinemia (above 510 ml/U, N=26), showed a trend towards higher baseline PANSS positive symptoms scores (Mann-Whitney U= 860.0, p=0.08) compared with women in the same age range but without hyperprolactinemia, N=47 (mean PANSS positive score= 13.23±5.83 vs 10.7±3.75, respectively). Moreover, longitudinal analyses showed a positive correlation between overtime

increases in prolactin levels and PANSS positive symptoms scores in the total sample (Spearman rho=0.332, p=0.004), and this association persisted in the group of women older than 40 (Spearman rho=0.36, p=0.012).

Discussion: Overall, hypoestrogenic conditions might affect the psychiatric presentation of women with pre-existing psychosis. Screening for and treating hormonal changes, as well as adjusting anti-psychotic medications accordingly, are crucial steps towards better care for women's mental and physical health.

F237. “AND GIVEN THAT OUR MEDICINES CAN CAUSE A PERSON TO DEVELOP DIABETES, I THINK IT COULD HAVE BEEN OUR OBLIGATION TO ACTUALLY FOLLOW UP ON IT” EXPERIENCES OF HEALTH PROMOTION WORK IN PSYCHOSIS CARE

Matilde Zerme Nilsson^{*1}, Carina Sparud Lundin¹, Katarina Eeg-Olofsson¹, Jarl Torgerson², Christopher Holmberg¹

¹*The Sahlgrenska Academy at University of Gothenburg*, ²*Sahlgrenska University Hospital*

Background: Severe mental illnesses, including schizophrenia, affect both mental and physical health, reducing life expectancy by 10-20 years attributed to several factors such as medication side effects, poor lifestyle habits, and limited healthcare access. It is therefore recommended to integrate physical health promotion into psychiatric care. However, a recent national evaluation in Sweden revealed varied adoption rates, and while there was a general increase of annually conducted health examinations, health promotion activities were not as common, and cardiometabolic mortality continued to rise. This study explores the experiences of healthcare professionals and unit leaders in Swedish psychosis outpatient units regarding health promotion efforts.

Methods: This study adopted an interview study design, using thematic analysis and abductive approach. Participants consisted of ten healthcare professionals (HCP) (e.g., physician, nurses, psychologist) and 3 heads of units from psychosis outpatient units. Self-determination theory was employed to explore motivation among HCPs and head of units regarding working with patients' physical health.

Results: The participants described their experiences of health promotive work with patients as complex and influenced by various factors. Theme 1, "Organizational prerequisites". Routines, working methods and HCPs perception of these means affects efficiency. Resources such as allocated time was a crucial, specialized HCPs and a supportive environment, e.g. nature access, enhanced health promotion.

“I know that we are very bad at doing annual follow-ups. We still try, and it is up to each HCP and the doctor to do it once a year. But I think only some people choose to do it.” Theme 2: "Health care professional's competences and attitudes". Attitudes and values held by HCPs impacted the execution of health initiatives and was crucial for motivation. HCPs varied in their strategies and approaches to promote physical health, including motivational work. Challenges lead to discontinuation, requiring recurring motivational approaches. “It is not only that we should increase physical health to reduce the risk of dying from cardiovascular diseases, but also to increase the mental well-being of the person.” Theme 3: "Patient related aspects". Participants detailed various patient-related factors influencing physical health and requiring interventions. Socio-demographic aspects and factors associated with schizophrenia, including lifestyle habits, symptoms and duration of illness perceived to have an impact. The negative

effect of antipsychotic medications on physical health is highlighted and pose a dilemma for HCPs. “You don’t seek help for your somatic problems very often. You wait and when you do seek help, you’re not received in the way another person would have been.”

Discussion: The study emphasizes the importance of organizational support, the competence of the HCP, and an understanding of patient-related aspects. The HCP's level of self-determined interest in physical health impacts engagement with health promotive measures. Having specialized staff with expertise in physical health within the psychiatric team promotes teamwork and reduces concerns about insufficient competence among HCP when addressing patients' physical health. The three tenets of Self-Determination theory (competence, relatedness, and autonomy) were evident across all themes, indicating a promising way forward to increase motivation for measurements focused on physical health within psychosis outpatient care.

F238. FACTORS ASSOCIATED WITH PHYSICAL ACTIVITY IN A BRAZILIAN SAMPLE OF PATIENTS WITH SCHIZOPHRENIA

Joao Salgado*¹, Breno Cruz¹, Edilene Silva¹, Vinícius Pietra², Lucas Mantovani²

¹*Federal University of Minas Gerais*, ²*Instituto Raul Soares*

Background: In individuals with schizophrenia, the average life expectancy is approximately 14.5 years less than that of the general population. Recent data indicate that physical illnesses account for 75% of deaths in this population, with cardiovascular diseases related to metabolic syndrome (MS) being the leading cause of death. Behavioral factors such as an unhealthy lifestyle, including low physical activity, substance abuse, smoking, and inadequate diet, contribute to the increased risk of cardiovascular diseases and MS among patients with schizophrenia. A meta-analysis by Stubbs et al. (2016) revealed significantly lower levels of physical activity, both moderate and vigorous, in patients compared to control individuals. Understanding the factors associated with this reduced physical activity, including their geographical and cultural nuances, is crucial. This study aims to assess the socioeconomic and clinical factors associated with physical activity in a Brazilian sample of patients with schizophrenia.

Methods: Sixty-three stabilized schizophrenia patients from three tertiary psychiatric centers were evaluated. Diagnosis confirmation was conducted using the SCID-5, and stability was determined by a score of less than 20 on the PANSS positive subscale. The Simple Physical Activity Questionnaire (SIMPAQ) was employed, with its subscales indicating bed rest, sedentary behavior, walking, physical exercise, and other physical activities. Patients also completed a sociodemographic-clinical questionnaire and the Simpson Angus scale for extrapyramidal symptoms. Due to non-normal distribution, correlations were assessed using the Spearman test.

Results: No significant correlations were found between positive and negative symptoms (evaluated by PANSS), age, gender, education, or family income with SIMPAQ variables. Negative symptoms showed a trend of correlation with subscale 3 (walking, $p = 0.06$) and 4 (physical activity, $p = 0.07$). Antipsychotic dosage, assessed by chlorpromazine equivalent, exhibited significant negative correlations with physical exercise (subscale 4) and overall physical activity (sum of subscales 3, 4, and 5). No significant correlation was observed between benzodiazepine or biperiden use and SIMPAQ variables. Extrapyramidal symptoms assessed by the Simpson-Angus Scale showed a significant positive correlation with time spent in bed (subscale 1, $p=0.01$) and sedentary behavior (subscale 2, $p=0.02$).

Discussion: The results suggest that antipsychotic dosage, assessed in chlorpromazine equivalent, and the presence of extrapyramidal effects, resulting from high doses of antipsychotics, are significant factors in the reduced physical activity of patients. These findings are preliminary, and the lack of a significant effect in some correlations (e.g., negative symptoms) may be due to the small sample size. Regression models to control intervening variables should be employed in future research.

F239. UNDERSTANDING THE DEMOGRAPHIC AND PSYCHOSOCIAL RISK FACTORS FOR PHYSICAL MULTIMORBIDITY IN PSYCHOSIS: A SYSTEMATIC REVIEW

Erin Lawrence^{*1}, Abigail Thomson¹, Kamaldeep Bhui², Mark Freestone¹, Georgina Hosang¹

¹*Queen Mary University of London*, ²*University of Oxford*

Background: People with psychotic disorders have a reduced life expectancy of up to 18 years relative to the general population. A key factor contributing to this premature mortality within this group is the high prevalence of physical multimorbidity (MM [co-existence of two or more physical long-term health conditions]). This includes the co-occurrence of cardiovascular, metabolic, and respiratory diseases, but little is known about the psychosocial factors, such as stress, that may elevate the risk of physical MM in this population. In view of this, we conducted a systematic review aiming to identify demographic and psychosocial risk factors for physical MM among individuals with psychotic disorders.

Methods: The systematic review protocol was registered with PROSPERO (CRD42022382661) and conducted in accordance with PRISMA guidelines. Three databases (Embase, PubMed, and PsychINFO) were searched from March 2023 with no limits for study design up to December 2023. Studies were eligible for inclusion if they assessed the impact of demographic and/or psychosocial factors on physical MM outcomes among people with psychotic disorders. Forwards and backwards citation searches were conducted on the study papers eligible for inclusion in the review. Grey literature such as preprints, PhD theses and public health research were also considered.

Results: Of 4361 articles, 11 met the inclusion criteria. Study quality was deemed reasonable for all included articles. Preliminary findings of this review identified the following demographic and psychosocial risk factors for physical MM in psychosis: gender, age, age of psychotic illness onset, ethnicity, material deprivation and childhood maltreatment. Groups at higher risk of physical MM include women, those with an earlier age of psychotic illness onset, Black African, Black Caribbean and Black British ethnic groups (compared to White British groups), Malay and Indian ethnic groups (compared to Chinese ethnic groups), those living in areas with high levels of material deprivation, and individuals who have experienced childhood abuse or neglect. The included studies reported mixed findings for age as a risk factor for physical MM.

Discussion: The findings provide insights into vulnerability factors that can inform strategies for preventing physical MM, aiming to improve the quality of life for individuals and mitigate premature mortality rates among individuals with psychotic disorders. However, risk factors for MM in psychosis remain understudied. Further research is needed to replicate and extend existing preliminary findings and identify additional potential psychosocial risk factors that are yet to be investigated, such as social isolation. Study limitations include varied definitions of MM. Future research should adopt a universal definition of physical MM to allow for valid comparisons across studies.

F240. PREDICTING METABOLIC RISK IN EARLY PSYCHOSIS - EXTERNAL VALIDATION OF THE PSYCHOSIS METABOLIC RISK CALCULATOR

Jaakko Keinänen*¹, Benjamin Perry², Saana Eskelinen³, Jaana Suvisaari⁴, Graham Murray²

¹*University of Helsinki*, ²*University of Cambridge*, ³*Helsinki University Hospital*, ⁴*Finnish Institute for Health and Welfare*

Background: The risk of cardiometabolic dysfunction, including metabolic syndrome, is high during the first years of early psychosis. We conducted an external validation of the psychosis metabolic risk calculator (PsyMetRiC), a cardiometabolic risk prediction tool tailored for young people with psychosis originally developed in the UK. PsyMetRiC has been validated in the UK and two Western European nations. We tested its predictive performance in a Finnish sample of individuals with first-episode psychosis (FEP) and high-risk for psychosis, with the aim of recognizing individuals with high risk for cardiometabolic dysfunction. Prediction of the metabolic risk is important to effectively target interventions to individuals with the highest risk of metabolic dysfunction, and testing in different populations is critical to confirm generalisability and likely clinical usefulness.

Methods: We conducted an external validation of PsyMetRiC in a sample of individuals over 18 years of age with early psychosis recruited to the Helsinki Early Psychosis Study and Turku Early Psychosis Study. After excluding those with baseline metabolic syndrome and individuals over 35 years, the sample consisted of 210 individuals. Of those, 146 were FEP patients from the Helsinki and Uusimaa Hospital District (n=97) and Turku and the Southwest Finland Hospital District (n=49). The cohort also included 104 individuals with high-risk for psychosis (n=60 fulfilled SIPS criteria; 47 clinically evaluated as high-risk). Discrimination (C-statistic), calibration (calibration plots), and decision curve analysis were used to assess the predictive performance and clinical utility of PsyMetRiC.

Results: We included 210 individuals with early psychosis (of them all were of White European ethnicity, 59% male, mean age 24.6 years, 39% smoking, mean BMI 23.7). Discrimination was better in the full model compared with partial model (full model C=0.73, 95% CI, 0.63–0.80, partial model C=0.68, 95% CI 0.60–0.75). For the high-risk for psychosis sample, discrimination C-statistics were 0.71 (95% CI 0.58-0.85) and 0.66 (95% CI 0.51-0.80) for the full and partial models, respectively. Calibration plots displayed evidence of minor miscalibration which corrected after recalibration. Decision curve analysis showed that PsyMetRiC offers clear evidence of likely clinical usefulness in improving cardiometabolic risk management in individuals both with psychosis, and those at high-risk for psychosis.

Discussion: This study showed that PsyMetRiC has utility in predicting cardiometabolic risk also in high-risk for psychosis population, as well as in individuals with FEP, in Finland. Predictive performance in this study was similar to external validations in other European nations, suggesting that PsyMetRiC is likely to be generalisable for use. Recalibration further improved the predictive accuracy of PsyMetRiC. Further studies with larger sample sizes and with samples from different geographical locations are needed to further improve the performance of the models. With adjustments to account for the differences in metabolic risk in different populations, PsyMetRiC can be used to target interventions effectively.

F241. EXPLORING SEX DIFFERENCES IN PHYSICAL ACTIVITY PATTERNS AMONG INDIVIDUALS WITH SCHIZOPHRENIA SPECTRUM DISORDER: INSIGHTS FROM THE DIAPASON PROJECT

Alessandra Martinelli*¹, Elena Toffol¹, Giulia Moncalieri¹, Silvia Leone¹, Jacopo Santambrogio², Matteo Rocchetti³, Manuel Zamparini¹, Martina Carnevale⁴, Stefano Calza⁴, Giovanni de Girolamo¹

¹*IRCCS St. John of God Clinical Research Centre*, ²*Adele Bonolis AS.FRA. Onlus Foundation, Vedano al Lambro (MB)*, ³*ASST of Pavia*, ⁴*University of Brescia*

Background: Schizophrenia Spectrum Disorders (SSD) affect females differently than males, yet there is limited research on Physical Activity (PA) levels and possible sex differences in patients with SSD. This is a prospective cohort study with the aim of comparing PA levels between patients with SSD and control participants, matched by sex and age, with a specific focus on sex differences.

Methods: As part of the DiAPAsen project, 132 patients with SSD, living either in a residential or outpatient setting (48 females and 84 males), and 113 healthy controls (46 females and 67 males) were assessed using standardised clinical tools. PA levels were monitored for seven consecutive days using a wearable actigraph; data on socio-demographics, clinical and anthropometric characteristics were collected along with assessments of symptom severity, cognition, and functioning. Descriptive and regression analyses were conducted.

Results: Levels and patterns of PA did not differ by sex among SSD patients, while female controls spent longer times in sedentary activity than male controls (787.3 vs 706.8 minutes, $p < 0.001$). Male patients spent more time in sedentary activity ($p < 0.001$) but less time in light PA (both $p < 0.001$) and MVPA (respectively, $p < 0.001$ and $p = 0.004$) compared to male controls. Outpatient and female residents spent longer time in Sedentary PA (respectively, $p = 0.006$ and $p = 0.020$) than female controls; female outpatients spent significantly less time in daily light PA ($p = 0.008$), and female residents in MVPA ($p = 0.002$) than female controls. Higher levels of psychosocial functioning were associated with higher moderate PA (*60 min/day: $B = 4.21$; 95%CI=0.70 to 8.33; percentage: $B = 0.57$; 95%CI=0.08 to 1.21) and MVPA bouts per weekday (*60 min/day) ($B = 5.34$; 95%CI=0.65; 11.40) in male patients only.

Discussion: Our findings suggest that male patients with SSD may benefit from MVPA-focused interventions across settings, while personalized PA interventions tailored to specific settings could be more beneficial for female patients.

F242. PSYCHOTHERAPY FOR PSYCHOSIS AS A SYNDROME: PROTOCOL OF A RANDOMIZED CONTROLLED TRIAL FOR A SYMPTOM-BASED MANAGEMENT APPROACH FOR PSYCHOSIS

Edo Jaya*¹

¹*University of Indonesia*

Background: In light of recent shortcomings in treatment developments derived from decades of researching the causes and treatment of psychosis, there has been a reevaluation of the disorder, considering it as a syndrome (e.g., Carpenter, 2016, 2022; van Os and Guloksuz, 2022). This perspective views the condition not as a singular disease necessitating a uniform treatment but as a cluster of symptoms stemming from various causes that demand specialized interventions. Notably, randomized controlled trials (RCTs) focusing on psychotherapies tailored to specific comorbidities among individuals with psychosis have not only alleviated the targeted disorder but also subsequently reduced psychotic symptoms (e.g., insomnia (Freeman et al., 2015)). In accordance with the syndrome model of schizophrenia, psychotic symptoms could be construed as emerging from a combination of coexisting mental disorder

symptoms, and improvements may thus manifest upon identification and treatment of these comorbidities. Cognitive Behavioral Therapy for psychosis (CBTp) has amassed substantial evidence of its efficacy in treating schizophrenia as a discrete disorder. Our aim is to devise a CBTp tailored for schizophrenia as a syndrome.

Methods: We plan to carry out a two-arm (treatment vs. treatment-as-usual), assessor-blinded Randomized Controlled Trial (RCT) involving 150 outpatients aged 18-65 diagnosed with psychosis (specifically, schizophrenia or schizoaffective disorder) from two Indonesian cities (Jakarta and Padang). The aim is to evenly split the sample between the two groups to detect a moderate-to-large effect size with 80% power and a significance level of 0.05. Crucial participant inclusion criteria will be a Psychotic Symptoms Rating Scale (PSYRATS) score of 2 or higher for either hallucinations or delusions, persisting for at least three months.

Exclusion criteria will entail a primary diagnosis of substance use disorder, organic syndrome (including brain injury), language deficits hindering engagement in therapy, or ongoing enrollment in other individual psychotherapy. Participants experiencing significant changes in pharmacotherapy must wait at least one month for stabilization of the new dosage. Random allocation (1:1) will be based on participants' city of residence.

Primary outcome measures will assess psychotic symptoms using PSYRATS, Brief Psychiatric Rating Scales (BPRS), and Community Assessment of Psychic Experience (CAPE-42). Secondary outcomes will cover depression, general anxiety, somatoform symptoms (Patient Health Questionnaire), panic symptoms (Panic Disorder Severity Scale), insomnia (Insomnia Severity Index), obsessive-compulsive symptoms (Obsessive-Compulsive Inventory-Revised), mania (Young Mania Rating Scale), trauma (International Trauma Questionnaire), and social anxiety (Social Phobia Inventory). Additionally, emotional regulation skills (Emotional Regulation Skills Questionnaire) and loneliness (UCLA Loneliness Scale 6) will be evaluated. Follow-up assessments are planned at 8 and 24 weeks.

The CBT for psychosis as a syndrome will systematically address comorbidities by utilizing case formulation to direct the treatment sequence. For instance, priority will be given to addressing social anxiety if it is identified as a trigger for depression through social withdrawal. Additionally, it will follow combinability principles, such as integrating behavioral activation for depression with sleep hygiene techniques for managing insomnia. The treatment manual will encompass a range of CBT techniques tailored for common comorbidities associated with psychosis. These techniques include exposure-and-response-prevention for managing symptoms of obsessive-compulsive disorder, sleep hygiene strategies for insomnia, behavioral activation to address depression, behavioral experiments targeting social anxiety, and interoceptive exposure techniques for managing panic disorder.

Statistical analyses will adhere to an intention-to-treat basis. A planned mediation analysis will investigate whether the reduction in comorbidities mediates the decrease in psychotic symptoms.

Results: The expected outcomes will include a significant reduction in psychotic symptoms, as assessed with the PSYRATS, BPRS, and CAPE-42 compared to treatment as usual. Additionally, significant improvement will also be anticipated in the secondary outcome measures. These significant differences will be expected to be observable during the 8 and 24-week follow-up. Furthermore, the longitudinal mediation analyses will be expected to demonstrate that changes in the secondary outcome measures lead to changes in psychotic symptoms.

Discussion: The trial results will shed light on the effectiveness of symptom-based management in treating psychosis, a complex disorder characterized by numerous comorbidities. Hopefully, the evidence gleaned from this trial may contribute to the discussion on whether schizophrenia can be regarded as a syndrome.

F243. “NO TEARS OR BRAIN WORDS”: A CASE REPORT ON SINGLE-SESSION DANCE/MOVEMENT THERAPY FOR INDIVIDUALS WITH SCHIZOPHRENIA

Jacelyn Biondo*¹

¹N/A

Background: Individuals diagnosed with schizophrenia face a multitude of challenges in their lifetime including complex symptomatology, co-morbid health concerns, profound levels of stigmatization, diminished access to quality care, and an overall lack of healthcare equity. Systemically racist provisions and social determinants of health further stigmatize these individuals, calling for action against such human rights violations. Globally, over 21 million people are diagnosed with schizophrenia, many of whom are experiencing healthcare disparities posing a significant public health concern. Dance/movement therapy (DMT) is an equitable healthcare provision situated in a strengths-based and trauma-informed psychotherapeutic framework. Dance/movement can support the symptomatic needs of schizophrenia including alternate reality orientations, thought and behavioral disorganization, and diminished interpersonal engagement.

Methods: This intrinsic case report examines the experience of a 37-year-old African American cisgender male who engaged in a single-session DMT intervention. This report explores an under-researched phenomenon of the lived experience of a DMT intervention for an individual with high symptom acuity. It will review the quantitative data, reviewing the Brief Psychiatric Rating Scale (BPRS) scores individually and as compared with other members of the DMT cohort. Additionally, the report will highlight the participant's experience in the DMT session through qualitative data collected in a semi-structured individual interview following the single-session intervention.

Results: Results showed that following the intervention, the participant exhibited a decrease in symptomatology as evidenced by the BPRS in total scores as well as subscales of psychological distress, positive symptoms, negative symptoms, and resistance. Moreover, in his interview, the participant expressed having a transformative experience in the single-session DMT intervention, feeling like a contributing member of the group process, exhibiting a sense of pride, experiencing the ability to engage in healthy relationships, and noting shared and meaningful experiences in his group process.

Discussion: This case report highlights the impactful effects of a single-session DMT intervention for a participant experiencing acute positive symptomatology and affective dysregulation associated with a diagnosis of schizophrenia. Historically, research has listed positive or acute exacerbations of schizophrenia as exclusionary criteria. This is not only a human rights violation (Hall et al., 2019; WHO, 2023), but is also deeply rooted in stigmatization against individuals diagnosed with schizophrenia. Moreover, this disallows data collection, phenomenological experiences, and overall voices of individuals with schizophrenia when making decisions regarding treatment, research, and policy. The particular participant identified in this case report is one who may have otherwise been excluded from both psychosocial treatment and research opportunities due to the acuity of his presentation. Details of this case report suggest that individuals experiencing acute symptomatology and high levels of positive symptoms can not only participate in appropriately designed

interventions, but they can also experience changes towards health in a brief intervention. The disparities faced by individuals diagnosed with schizophrenia are a violation of human rights and dehumanize this population by diminishing their value through limited quality and accessibility of healthcare options. Dance/movement therapy is an inclusive, strengths-based, trauma informed psychotherapeutic treatment option that aims to reduce stigma, increase accessibility, and create spaces of inclusion and belonging. Its focus on non-verbal communication and processing of unconscious material through the arts and creative expression makes DMT an innovative and promising intervention for those who may not prioritize verbal language and may experience alternate reality bases as compared to the general population. Moreover, the trauma-informed approach of DMT provides consideration, awareness, and incorporation of social determinants of health as factors that contribute to diagnoses and symptomatology.

F244. ATHENS MULTIFAMILY GROUP THERAPY PROJECT (A- MFGT) AFTER A FIRST PSYCHOTIC EPISODE: PRELIMINARY CLINICAL RESULTS

Mirjana Selakovic*¹, Dimitris Galanis², Afrodite Zartaloudi³, Afrodite Feretzaki¹, Irine Ralli⁴, Vasiliki Efsthathiou⁵, Valeria Pomini⁴

¹*GH Sismanogleio*, ²*EPAPSY*, ³*Nursing University of West Attica*, ⁴*National and Kapodistrian University of Athens Medical School, Eginition Hospital*, ⁵*School of Medicine, National and Kapodistrian University of Athens*

Background: Family interventions have been shown to reduce the likelihood of relapse for individuals across the spectrum of psychosis and are recommended in practice guidelines for psychosis internationally (Mc Farlane, 2016). The Athens Multifamily Group Therapy Project (A- MFGT) aims to provide systemic multifamily therapy to youths who experienced a first psychotic episode and their families.

Methods: A group of 22 young adults who presented a first psychotic episode participated with their families to multi-family group systemic therapy, after discharged from in-patient treatment. Sessions were conducted by three therapists twice a month, for nine months and supervision meetings were provided once a month. Six groups of families have been conducted since 2017. Clinical outcome was assessed through PANSS at baseline, one month later after patient's discharge from in-patient treatment, and one year after, at the end of the multifamily group treatment. Time intervals till relapse were also assessed. Participants' clinical findings were compared with findings from a matched group of 40 patients who did not attend the multifamily therapy program and were treated as usual.

Results: Two-way mixed ANOVA was conducted to assess PANSS scores change over time (t1: at base line, t2: at one month and t3: one year), while differences were investigated between the two groups of patients and interactions were checked. Regarding PANSS-positive scale and PANSS-general scale, no differences were found between the two groups in neither of the three time points; Regarding PANSS-negative scale, patients attending MFGT presented statistically significantly lower scores in t3 than patients treated as usual, but not in t1 and in t2 (i.e., prior to therapy). Moreover, both patients' group showed improvement from t1 to t2, but only patients attending MFGT further improved from t2 to t3. Among patients attending MFGT 2 (9.1%) had a relapse compared to 9 (22.5%) of the patients treated as usual, however this comparison did not reach statistical significance ($p = 0.300$).

Discussion: MFGT seems to be a viable way to support the patient as well as the whole system facing psychosis, with the aim of preventing relapse and implementing quality of life for all the participants.

F245. FORMATION OF A WORKING ALLIANCE AND POTENTIAL EFFICACY OF A DIGITAL THERAPEUTIC TO TREAT EXPERIENTIAL NEGATIVE SYMPTOMS OF SCHIZOPHRENIA

Cornelia Dorner-Ciossek¹, Cassandra Snipes², Eehwa Ung³, Brendan D Hare^{*4}, Alankar Gupta⁵, Shaheen E Lakhan²

¹Boehringer Ingelheim International GmbH, ²Click Therapeutics, Inc., ³Click Therapeutics, Inc. (at time of study); University of California, San Francisco (USCF), ⁴Boehringer Ingelheim Pharmaceuticals, Inc.; Click Therapeutics Inc. (at time of study), ⁵Click Therapeutics, Inc. (at time of study)

Background: Experiential negative symptom (ENS) severity predicts real-world functioning in schizophrenia. However, currently there are no FDA-cleared pharmacological treatments for schizophrenia that satisfactorily address ENS. A digital therapeutic (DTx) designed to impact ENS could deliver evidence-based care while addressing access barriers given widespread smartphone ownership. The development, approval and use of DTx are steadily increasing, although there has been limited testing in schizophrenia. Here we report results from two exploratory studies to evaluate a beta version of CT-155 for the treatment of ENS in patients diagnosed with schizophrenia. These studies aimed to explore whether patients living with schizophrenia could form and maintain a digital working alliance (DWA) with a beta version of CT-155 (Part 1) and assess the impact of using a beta version of CT-155 on ENS (Part 2).

Methods: Part 1: Single arm, 3-week, multi-centre study of a beta version of CT-155 in adults with ENS of schizophrenia. Part 2: Single-arm, 7-week, multi-centre study of a second beta version of CT-155 in adults with ENS of schizophrenia. For both studies, patients were aged ≥ 18 years with schizophrenia, self-reported ENS (score of ≤ 30 on the Motivation and Pleasure-Self Report) and were on stable antipsychotic medication for ≥ 12 weeks. Patients had on-demand access to a beta version of CT-155 and engagement was measured throughout the studies. ENS were assessed at baseline using the Clinical Assessment Interview for Negative Symptoms Motivation and Pleasure Scale (CAINS-MAP). DWA was assessed weekly via the mobile Agnew Relationship Measure (mARM) in Part 1, and at Week 3 in Part 2.

Results: In Part 1, 49 adult patients were enrolled of whom 46 (94%) completed the study. In Part 2, 50 adult patients enrolled of whom 43 (86%) completed the study. In both studies, the majority of patients were male (71% and 80%, respectively), non-white (57% and 70%), and never attended college (63% and 64%), with a median age of 46 and 54 years, respectively. In Part 1, total and subscale mARM scores indicated that a positive DWA was established with a beta version of CT-155 after one week (mean [standard deviation; SD]: 5.15 [0.7]) and was maintained over 3 weeks (5.16 [0.8]). As expected, mARM scores positively correlated with number of sessions completed ($r^2=0.4$, $p=0.01$). We did not observe a significant difference in mARM depending on ENS severity. In Part 2, a DWA was again established within 3 weeks (mean [SD] mARM score: 5.36 [1.1]). Patients opened a beta version of CT-155 on 77% of the 49 study days and engaged for ≥ 60 seconds in a mean (SD) of 42 (19.6) sessions. ENS (CAINS-MAP score) were significantly reduced ($p=0.004$) in the 7 weeks from baseline (mean [SD]: 20.2 [8.6]) to end of study (16.8 [7.8]; $n=43$). In both studies, no relationship between CAINS-

MAP and lesson completion was observed. There were 3 non-serious and non-treatment-related adverse events reported in Part 2.

Discussion: Patients formed and maintained a positive DWA with a beta version of CT-155 over the 3-week period and use of this DTx significantly improved ENS symptoms in patients diagnosed with schizophrenia. These highly favourable findings alongside the positive safety profile support advancing CT-155 into late-phase clinical development.

Clinical research was funded by Boehringer Ingelheim and Click Therapeutics.

F246. BRAIN (BETTER UNDERSTANDING AND PREVENTION OF NEUROPSYCHOLOGICAL DIFFICULTIES): A TOOLKIT OF KNOWLEDGE TRANSFER DEVELOPED WITH AND FOR PERSONS WITH LIVED EXPERIENCE

Caroline Cellard^{*1}, Caroline East-Richard¹, Élisabeth Thibaudeau², Geneviève Dufour³, Ariane Giguère-Rancourt¹, Éva Racine¹, Mélissa Turcotte¹, Andréanne Simard¹, Gabriel Demers¹, Jean-Jacques Tremblay¹

¹Université Laval, ²McGill University, Douglas Mental Health University Institute, ³CIUSSS de la Capitale Nationale

Background: “I might not be as smart as my friends” or “I forgot my books at home... again” are cognitive subjective complaints reported by people with cognitive impairments. Cognition is defined as the perception, learning, understanding, and use of information that involves domains such as attention, memory and executive functions. Cognitive impairments are highly prevalent in people with schizophrenia spectrum disorders and have detrimental effects on daily functioning and recovery. Despite the prevalence and consequences of these impairments, a gap remains in knowledge transfer, regarding cognitive impairments and their impacts, from research to the general population, including people with schizophrenia spectrum disorder. As such, providing an informational toolkit of evidence-based and accessible information regarding cognition and cognitive impairments could help individuals better understand their difficulties and receive timely and appropriate care. However, to increase the relevance of this information, it is essential to co-develop these tools in collaboration with health care professionals as well as people with lived experience of schizophrenia spectrum disorders.

Methods: The co-development of a toolkit called BRAIN (Better undeRstanding And prevention of Neuropsychological difficulties) will be presented. Open science principles on co-design and knowledge transfer were used to develop BRAIN. Both health care professionals and people with lived experience were involved in the iterative development of the toolkit from the discussions about their needs to comments about the different versions of the toolkit. This co-design methodology was used to ensure that the toolkit was both clinically relevant and responded to the needs of everyone involved.

Results: An initial theoretical booklet was developed to explain cognitive functioning, the impact of cognitive impairments on daily life, as well as the factors that can influence the development of cognitive impairments (e.g. mental disorders). This was followed by the development of several clinical booklets intended for various ages and groups, including adolescents, young adults, as well as family and friends. Additionally, a web platform comprised of 27 video capsules explaining different cognitive domains and strategies was recently developed.

Discussion: The co-design of the BRAIN toolkit led to engaging, flexible and service user-focused information about cognition to increase knowledge transfer from research to the daily lives of people with lived experience of schizophrenia spectrum disorders and the clinical practice of their health care professionals. The next step will be to evaluate the acceptability of the Brain toolkit in clinical settings.

F247. CO-STARS: A CO-PRODUCED, CULTURALLY APPROPRIATE MENTAL HEALTH LITERACY TRAINING PACKAGE TO REDUCE MENTAL HEALTH INEQUALITIES FOR BLACK MINORITY GROUPS FROM UNDERSERVED COMMUNITIES

Sian Lowri Griffiths*¹, Eliza Cherrington¹, Gerald Jordan², Luke Brown¹, Megan Pope¹

¹*University of Birmingham*, ²*Yale University*

Background: Psychotic disorders are among the most disabling illnesses worldwide and disproportionately affect minoritized ethnic groups and those in socioeconomic disadvantage. Within the UK, people from Black ethnic backgrounds (African, Caribbean, British) are 3-5 times more likely to experience a first episode of psychosis (FEP), five times more likely to be detained, and are more likely to be subjected to the Mental Health Act than White British people. Factors contributing to these disparities are complex and influenced by wider inequities within and beyond health systems, including bias, discrimination, cultural insensitivities, and racism towards Black individuals. This often perpetuates feelings of mistrust, disempowerment, and disengagement with services, which is further compounded by stigma and lack of recognition of the symptoms of mental illness within Black communities. There is a clear need for services to improve cultural awareness and understanding of the broader social needs of minoritized groups, as well as the eradication of racial bias and discrimination from mental health services. Improving mental health literacy within Black communities will empower individuals to advocate for their mental health, seek timely support, and identify gaps in service provision.

Methods: Co-STARS is a participatory social action research study which aims to co-produce a culturally appropriate mental health literacy training package delivered by young people with lived experience to underserved communities across Birmingham, UK, and via an e-learning package implemented within Early Intervention Services (EIS).

Results: Eight young people (18-30 years) from Black ethno-racial Background:s with lived experience of severe mental illness are participating in a series of co-produced workshops and 1:1 interviews to develop training outputs (completion February 2024). Clinical staff from EIS (N=8) will also be recruited along with carers (N=6). Interview transcripts and workshop observation notes will be subjected to thematic analysis by two researchers (e.g., research associate and peer researcher) to identify recurrent and important themes, using computer-assisted qualitative data analysis software (NVivo).

Discussion: The outputs from the co-production will provide a novel, culturally adapted mental health training package to tackle mental health inequalities in care access and outcomes for underserved groups. The second phase of this project will co-evaluate the implementation of the training resources within a feasibility study adopting participatory Methods: and novel epidemiological analyses to explore downstream effects of the training (i.e., improved care access and reductions in compulsory detentions for Black ethno-racial groups within a targeted intervention area in Birmingham, UK).

F248. SPEAKING ABOUT STIGMA: EXPERIENCES OF STIGMA AND SELF-STIGMA IN YOUNG PEOPLE AT-RISK OF PSYCHOSIS

Zoe Waters*¹, Yael Perry², Ashleigh Lin¹, Jeneva Ohan¹

¹University of Western Australia, ²Telethon Kids Institute, University of Western Australia

Background: The stigma associated with mental illness has a profound effect on those that experience it, and may give rise to self-stigma, which involves the internalisation of negative public stereotypes. Stigma and self-stigma are known to produce harmful outcomes such as reduced self-esteem, and increased hopelessness and suicidality. While psychotic disorders are widely recognised as the most stigmatising of all mental health disorders, there is currently a dearth of research investigating how stigma and self-stigma are experienced by young people at ultra-high risk for psychosis. Consequently, the current qualitative study sought to explore how young people at ultra-high risk of psychosis experience stigma and self-stigma.

Methods: 12 young people identified as being at ultra-high risk for psychosis aged 14-25 participated in this study. 6 participants were interviewed in a one-on-one meeting about their experiences with stigma and self-stigma, and 6 took part in an online workshop exploring stigma and self-stigma in the ultra-high risk of psychosis population. The interviews and focus group were transcribed and analysed using reflexive thematic analysis.

Results: Five themes were developed through reflexive thematic analysis, including: 1) Being UHR is an inherently difficult, uncertain experience; 2) Stigma is a pervasive force; 3) Stigma becomes internalised; 4) Stigma is painful; and 5) Defending against stigma, which contains three subthemes including 5i) Hiding one's UHR status; 5ii) Rebutting stigma; and 5iii) Educating self and others. All participants identified experiences with stigma and self-stigma, reflecting the widespread impact of stigmatising beliefs and attitudes upon these young people.

Discussion: Results indicated that although they are not necessarily diagnosed with a psychotic disorder, young people at UHR for psychosis experience pervasive stigma that has detrimental consequences for them and leads them to seek ways to protect themselves and others from stigma. Given the complexity of the ultra-high risk population, where co-occurring mental health conditions are the rule rather than the exception, there is a clear need to understand experiences of stigma and self-stigma from an intersectional lens that includes consideration of other mental health diagnoses. Additional research is required further explore the effects of stigmatising beliefs upon this vulnerable population.

F249. QUALITATIVE ANALYSIS OF MENTAL HEALTH CLINICIANS' EXPERIENCES OF TALKING WITH PEOPLE ABOUT HEARING VOICES

Kriti Sharma*¹, Jenny Barnes², Aikaterini Rammou³, Mark Hayward⁴, Neil Thomas¹

¹Swinburne University of Technology, ²Canterbury Christ Church University, ³University of Sussex, ⁴Sussex Partnership NHS Foundation Trust

Background: Hearing voices is a common symptom of schizophrenia that can often be distressing and disabling for many individuals. In contrast to the amount of research investigating formal therapies such as cognitive behavioural therapy for psychosis (CBTp), there has been very little examining practice models for the broader mental health workforce to incorporate into day-to-day work with clients who hear voices. The current study aimed to identify the types of questions asked and the range of strategies that frontline mental health practitioners currently use when talking with people who hear voices.

Methods: A sample of 148 UK National Health Service mental health staff completed an electronic survey regarding their experiences of speaking with clients about their experiences of hearing voices. Adopting an inductive approach, content analysis was used to analyze the survey responses and code subcategories relevant to the research questions. These were then grouped into categories and overarching themes.

Results: The themes which emerged were to: (1) help the person feel understood and safe to discuss voices; (2) explore the person's experience of voices; (3) discuss how the experience of voices affects the person; (4) discuss meaning associated with voices; (5) give information about the experience of hearing voices; and (6) help the person be less impacted by the voices. Themes 1 and 6 were the two most frequently endorsed themes, with both reported by more than half of practitioners surveyed (54.1% and 61.5% respectively).

Discussion: This study identified a range of strategies currently used by practitioners in their interactions about hearing voices. Many of these are common factors of general mental health practice and are not unique to conversations about hearing voices. The strategies which emerged also converged with common practices within noted approaches to support voice hearers such as CBTp and Hearing Voices Network (HVN) groups. The results indicate the utility of future research evaluating the usefulness of a combination of strategies from both modalities and increased synergy between professionals and HVN groups. However, by comparing the results of the current study with past research there were potential discrepancies highlighted between how various professional disciplines approach interactions about voices. This should be further investigated and may be remedied by the formulation of multidisciplinary practice guidelines. The results of the current study are being used to formulate a Delphi seeking consensus on which elements of practice are essential when supporting someone hearing voices.

F250. EXPERIENCES OF CHILDHOOD POVERTY AMONG COORDINATED SPECIALTY CARE SERVICE USERS AND ASSOCIATIONS WITH CLINICAL OUTCOMES: PRELIMINARY DATA FROM THE CALIFORNIA EPI-CAL PROJECT

Kathleen E. Nye^{*1}, Valerie L. Tryon¹, Stephania L. Hayes¹, Deanna M. Barch², Mark Savill¹, Sabrina Ereshefsky¹, Katherine Pierce¹, Chelyah Miller¹, Madison J. Miles¹, Amanda McNamara³, Merissa Kado-Walton³, Khanh Linh H. Nguyen¹, Nitasha Sharma¹, Christopher K. Hakusui¹, Viviana Padilla¹, Maliha Safdar³, Rachel Loewy⁴, Laura M. Tully¹, Andrew J. Padovani⁵, Leigh Smith¹, Adam B Wilcox², Lindsay M. Banks¹, Karina Muro¹, Daniel I. Shapiro¹, Khalima A. Bolden¹, Renata M. Botello¹, Rebecca E. Grattan¹, Yi Zhang⁵, Joy Melnikow⁵, Daniel J. Tancredi¹, Bonnie Hotz¹, Sonya Gabrielian⁶, Steven R. Lopez⁷, Lisa Dixon⁸, Cameron S. Carter¹, Tara A. Niendam¹

¹University of California, Davis, School of Medicine, ²Washington University in St. Louis, ³Herbert Wertheim School of Public Health and Human Longevity Science, University of California, San Diego, ⁴Weill Institute for Neurosciences, University of California, San Francisco, ⁵Center for Healthcare Policy and Research, University of California, Davis,, ⁶David Geffen School of Medicine, University of California, Los Angeles, ⁷University of Southern California, ⁸NYSPI/Columbia University Medical Center

Background: Coordinated Specialty Care (CSC) is an evidenced-based practice for early psychosis (EP). The effectiveness of CSC outside of clinical trials continues to be evaluated, including by NIH's EPINET project (<https://nationalepinet.org/>) which has created a network

of EP program hubs across the country, including California's EPI-CAL project (<https://epical.ucdavis.edu>). Recent studies suggest that CSC is not as effective for individuals with less economic advantage. This is critical, as approximately 37 million, or 12%, Americans, lived in poverty each year between 2020 and 2022. In 2022, 15% of American children lived in poverty, noteworthy because childhood economic disadvantage is predictive of both development of psychosis-spectrum disorders as well as other health problems. To better understand early experiences of poverty of service users in community CSC programs, this analysis examined experiences of early childhood poverty of EPI-CAL service users and explored how these experiences are related to high-priority clinical outcomes.

Methods: CSC service users and their primary support persons (PSP) completed surveys at EPI-CAL enrollment and every 6 months throughout treatment. PSP who lived with the service user before they turned five reported subjective poverty indicators experienced in the household during that time. Participants also reported their demographics and clinical outcomes, including symptoms (Modified Colorado Symptom Index (MCSI)), recovery (Questionnaire about the Process of Recovery (QPR)), and quality of life (Personal Wellbeing Index (PWI)). Descriptive analyses summarized demographics and poverty indicators. Independent-samples t-tests were run to determine if there were differences in specific outcomes (MCSI, QPR, and PWI) between service users with and without a history of early poverty, and family-wise error rate was adjusted to correct for multiple comparisons. Chi-square tests were used to examine group differences between specific demographic factors and those with and without childhood poverty experiences.

Results: At enrollment, 165 PSPs (Ages 16-66, M=45.76, SD=9.17) reported on subjective experiences of poverty had by the service user (ages 12-32, M=17.78, SD=3.72; 66% FEP, 27% CHR, 11% Diagnosis Unconfirmed) prior to age five. We found 29 (18%) PSPs who endorsed that the service user had at least one subjective experience of poverty prior to age 5. When examining demographic factors, there was a significant association between race and experience of childhood poverty ($\chi^2(4) = 14.91$, $p < .01$) with African American/Black individuals reporting more childhood poverty experiences than expected. Individuals who had subjective experiences of poverty during childhood reported worse clinical outcomes on the recovery measure at baseline, with individuals without poverty experiences having higher scores on the QPR (M = 34.63, SD = 8.90) than those with poverty experiences (M = 27.94, SD = 11.00; $t(49) = 2.31$, $p = .01$, corrected $p = .038$).

Discussion: To date, the proportion of individuals with experiences of childhood poverty is higher than the general American population. These experiences of poverty disproportionately affect Black and African American service users. Individuals with these experiences were less likely to agree with statements indicating recovery at their first recorded assessment in CSC. This continues to support that socioeconomic experiences should be considered as a factor contributing to clinical outcomes. Future analyses will examine current socioeconomic status (SES) as a moderator of clinical outcomes at baseline and explore how childhood poverty and current SES may moderate change in clinical outcomes throughout CSC treatment.

F251. IMPLEMENTATION OF GUIDELINES ON FAMILY INVOLVEMENT FOR PERSONS WITH PSYCHOTIC DISORDERS (IFIP): IMPACT ON PATIENTS, RELATIVES, AND SUPPORT SERVICES

Irene Norheim^{*1}, Reidar Pedersen², Maria Lie Selle³, Jan Ivar Røssberg⁴, Lars Hestmark², Kristin Sverdvik Heiervang⁵, Torleif Ruud⁶, Vilde Maria Åsholt¹, Kristiane Hansson², Paul Møller¹, Roar Fosse¹, Maria Romøren²

¹Vestre Viken Hospital Trust, , ²Centre for Medical Ethics, Institute of Health and Society, University of Oslo, ³Health Services Research Unit, Akershus University Hospital, ⁴Institute of Clinical Medicine, University of Oslo, Oslo University Hospital, ⁵Division of Mental Health Services, Akershus University Hospital, ⁶Institute of Clinical Medicine, University of Oslo

Background: Psychotic disorders often lead to functional and social impairment, affecting the life and well-being of both patients and relatives. Relatives may provide a unique and long-lasting social support, while being a rehabilitation resource for the patients. At the same time, the nature of psychosis constitutes a great burden for relatives and may lead to depression, stress and burnout. Family involvement is therefore a decisive part of treatment, aiming to improve conditions for patients' and relatives' psychosocial health and well-being. Despite family interventions are recommended in treatment guidelines worldwide at all stages of psychotic disorders, it is scarcely provided in routine clinical practice. This sub-study is part of The Implementation of guidelines on Family Involvement for persons with Psychotic disorders (IFIP)' trial. The aim is to examine how much family involvement the patients and their relatives received in the intervention- and control arm, and the patients' and relatives' service satisfaction, perceived psychosocial health and quality of life.

Methods: A multicenter, parallel cluster randomized controlled trial randomly assigned 15 Norwegian Community Mental Health Center (CMHC) units to "The IFIP intervention" or treatment as usual (TAU). The intervention consisted of 1. Clinical interventions: Basic family involvement practices (BFIS) and family psychoeducation (FPE); 2. Implementation interventions: Implementation team, family coordinator, training etc.; 3. Implementation strategies: Leadership commitment, whole ward approach and responsive evaluation. The units recruited patients with psychotic disorders and their closest relative in pairs to answer a questionnaire at baseline, 6 and 12 months follow-up. The primary outcome for patients was the relationships subscale of The Behavior and symptom identification scale (Basis-24), and for the relatives the experienced support from the health services of Carer well-being and support questionnaire (CWS-B).

Results: Totally 231 patient-/relative pairs were analyzed (135 intervention; 96 TAU). Response rate for instrument completion at 6 and 12 months follow-up was 89 and 90 % for patients and 84 and 89 % for relatives. Except 25% of the 6 months questionnaires, the follow-up data were collected during the COVID-19 pandemic. The IFIP intervention significantly increased the amount of various types of family involvement and support services from the CMHC units, including FPE. Preliminary analyses of the patients and relatives' outcomes indicate differences in service satisfaction and psychosocial health between the intervention and the TAU group. The analyses will be finished this year.

Discussion: To our knowledge, this is the first study to investigate the direct impact of an intervention on family involvement and support services and indirectly on the patients and relatives during a comprehensive, system-wide implementation of family involvement in routine mental health services. The results indicate that the IFIP intervention, despite being substantially affected by the pandemic, did increase the amount of BFIS and FPE, and preliminary results shows some positive outcomes for patients and relatives in the intervention arm. Findings from this study confirms the importance of CMHC units ensuring routines, knowledge, and competence among clinicians to offer family involvement tailored to the needs of each patient and their families in everyday mental health practices.

F252. OCCUPATIONAL IMPACT OF TARDIVE DYSKINESIA: A CROSS-SECTIONAL, INTERNATIONAL SURVEY ASSESSING THE PERCEPTIONS AND EXPERIENCES OF PATIENTS WITH TD AND PHYSICIANS WHO TREAT TD

Rinat Ribalov¹, Ayelet Yaari^{*2}, Aviva Peyser Levin³, Amy Yang⁴, Dahbia Horchi⁵, Erwan Berjonneau⁵, Perrine Le Calvé⁵, Marc Tian⁶, Shoshana Reshef⁷, Suzanne Reed⁵

¹Teva Pharmaceutical Industries Ltd., Global Health Economics and Outcomes Research,

²Teva Pharmaceutical Industries, Ltd., ³Teva Pharmaceutical Industries Ltd., International Markets Medical Affairs, , ⁴Teva Branded Pharmaceutical Products R and D, Inc., Global Health Economics and Outcomes Research, ⁵Oracle, Paris, ⁶Teva Branded Pharmaceutical Products R and D, Inc., Real World Evidence Statistics, ⁷Teva Branded Pharmaceutical Products R and D, Inc., Epidemiology and Global Health Economics and Outcomes Research, Parsippany,

Background: Tardive dyskinesia (TD) is an involuntary, hyperkinetic movement disorder that markedly affects the quality of life of involved patients. This study assessed patient and physician perceptions of the impact of tardive dyskinesia (TD) on occupational functionality.

Methods: Adults (aged ≥ 18 years) with self-reported physician diagnoses of TD and schizophrenia or schizoaffective disorder, bipolar disorder, or major depressive disorder and TD-related movements were invited to complete an online questionnaire (27 June–17 October 2022). Certified physicians (neurologists and psychiatrists) practicing for ≥ 3 years, with $\geq 60\%$ of their time in direct patient care and treating ≥ 3 patients with TD in the prior 2 years, were also invited to complete an online questionnaire (27 June–27 July 2022). Physicians' and patients' data and questionnaires were unlinked.

Results: Patients (n=435; mean age, 42.4 years, 52% female) from Australia, China, South Korea, and Brazil and physicians (n=340; 61% psychiatrists) from Australia, China, South Korea, Brazil, and Israel were included in the study. Across countries, 248 (57%) patients reported not currently working. Among the 248 patients not working, 124 (50%) stated that TD symptoms are behind the fact that they are not working. Among these 124 patients, 44% cited physical limitations because of TD symptoms as the primary reason, followed by not being able to find an employer that will employ them because of TD symptoms (23%), embarrassment about TD symptoms (19%), and having to take a step down or change industry (15%). 61% of physicians reported "often"/"always or almost always" assessing impact of TD on occupational functioning. 75% and 72% of physicians perceived a "moderate"/"very strong" impact of TD on obtaining/maintaining employment and on the inability or reduced ability of patients to perform job duties, respectively.

Discussion: In these surveys, patients and physicians agreed that TD considerably impacts occupational functionality. Among patients who were unable to work because of their TD, the most common reason for not working was because of TD-related physical limitations.

F253. ATTITUDES DRIVING REGIONAL DIFFERENCES IN LAI ANTIPSYCHOTIC UTILIZATION FOR SCHIZOPHRENIA AMONG HEALTHCARE PROFESSIONALS, PATIENTS, AND CAREGIVERS (ADVANCE): PATIENT AND CAREGIVER QUALITATIVE INTERVIEWS

Kelli R. Franzenburg^{*1}, Rolf T. Hansen², Mark Suett³, Ayelet Yaari⁴, Aviva Peyser Levin⁴, Martin Sergerie⁵, Alma Gonzalez⁶, Kameron Sedigh⁷, Stephan Heres⁸, Martha Sajatovic⁹

¹Teva Branded Pharmaceutical Products R and D, Inc., ²Teva Branded Pharmaceutical Products R and D, Inc., North America Medical Affairs, ³Teva UK Limited, Global Medical Affairs, ⁴Teva Pharmaceutical Industries Ltd., International Markets Medical Affairs, , ⁵Teva

Canada, Medical Affairs, ⁶Teva Branded Pharmaceutical Products R and D, Inc., Global Medical Affairs, ⁷Syneos Health New York, ⁸kbo-Klinik für Psychiatrie und Psychotherapie Nord. ⁹University Hospitals Cleveland Medical Center, Case Western Reserve University School of Medicine,

Background: Schizophrenia imparts a substantial burden on individuals and society and is increasing in prevalence. Long-acting injectable antipsychotics (LAIs) improve adherence and reduce relapse and hospitalization rates compared with oral treatments for schizophrenia, yet rates of LAI use are low and inconsistent across regions. The objective of the Attitudes DrIVING regional differences in LAI ANTipsychotic utilization for schizophrenia among healthcare professionals (HCPs), patients, and CaregivErS (ADVANCE) study is to observe attitudes towards LAI use across regions.

Methods: Patients with schizophrenia and caregivers of patients with schizophrenia were recruited from Australia, Canada, China, Germany, Israel, Spain, South Korea, and the United States. Patients were ≥ 18 years of age and were being treated with LAIs or recommended LAI treatment for schizophrenia. Caregivers were actively participating in the management and treatment of schizophrenia for the person for whom they cared. For this qualitative portion of the ADVANCE study, qualified patients and caregivers completed a 60-minute interview.

Results: Twenty patients and 19 caregivers participated. Depending on their initial experience, 2 distinct patient treatment/disease management pathways emerged: 1) treatment at diagnosis early in symptom development with strong support in the outpatient setting, and 2) severe, acute episodes that required hospitalization—each with contrasting downstream effects on patient perspectives on LAI treatment. Patients who received initial outpatient treatment tended to be motivated to treat their condition and return to their pre-diagnosis state of being. They also tended to trust in the healthcare system, and to feel involved and collaborative regarding their treatment. Some noted the important role that their families play in their treatment. Patients who received initial outpatient treatment were likely to prefer an LAI over an oral treatment or to accept a recommendation of an LAI. Patients who initially received inpatient treatment had fears associated with treatment, felt a lack of control, and felt social stigma regarding their condition; they appeared unlikely to accept an LAI for long-term care because of a desire for autonomy or control over their treatment and/or a negative experience with injectable antipsychotics during their hospitalization. In general, patients with positive perceptions of LAIs were more likely to have strong family support, early disease detection, LAI use early in the disease course, and strong trust in their HCPs. Those with negative perceptions of LAIs likely had multiple hospitalizations, inconsistent or no family support, a history of forced/coerced treatment, and a lack of continuity of care from inpatient to outpatient care. Caregivers played various roles in disease management for those for whom they care and tended to focus on elements of patient quality of life rather than treatment management. The key caregiver-reported advantage of LAIs was less frequent reminders of the disease for both the patient and the caregiver; cost was also noted as a barrier towards LAI adoption. Caregivers reported receiving little education about treatment options available for schizophrenia.

Discussion: Initial schizophrenia presentation, family support, hospitalizations, HCP trust, and logistical challenges may all play a role in patient outcomes and perceptions of LAIs. Unfavorable early experience, especially in an inpatient setting, can have detrimental impact on patient perception of and willingness to accept LAIs. Ongoing research aims to extricate these variables influencing LAI acceptability in schizophrenia.

F254. ATTITUDES DRIVING REGIONAL DIFFERENCES IN LAI ANTIPSYCHOTIC UTILIZATION FOR SCHIZOPHRENIA AMONG

HEALTHCARE PROFESSIONALS, PATIENTS, AND CAREGIVERS (ADVANCE): HEALTHCARE PROFESSIONAL QUALITATIVE INTERVIEWS

Kelli R. Franzenburg*¹, Rolf T. Hansen², Mark Suett³, Ayelet Yaari⁴, Martin Sergerie⁵, Sigal Kaplan⁶, Alma Gonzalez⁷, Kameron Sedigh⁸, Stephan Heres⁹, Martha Sajatovic¹⁰

¹*Teva Branded Pharmaceutical Products R and D, Inc.*, ²*Teva Branded Pharmaceutical Products R and D, Inc., North America Medical Affairs*, ³*Teva UK Limited, Global Medical Affairs*, ⁴*Teva Pharmaceutical Industries Ltd., International Markets Medical Affairs*, ⁵*Teva Canada, Medical Affairs*, ⁶*Teva Pharmaceutical Industries Ltd., Global Health Economics and Outcome Research*, ⁷*Teva Branded Pharmaceutical Products R and D, Inc., Global Medical Affairs*, ⁸*Syneos Health New York*, ⁹*kbo-Klinik für Psychiatrie und Psychotherapie Nord*. ¹⁰*University Hospitals Cleveland Medical Center, Case Western Reserve University School of Medicine*,

Background: Healthcare professional (HCP) views on and use of long-acting injectable antipsychotics (LAIs) in schizophrenia treatment vary widely despite known benefits. Here, a subset of data generated in a novel, multi-national survey study, Attitudes DriVing regional differences in LAI ANTipsychotic utilization for schizophrenia among HCPs, patients, and CaregivErs (ADVANCE), was leveraged to elucidate qualitative data on HCP attitudes on LAI use.

Methods: HCPs from Australia, Canada, China, Germany, Israel, Spain, South Korea, and the United States (US) were screened via questionnaire and included if they specialized in psychiatry, spent ≥65% of their time providing direct patient care, managed ≥10 adult patients with schizophrenia monthly, and reported treating patients with second-generation LAIs. HCPs who met inclusion criteria were interviewed regarding their experience managing and treating patients with schizophrenia, including the role of LAIs.

Results: Ten psychiatrists (spending an average of 45% of their time at hospital-based outpatient clinics) and 7 psychiatric nurses (averaging 47% of time at community mental health centers) were interviewed. HCPs reported that patients often follow a treatment and relapse cycle leading to encounters with inpatient and outpatient systems and providers. Systemic factors, including lack of community psychiatrists (Australia, Canada, China, Germany, and Israel) and low cost of inpatient care for the patient (Australia, Canada, and Germany), may drive patients toward inpatient care. Inpatient treatment focuses on acute symptom management and crisis stabilization, while outpatient treatment is more likely to incorporate patient perspectives and prioritize long-term quality-of-life considerations. Treatment objectives of psychiatrists were particularly focused on managing positive symptoms, especially in the inpatient setting, whereas psychiatric nurses were more focused on patient quality of life. Psychiatrists and psychiatric nurses reported mean (range) LAI use of 27% (10%–50%) and 30% (5%–60%), respectively. Overall, HCPs conveyed positive perspectives of LAIs and noted that side effects were a key consideration when choosing an LAI. There was a lack of consensus about the ideal patient profile for LAIs; however, most HCPs were aligned that use in younger patients or those with less severe disease should be limited. The most common barriers to LAI use were patient aversion to injections, logistical challenges (lack of staff and training), patient trauma from prior forced injection, and lack of product availability/cost; HCPs from Israel and the US also noted private insurance coverage issues, and HCPs from China reported cost to the patient as the key barrier towards LAI adoption. In the inpatient setting, costs and logistical considerations for LAIs were deemed less of a barrier. Community treatment orders or involuntary treatment with LAIs (Australia, Canada, and Israel) may lead to negative patient perceptions of LAIs.

Discussion: HCPs reported that patients with schizophrenia had cyclical encounters with HCPs in inpatient and outpatient settings as well as barriers to care, which may influence treatment planning, including LAI recommendations and patient acceptance. In some countries, HCPs report that systemic factors drive patients to inpatient care settings where the focus on positive symptom control may lead to negative patient experiences with LAIs. Regional differences in LAI utilization rates are likely influenced by a combination of factors, including systemic, HCP, and patient factors. Ongoing research aims to disentangle these factors and understand the impact on regional LAI utilization rates.

F255. PERSONAL RECOVERY SELF-REPORT OUTCOME MEASURES IN SERIOUS MENTAL ILLNESS: A SYSTEMATIC REVIEW OF MEASUREMENT PROPERTIES

Simon Felix^{*1}, Valery Kevin-Marc¹, Meryl Caiada¹, Sarah Guionnet¹, Julien Bonilla-Guerrero², Jean-Marc Destailhats², Antoinette Prouteau³

¹University of Bordeaux, ²Jonzac Hospital, ³University of Bordeaux, Jonzac Hospital

Background: Consumer movements of people with lived experience of mental illness have long advocated for the acknowledgement of personal recovery. Personal recovery in mental illness can be defined as “a deeply personal, unique process [...] a way of living a satisfying, hopeful, and contributing life even with limitations caused by illness” (Anthony, 1993). By challenging the traditionally established biomedical models and practices surrounding the notion of mental illness, personal recovery thus represents a paradigm shift in mental healthcare (Davidson et al., 2005). The transformation of mental health services towards both person and recovery-centered care has therefore been defined as a priority by the World Health Organization (WHO, 2021). Yet, it has proven difficult to create recovery-oriented health services that consider users subjectivity and perspectives: there is a need to shift from traditional clinical outcome measures to assess specific personal recovery processes (Slade et al., 2014). Validated self-report outcome measures (Patient Reported Outcome Measures, PROMs) are therefore needed to facilitate the transformation towards recovery-oriented practices and services. Objectives were to identify published measures and analyze their measurement properties using a standardized methodology.

Methods: Following the COSMIN guidelines (Prinsen et al., 2018, Mokkink et al., 2017), we conducted a systematic review of personal recovery PROMs in serious mental illness. The MEDLINE, PMC, PsycINFO, PsycARTICLES, PBSC and Scopus electronic databases were searched for articles published between May 2012 and October 2023. Full-text articles from a previous systematic review were also examined. A broad spectrum of psychometric properties was reported and analyzed using standardized criteria. A supplementary content validity analysis was conducted.

Results: 118 studies were included in the review, describing 25 PROMs. Ten of them had not been identified in previous reviews. Quality of evidence was globally poor for most PROM measurement properties. Very little evidence was found for cross-cultural validity, measurement invariance, measurement error and criterion validity. The Recovery Assessment Scale and Questionnaire about the Process of Recovery showed the strongest evidence for sufficient psychometric data on a wide range of measurement properties.

Discussion: Several personal recovery measures are now available. While research is still needed to enhance their validity on some psychometric properties, the current tools appear sufficient to cover most research and clinical needs.

F256. BUILDING A CONTINUUM OF CARE FOR TREATMENT-RESISTANT SCHIZOPHRENIA SPECTRUM DISORDERS

Rocco Marotta*¹, Irene Bihl², Meriwether Brown³, Suma Srishaila³, Sophia Walker⁴, Katharine Cutts Dougherty³, Lisa Mann³, David Rowe³, Robert Laitman⁵

¹*Silver Hill Hospital, Yale University*, ²*Sage Healthcare, Yale University*, ³*Silver Hill Hospital*, ⁴*Silver Hill Hospital, NYU*, ⁵*Bronx Westchester Medical Group*

Background: Schizophrenia Spectrum Disorder (SSD) continues to pose a tremendous burden on human societies. Despite decades of research, treatment outcomes are still not fully encouraging. Clozapine is universally recognized as the most effective antipsychotic available but is still underutilized and in many institutions, is regarded as a last resort treatment choice for resistant cases only.

Methods: We at Silver Hill Hospital (SHH), Project Daniel, and Sage Healthcare at the Bridgeport Rescue Mission, are developing a continuum of care to make clozapine available more widely. The prototype comprehensive program on campus of Silver Hill Hospital, evaluates and treats a unit maximum of 14 patients for SSD, and those with treatment resistance are prescribed clozapine, which, when appropriate, is supplemented with oxytocin, modafinil, lamotrigine, or another antipsychotic. These patients are followed over many months to years and those who have continued in follow-up (N=60), have shown a promising course, with outcomes including finishing their education, many to the graduate level, working, maintaining sobriety, living independently and reconnecting with family. The high cost of such continuity of care in a residential setting has been addressed by the development of Team Daniel, that provides an outpatient program, following over 200 patients, some of whom were referred from SHH. Patients in Team Daniel follow a strict protocol involving clozapine treatment, mixed medication when appropriate, along with group therapy and family involvement. This program has sustained a meaningful recovery rate of over 70%, and reduced hospitalization from 93% in the two years prior to joining the practice to 15% readmitted.

Results: Our work up to this point clearly demonstrates that the five pillars of successful treatment include: 1) sobriety; 2) medication management and compliance; 3) therapeutic alliance between patient, family, and healthcare provider; 4) support in maintaining social connectedness; and 5) long-term, lasting clinical follow-up. Clozapine's particular effectiveness, not only in controlling positive symptoms of psychosis, but also its significant effects in controlling substance use, impulsivity, suicidality, long-term remission, and overall increased survival, compels us to seek ways to use it effectively in vulnerable communities of high risk. We recognize our responsibility to extend this treatment model, including to those with limited economic resources and a high level of illicit substance use.

Discussion: In this presentation, we outline a model of treatment that has evolved as an extension to Silver Hill Hospital's treatment plan but is targeted at the most vulnerable, complex, inner-city population through the operation of a free community healthcare clinic, Sage Healthcare. The model provides for local university faculty and students in various healthcare disciplines to identify clients with the diagnosis of schizophrenia, and implement a detailed clozapine treatment protocol, managing side effects, adjunctive medications, and evaluating outcomes through the use of psychosis rating scales such as PANSS. Group therapy, family engagement, as well as the supportive structure of Bridgeport Rescue Mission itself emulates the SHH program. Experienced SHH clinicians play a major role in the development and support of this program. The goal is to replicate in the community, a residential setting

through which patients can be followed daily, treated primarily with clozapine and return to long-term stability and a meaningful life.

F257. THE LONG-TERM FOLLOW-UP OF THE TREATMENT AND EARLY INTERVENTION FOR PSYCHOSIS PROJECT: LOFT STUDY PROTOCOL

Teya Petrova*¹, Philippe Golay¹, Paul Klauser², Raoul Jenni³, Nadir Mebdouhi¹, Philippe Conus¹, Luis Alameda¹

¹*Service of General Psychiatry, Lausanne University Hospital and University of Lausanne,*

²*Center for Psychiatric Neuroscience and Service of Child and Adolescent Psychiatry, Lausanne University Hospital,* ³*Center for Psychiatric Neuroscience, Lausanne University Hospital*

Background: Psychotic disorders represent a leading cause of chronic disability. While early intervention (EI) in psychosis is the gold standard to treat patients after a first episode of psychosis (FEP), knowledge of the evolution and the long-term effects of such type of intervention is limited, underscoring the critical importance of early detection and intervention. To date, very few studies have examined the long-term impact of such type of treatments as well as the long-term outcome of FEP patients. The Long-term Follow-up of Treatment and Early Intervention for psychosis (LOFT) is a up to 20-year longitudinal study within a clinical epidemiological cohort of nearly 1000 patients who completed a three-year program specialized in early intervention for the initial stages of psychotic disorders, called Treatment and Intervention in Psychosis Program (TIPP) in Lausanne, Switzerland, and who went through a deep phenotyping during assessment their first years of treatment. Hence, the objective of this study is to gain insight into the long-term evolution of physical and mental health, as well as in term the neurobiological functioning of the patients treated after a first psychotic episode in TIPP.

Methods: Around 700 patients treated in TIPP between 2004 and 2019 will be recontacted and reevaluated at either 5, 10, 15 and 20 years after their entry in the TIPP program. Static factors such as demographics, childhood trauma history and variations in the level of insight, as well as dynamic changes in clinical variables over time will be analyzed using traditional group level and machine learning methods to provide prognostic insights. A subsample of the patients who took part in a research program will be invited to undergo additional neurobiological assessments to explore specific biomarkers.

Results: -

Discussion: The study protocol of the recently funded study will be presented alongside with an update on recruitment. Identifying determinants of the long-term evolution in relation to past TIPP program evaluations should enable us to generate avenues of improvement for clinical treatment strategies and advance the path toward precision medicine for individuals with psychotic disorders. We hope LOFT will help reshape and redefine current interventions for subgroups of patients at risk of poorer outcome.

F258. INTERVENTIONS TARGETING IDENTITY: A TRANSDIAGNOSTIC SCOPING REVIEW WITH IMPLICATIONS FOR ADULTS WITH A SEVERE MENTAL ILLNESS

Lisette Van der Meer*¹, Elske Kronemeijer¹, Hanneke Muthert¹, Ellie van Setten², Marieke (Gerdina) Pijnenborg¹

¹University of Groningen, ²On personal affiliation

Background: People with a severe mental illness (SMI) often face challenging life-experiences that impact their identity. Nevertheless, no overview exists of interventions on the way mental health professionals may support people in the process of regaining (grip on) identity. We conducted a transdiagnostic scoping review of evaluated interventions that target identity or self-concept in people with severe mental illness (SMI), 2) acquired brain injury (ABI), and 3) intellectual disability (ID).

Methods: We conducted a literature search in November 2021 (with an update in November 2023) in the databases PsycInfo, Medline, the Psychology and Behavioral Sciences Collection, CINAHL, Academic Search Premier, EBSCO open dissertations, and Web of Science. Search terms included search strings related to a) relevant concepts (e.g. identity, self-concept, etc.) and b) interventions or evaluation methods and c) target groups.

Results: Thirty studies were included. Most studies included small groups, were feasibility studies or qualitative evaluations. Most interventions were group-based, relatively brief and varied in theoretical background and intervention characteristics. Qualitative data showed positive results for narrative interventions, as well as (un)structured peer group interventions. Quantitative studies suggest that programs explicitly targeting identity or self-esteem may be effective.

Discussion: Some promising identity-based interventions have been developed, but future research is needed to investigate the effect of intervention content and format. In general, quantitative identity outcomes are lacking for less structured supportive peer-groups, while qualitative evaluations are lacking for structured identity-based programs.

F259. HYBRID MHEALTH CARE: PATIENT PERSPECTIVES OF BLENDED TREATMENTS FOR PSYCHOSIS: A SYSTEMATIC REVIEW

Frances Greenway*¹, Mark Weal¹, Emma Palmer-Cooper¹

¹University of Southampton

Background: Disengagement rates for first episode psychosis intervention services are currently higher than those of other mental health services. As such, mHealth interventions have been extensively employed in mental health research, showcasing their potential to address the significant treatment gap. While numerous studies underscore the advantages and functionalities of mHealth, challenges persist regarding patient uptake and sustained engagement, especially among individuals with schizophrenia and non-affective psychosis. There is a growing recognition that integrating mHealth interventions with face-to-face interactions could enhance overall care. Hybrid healthcare, characterised by the interaction of digital tools and in-person care, empowers patients to take more control of their health while benefiting from clinician support. Given the global initiative to incorporate mHealth into traditional mental health care, this review aims to explore individual-level barriers and facilitators to engagement with hybrid digital systems, aiming to uncover strategies for promoting trust and enhancing engagement. By identifying key factors that impact the outcomes of these interventions, particularly understanding participant engagement, this research contributes valuable insights to the development of accessible and effective mental health interventions.

Methods: The search yielded 5,255 studies but only 16 were included in the final review. An inductive approach was taken to derive themes and patterns from the primary data, adhering to the primary studies own interpretations. Four electronic databases were systematically searched (Medline, Web of Science, CINAHL, and PsychINFO) to identify hybrid digital interventions being used to treat psychosis spectrum disorder. The primary interest was to understand individual level barriers and facilitators to engagement with hybrid digital systems. Studies that only reported the efficacy of the interventions were excluded.

Articles of all study designs, written in English and had been featured in a peer reviewed journal between inception and May 2023 were included in the primary search. Reasons for exclusion were primarily due an absence of an in-person presence throughout the intervention and did not explore participants experiences of the intervention.

Results: Seven analytic themes were identified: (1) Tool to Aid Communication; (2) Central Role of the Therapist; (3) Increased Sense of Support; (4) Greater Insight into Voices; (5) Enabling Technologies (6) Sense of Community; (7) Barriers to Engagement. A number of participants conveyed a heightened sense of control and understanding of their symptoms, with daily reflection and monitoring features among the most positively regarded. Obstacles such as difficulties using technology and feelings of paranoia were recognised as challenges to effective engagement with mHealth in 8 of the included studies. However, regular interaction with a therapist was noted to alleviate some of these barriers and helped participants to feel more support.

Discussion: The themes identified in this review highlight the potential impact of hybrid digital interventions within this population. Context-aware systems, customised for each individual, may prove especially valuable in improving engagement and enhancing therapeutic alliance. This review aims to guide and shape the design and development of innovative hybrid digital interventions, offering valuable insight for researchers and clinicians involved in the development of new interventions and the seamless integration of mobile health (mHealth) into conventional healthcare practices.

F260. PERCEIVED SOCIAL DEFEAT AS A MECHANISM BETWEEN CHILDHOOD ADVERSITY AND SUBCLINICAL PSYCHOTIC PHENOMENA: AN EXPERIENCE SAMPLING STUDY

Pilar Torrecilla^{*1}, Manel Monsonet¹, Thomas R. Kwapi², Neus Barrantes-Vidal¹

¹*Universitat Autònoma de Barcelona*, ²*University of Illinois at Urbana-Champaign*,

Background: The experience of social defeat, described as the negative experience of being excluded from the majority group, has been suggested as an underlying mechanism between several psychosocial risk factors and psychosis expression. Increasing evidence has shown that social defeat plays a role explaining the effects of childhood adversity on the development of psychotic symptoms. However, limitations regarding the definition and measurement of social defeat have been acknowledged, and most studies have focused on clinical populations or individuals at clinical high risk for psychosis. The study of the psychological mechanisms underlying psychosis expression may benefit from examining nonclinical populations exhibiting subclinical psychotic-like experiences (PLE) without the burden of a clinical status. To this aim, the present study ecologically assessed the subjective experience of perceived social defeat using Experience Sampling Methodology (ESM), and examined for the first time its association with psychotic-like and affective expression as well as its potential mediating

role between different dimensions of childhood adversity and subclinical experiences in the flow of daily life.

Methods: The study is embedded in the Barcelona Longitudinal Schizotypy Study (BLISS) and comprises data for 159 nonclinical young adults (mean age=28, sd=2.3) with a wide distribution of schizotypy traits. Participants were longitudinally assessed from Time 1 to Time 5 (mean time interval=7.8 years). Participants completed interview-based and self-report measures of childhood adversity at Time 1 and were assessed with ESM at Time 5. Social defeat was measured with two ESM items capturing appraisals of inferiority and outsider status. Multilevel structural equation models were used to assess the relationship between social defeat scores and daily-life subclinical experiences, and a series of multilevel mediation models were conducted to examine the within-person indirect effect of the associations between empirically-derived early adversity dimensions and momentary subclinical experiences (paranoia, positive PLE, negative PLE, disorganization, negative affect and positive affect) through momentary social defeat.

Results: Social defeat was positively associated with momentary levels of paranoia, positive PLE, negative PLE, disorganization and negative affect, and negatively associated with positive affect. Multilevel mediation analyses indicated that the indirect effect of childhood experiences of deprivation and sexual abuse to paranoia, positive PLE, negative PLE, disorganization, low positive and high negative affect through appraisals of social defeat were statistically significant.

Discussion: Perceived appraisals of social defeat impact psychotic and affective experiences in daily life. The study adds on previous literature supporting the mediating role of social defeat in the association of childhood adversity and psychosis expression captured in individuals' real context, and extends findings by suggesting that specific forms of adversity (i.e., deprivation and sexual abuse) may particularly increase the experience of social defeat as compared to other forms of adversity (e.g., physical or emotional abuse). These findings highlight the relevance of exploring different types of adversity when investigating the underlying psychological mechanisms and that socially excluded and minority groups are an important target to implement prevention and intervention strategies to reduce psychosis risk.

F261. HOMELESSNESS, PSYCHIATRIC DISORDERS, AND VIOLENT OFFENDING: A NATIONWIDE, REGISTER-BASED COHORT STUDY

Sandra Nilsson^{*1}, Thomas Munk Laursen², Lars Højsgaard Andersen³, Merete Nordentoft⁴, Seena Fazel⁵

¹*Copenhagen Research Center for Mental Health - CORE*, ²*Aarhus University*, ³*ROCKWOOL Foundation Research Unit*, ⁴*Mental Health Centre Copenhagen*, ⁵*University of Oxford*

Background: Psychiatric disorders are linked to increased risk of violent offending and are prevalent in people experiencing homelessness, but little is known about how homelessness is linked to violent crimes. We aimed to examine the association of homelessness and schizophrenia spectrum disorder with the risk of violent offending.

Methods: We did a nationwide, register-based cohort study of people living in Denmark between Jan 1, 2001, and Dec 31, 2021, aged 15 years or older. The study population was obtained from the Danish Civil Registration System, which was linked to several other registers (The Danish Homeless Register, the Danish Central Criminal Register, the Danish National Patient Register, and the Danish Psychiatric Central Research Register). Outcome was first violent offending, defined as first date of a police-recorded violent crime leading to a conviction. We calculated incidence rates per 10,000 person-years, incidence rate ratios (IRRs)

using Poisson regression analysis, and probability of violent offending. Analyses were stratified by sex. Age, calendar year, country of origin, and highest educational level were included as confounders.

Results: The study cohort included 1,786,433 Danish residents aged 14-42 years living between Jan 1, 2001, and Dec 31, 2021, contributing with 21,336,322 person-years at risk. Overall, 57,084 (3.2%) individuals had a police-record of any violent offending during follow-up. After five years follow-up, the probability of any violent crime in males and females experiencing homelessness was: 15.8% (95% CI 14.8-16.8) and 5.1% (95% CI 4.4-5.9), respectively. The incidence of violent offending in individuals with history of homelessness and schizophrenia spectrum disorder was 395.1 per 10,000 person-years (95% CI 350.9-444.8) in males and 187.9 per 10,000 person-years (95% CI 151.5-233.0) in females; after adjustment for age and calendar year, the IRRs were 20.2 (95% CI 18.0-22.8) in males and 64.9 (95% CI 52.1-80.8) in females compared with those without history of homelessness and no schizophrenia spectrum disorder. The IRRs were higher than in those only experiencing homelessness (IRR 11.1, 95% CI 10.4-11.9 in males and 19.6, 95% CI 17.0-22.6 in females) and in those who only had a schizophrenia spectrum disorder (IRR 4.5, 95% CI 4.3-4.8 in males and IRR 10.6, 95% CI 9.7-11.6 in females). The risk estimates were reduced but remained high after adjustment for country of origin and educational level.

Discussion: Homelessness was associated with increased risk of violent offending independently and in combination with schizophrenia spectrum disorder. Individuals experiencing homelessness and having a schizophrenia spectrum disorder constitute a high-risk group of violent offending. Improved efforts to mitigate and prevent homelessness and support people with schizophrenia spectrum disorder are needed.

F262. OPEN BOARD

F263. EXPOSOME SCORES AND PROTECTIVE FACTORS IN PSYCHOSIS PRONENESS

Eda Karaca¹, Didenur Şahin¹, Seda Arslan¹, Tuba Şahin¹, Simge Merve Vit¹, Su Barış Karakelle¹, Timothea Touloupoulou², Didenur Sahin Cevik*¹

¹*Bilkent University*, ²*Interdisciplinary Neuroscience Program, Bilkent University; National Magnetic Resonance Research Center (UMRAM), Aysel Sabuncu Brain Research Centre (ASBAM), Bilkent University; National and Kapodistrian University of Athens, Icahn School of Medicine at Mount Sinai*,

Background: Psychosis is a mental disorder in which the contribution of the environment, along with genetic factors, in its etiology, is significant. This contribution can be measured in aggregate quantitatively, creating an exposome score. On the other hand, some protective factors that could reduce the likelihood of disease development have been recently identified. For example, healthy relationships, high IQ, and positive self-esteem are some of the factors that are thought to be protective and expected to significantly alter the impact of the environmental risk. We aimed to explore the role of the exposome score on psychosis proneness and whether protective factors moderate this relationship.

Methods: 488 healthy individual twins and siblings, some oversampled for a family history of psychosis (229 twin pairs, 30 healthy siblings of first episode psychosis patients) aged between 14-23, were assessed with CAPE-42 and environmental assessments (17 variables). Exposome

scores of each participant were calculated and included, cannabis use, abuse, neglect, bullying, winter birth and hearing impairment (a measure of environmental risk specific to psychosis). An overall protective factor score was calculated with 12 factors: IQ, social class, relationship status, religious affiliation, number of friends, support, social cohesion, feeling love in the family, having a close family, strong family bonds, positive self-esteem, positive thoughts about others. Each score was calculated according to whether the participant had this protective factor (scored as 1) or not (scored as 0) (mean+ SD was used as a threshold in the continuous variables) out of 12.

Results: Linear regression showed a significant effect of exposome score on psychosis proneness (total CAPE score) (Estimate=4.74, $t=6.99$, SE= 0.68, $p < 0.001$), indicating that higher exposome score was associated with higher psychosis proneness. There was also a significant effect of overall protective factor score on psychosis proneness (Estimate=-2.62, $t=-6.83$, SE= 0.38, $p < 0.001$), implying that a higher overall protective factor score was associated with lower psychosis proneness. The effect of exposome on psychosis proneness was moderated by a significant interaction between exposome and overall protective factor score (Estimate=-1.91, SE=0.39, $z=-4.96$, $p < 0.001$), suggesting that the effects of exposome on psychosis proneness varied depending on the overall protective factors score.

Discussion: The exposome scores, which measure different environmental risk factors, showed a strong relationship with a higher risk of psychosis. Conversely, an overall protective factor score showed an association with a lower risk of psychosis. The interaction analysis suggested that the overall protective factor score moderated the effect of the exposome on psychosis proneness, highlighting the dynamic and interrelated nature of these influences. This nuanced understanding offers a more comprehensive approach to the management and prevention of psychosis by offering insightful information for creating focused interventions and preventive measures.

F264. MAINTENANCE OF EFFICACY OF KARXT (XANOMELINE AND TROSPIMUM) IN SCHIZOPHRENIA

Inder Kaul¹, Elan A. Cohen², Andrew C. Miller¹, Amy Claxton¹, Steven M. Paul¹, Stephen K. Brannan¹, Stephen Brannan*¹

¹Karuna Therapeutics, ²CenExel Hassman Research Institute

Background: A high unmet medical need exists for more effective, better tolerated treatments for schizophrenia with novel mechanisms of action. All currently approved treatments for schizophrenia have D2 dopamine receptor blocking activity; the efficacy and tolerability limitations of these therapies are well known. KarXT, an investigational medication, combines the dual M1/M4 preferring muscarinic acetylcholine receptor agonist xanomeline and the peripherally restricted muscarinic receptor antagonist trospium chloride. KarXT is designed to preserve the beneficial central nervous system effects of xanomeline while reducing adverse events (AEs) due to peripheral muscarinic receptor activation. The efficacy and safety of KarXT in schizophrenia were demonstrated in the 5-week, randomized, double-blind, placebo-controlled EMERGENT-1 (NCT03697252), EMERGENT-2 (NCT04659161), and EMERGENT-3 (NCT04738123) trials. The Phase 3, multicenter, 52-week, outpatient, open-label extension EMERGENT-4 (NCT04659174) trial evaluated long-term safety, tolerability, and efficacy of KarXT in adults with schizophrenia.

Methods: The EMERGENT-4 trial enrolled participants who previously completed the treatment period of one of the Phase 3 double-blind studies, EMERGENT-2 or EMERGENT-

3. Regardless of previous treatment, eligible participants were started on KarXT dosing (xanomeline/trospium) at 50 mg/20 mg twice daily (BID) and increased to a maximum of 125 mg/30 mg BID. Efficacy analyses were conducted in the modified intent-to-treat population, defined as all randomized participants who received ≥ 1 trial drug dose and had a baseline and ≥ 1 postbaseline PANSS assessment. Efficacy measures included a change from acute study baseline to Week 52 in Positive and Negative Syndrome Scale (PANSS) total score, PANSS positive subscale, PANSS negative subscale, PANSS Marder negative factor, and CGI-S scores.

Results: Prior to receiving KarXT in the EMERGENT-4 study, all participants previously completed the treatment period of one of the Phase 3 double-blind studies and received KarXT or placebo. Participants who had received KarXT in the previous study had a lower mean PANSS total score at baseline compared to those who had received placebo (76.1 vs 86.5), reflecting greater improvement during 5 weeks of active treatment. After initiating treatment with KarXT, participants who received placebo in the previous studies exhibited rapid improvement in symptoms as early as the first assessment point in EMERGENT-4 (Week 2). After 4 weeks of KarXT treatment in EMERGENT-4, there were no meaningful differences in PANSS total score between participants who had previously received KarXT versus those who had received placebo. For all participants, improvements from baseline continued through 52 weeks of treatment for PANSS total score, PANSS positive subscale, PANSS negative subscale, PANSS Marder negative factor, and CGI-S scores. Data are continuing to be recorded in this ongoing study, and updated analyses will be available at the time of the meeting.

Discussion: In the interim analysis of the open-label extension EMERGENT-4 trial, average participant improvement continued throughout the 52-week trial regardless of whether participants have received previous treatment with KarXT or placebo. These findings support the potential of KarXT to be first in a new class of medications to treat schizophrenia based on muscarinic receptor agonism and without any direct dopamine D2 receptor blocking activity.

F265. MOTHERHOOD IMPACT ON WOMEN WITH A FIRST EPISODE OF PSYCHOSIS: 3-YEAR FOLLOW-UP STUDY ON CLINICAL, FUNCTIONAL AND NEUROCOGNITIVE OUTCOMES

Alexandre Díaz-Pons¹, Marina Soler-Andrés², Víctor Ortiz-García de la Foz¹, Nancy Murillo-García¹, Ángel Yorca-Ruiz¹, Rebeca Magdaleno Herrero¹, Sara Barrio-Martínez¹, Sergio Castaño-Castaño³, Alexandre González-Rodríguez⁴, Esther Setién Suero⁵, Rosa Ayesa-Arriola¹, Rosa Ayesa-Arriola⁶, Nancy Murillo-García^{*7}

¹IDIVAL, ²University of Oviedo, ³University of Oviedo, ⁴Mutua Terrassa, ⁵European University of the Atlantic, ⁶Valdecilla Biomedical Research Institute, IDIVAL Research Group on Mental Illness, Marqués de Valdecilla University Hospital, University of Cantabria, ⁷Valdecilla Biomedical Research Institute; Research Group on Mental Illnesses

Background: Women facing a first episode of psychosis (FEP) deal with distinct challenges, amplified by the added responsibility of parenthood. Current research suggests that parental rates seem to be higher among FEP women (50-60%) than FEP men, making them more likely to confront this role alongside the inherent challenges connected to the illness. Limited scientific literature on how parenthood affects female with psychosis presents mixed perspectives. The aim of the present study was to explore factors contributing to diminished parental rates in FEP patients and exploring its impact on FEP women.

Methods: This study focused on 610 FEP patients from the PAFIP program in Santander, Spain (2001-2017). Categorizing based on pre-illness-onset parenthood status, men constituted 57.54% (n=351) of the sample, and only 5.41% (n=19) were fathers, while women represented 42.55% (n=259) of the sample, with 36.29% (n=94) of them being mothers. ANCOVA analyses compared baseline and 3-year follow-up outcomes, considering age and education influence.

Results: Parents exhibited older ages at illness onset and program inclusion compared to both non-parent groups ($p \leq 0.001$). Non-mothers surpassed non-fathers in educational levels, IQ, and employment rates ($p \leq 0.05$). Mothers demonstrated a shorter duration of untreated illness and were more likely to come from a low socioeconomic-status family than non-mothers ($p \leq 0.05$). Mothers exhibited superior premorbid adjustment compared to both non-mothers and non-fathers ($p \leq 0.001$). Non-fathers presented higher rates of tobacco, cannabis, and alcohol consumption, along with poorer premorbid adjustment than mothers and non-mothers ($p \leq 0.001$). At three-year follow-up mothers showed lower global neurocognitive deficit scores, and general disability than non-mothers ($p \leq 0.05$). Specifically, mothers exhibited better attention, executive functions, and motor dexterity outcomes ($p \leq 0.05$). Over time, positive and disorganized dimensions were impacted in both groups ($p \leq 0.001$), along with executive functions and motor dexterity ($p \leq 0.05$).

Discussion: Women presented higher rates of pre-illness-onset parenthood status than men. Mothers experienced delayed psychosis onset, suggesting a logical connection between preexisting motherhood and onset age. Prolonged psychosis-free periods may enhance parenthood opportunities, suggesting a potential stability or resilience phase before symptoms. This aligns with findings of superior neurocognitive performance and diminished disability in mothers. Interestingly, these advantages seem present before illness onset, as indicated by better premorbid adjustment. While both groups improved over time, no differences emerged in time by group interaction, suggesting motherhood did not distinctly influence outcomes. An alternative interpretation posits improved initial circumstances or traits, like better premorbid adjustment among mothers, enhancing parenthood likelihood. These considerations have potential implications for treatment planning.

F266. RANDOMIZED, DOUBLE-BLIND, SHAM-CONTROLLED TRIAL TO EVALUATE THE EFFICACY AND TOLERABILITY OF ELECTROCONVULSIVE THERAPY IN PATIENTS WITH CLOZAPINE-RESISTANT SCHIZOPHRENIA

Helio Elkis^{*1}, Debora Melzer-Ribeiro¹, Isabel Napolitano¹, Samuel Leite¹, Joston A. de Souza¹, Adriana Vizzotto¹, Elaine Di Sarno¹, Marisa Fortes¹, Monica Gomes¹, Graça de Oliveira¹, Belquiz Avrichir¹, Leda Talib¹, Christoph Correll²

¹*Institute of Psychiatry University of São Paulo*, ²*The Zucker Hillside Hospital*

Background: Clozapine is the only antipsychotic indicated for Treatment-Resistant Schizophrenia (TRS) but there is no established treatment for patients with clozapine-resistant schizophrenia (CRS). Clozapine augmentation with antipsychotics or other substances is effective in comparison with placebo while augmentation with electroconvulsive therapy (ECT) showed to be effective in comparison with treatment as usual, but not with placebo (sham-ECT). The aim of the present study was to compare ECT vs Sham- ECT in patients defined as CRS by the Treatment Response and Resistance in Psychosis Working Group Consensus Guidelines on Diagnosis and Terminology (TRRIP).

Methods: This was a double-blind, randomized, controlled-trial that compared 40 outpatients with DSM-5 schizophrenia randomized to receive 20 sessions of ECT (n=21) or sham-ECT

(n=19). All patients received anesthesia by hypnotic induction using intravenously (IV): Propofol, Atropine, and Suxamethonium for muscle relaxation. The sham-ECT procedure used the same drugs, except for muscle relaxation, but, instead, 3 mg of midazolam IV for mild hypnotic induction. ECT or sham-ECT was administered twice weekly, with an inter-treatment interval of ≥ 3 days, until the patients completed 20 sessions (10-12 weeks). All participants and their relatives signed the informed consent. The study was approved by the institutional review board of Hospital das Clínicas of the University of São Paulo and registered in Clinicaltrials.gov. Patients were included based on the TRRIP criteria: 1- a confirmed diagnosis of TRS; 2- use of clozapine for ≥ 3 months, with plasma levels ≥ 350 ng/mL. Additionally, patients needed to have a total Positive and Negative Syndrome Scale (PANSS) score GREATER THAN 60 and a score of ≥ 4 in ≥ 2 of the seven items of the PANSS positive subscale. The primary outcome was the $\geq 50\%$ PANSS Total Score reduction; secondary outcomes were the change in scores of the PANSS subscales, the PANSS five-factor dimensions (Negative, Positive, Anxiety-Depression, Disorganized-Cognitive, Excitement), the PANSS-6 (delusions, conceptual disorganization, hallucinatory behavior, blunted affect, social withdrawal, and lack of spontaneity of conversation flow) and the Calgary Depression Rating Scale (CDRS). Treatment response was analyzed by percentage reduction, Linear Mixed Models and effect sizes.

Results: At baseline, patients were 37.40 (± 9.62) years old, predominantly male (77.5%), and ill for 14.95 (± 8.32) years. The mean total PANSS score was 101.10 (± 24.91), and clozapine plasma levels were 909.25 (± 684.6) ng/mL, both values higher in comparison with the international literature. Groups were similar at baseline except for years of school education (included as a covariate). Two patients in each group dropped out during the study. At endpoint 1/19 of the completers (5.26%) in the ECT group and 0/17 in the sham-ECT group showed a $\geq 50\%$ total PANSS score reduction. Both groups showed no significant differences of the total PANSS score ($F=0.12$; $p=0.73$), Positive ($F=0.27$, $p=0.61$), Negative ($F=0.25$, $p=0.62$), and General Psychopathology scores ($F=0.01$, $p=0.94$) as well for all PANSS five factors, the PANSS-6 and CDRS. There were also no significant statistical differences between groups regarding adverse effects.

Discussion: The present study showed that ECT augmentation of clozapine was tolerable but not more efficacious than Sham-ECT. However, the findings may not be generalizable due to the relatively small sample size and the degree of severity of the population. Future studies with larger number of participants who are less compromised are warranted to assess the potential utility of ECT augmentation of clozapine in patients with CRS.

F267. PROSPECTIVELY ASCERTAINED CHILDHOOD PREMORBID PSYCHOLOGICAL FACTORS IN A COHORT OF 719 PATIENTS WITH SCHIZOPHRENIA AND 49,451 CONTROLS

Javiera Vásquez¹, José Conejeros², Camila Díaz Delarrosa³, Cristian Mena⁴, Juan Undurraga⁵, Alfonso Gonzalez-Valderrama⁶, Susana Claro⁷, Eduardo Undurraga⁸, Nicolas Crossley⁹

¹School of Medicine, Pontificia Universidad Católica de Chile, Santiago, ²Pontificia Universidad Católica de Chile, ³Instituto Psiquiátrico Dr. José Horwitz Barak, ⁴Early Intervention Program, J. Horwitz Psychiatric Institute, ⁵Clínica Alemana Universidad del Desarrollo, Early Intervention Program, José Horwitz Psychiatric Institute, ⁶Early Intervention in Psychosis Program at J. Horwitz Psychiatric Institute, Finis Tearrae University, ⁷Stanford University, ⁸School of Government, Pontificia Universidad Católica de

Chile, ⁹Institute of Psychiatry, Psychology and Neuroscience, KCL; and School of Medicine, Pontificia Universidad Católica de Chile

Background: Understanding the premorbid socioemotional trajectories of severe mental disorders, such as schizophrenia and bipolar disorder, is crucial for early identification and the implementation of effective interventions. Factors such as self-esteem, motivation, growth mindset, and perception of family support, have all been associated with mental health difficulties in adolescence. Studies in adults with severe mental illness have also pointed to the existence of similar premorbid difficulties in their earlier lives and could potentially guide preventive interventions. However, these studies are limited by the retrospective nature of their design. Using information collected from national educational assessments in Chile, we examined potential differences in prospectively-ascertained measures of 1) Self-esteem and School Motivation, 2) Perceived Parental Academic Support, and 3) Growth Mindset, in children who later developed resistant and non-resistant schizophrenia and bipolar disorder compared to their classmates.

Methods: This retrospective cohort included 719 children and adolescents born after 1990, later diagnosed with schizophrenia or bipolar disorder, alongside 49,451 healthy controls. The cohort consisted of 584 participants who subsequently initiated treatment with Clozapine for treatment-resistant schizophrenia, identified through the Chilean National Hematological Monitoring Service, and 135 individuals who were diagnosed with a first episode of schizophrenia at the Horwitz Psychiatric Institute in Santiago between 2007 and 2020 (without Clozapine prescription). As comparators, we included 111 patients diagnosed with bipolar disorder in the same institution during the same years and a group of 49,451 healthy controls consisting of each patient's classmates. We obtained anonymized data from the Chilean Ministry of Education's System for Measurement of Educational Quality (SIMCE) tests conducted in 4th, 8th, and 10th grades between 2012 and 2019. We constructed indicators of 1) Self-esteem and School Motivation, 2) Perceived Parental Academic Support, and 3) Growth Mindset. These metrics were z-normalized for every patient with their school classmates of that year. This normalization procedure controlled for cohort effects and socioeconomic status in the context of the economically-segregated nature of the Chilean education system. We estimated mixed linear models to adjust for repeated measurements and the variable number of observations for each participant. The models included group membership (Resistant and Non-resistant Schizophrenia, Bipolar, and Healthy Controls), grade level, gender, and final grade as covariates, in addition to a random effect for school.

Results: We found that children subsequently diagnosed with schizophrenia perceived less parental academic support than their classmates (effect size -0.286, 95%CI -0.399SD to -0.1736SD p LESS THAN 0.001). They also scored higher in growth mindset (effect size 0.251, 95% CI 0.0397SD to 0.462SD $p=0.019$). After adjusting for gender, grade level, and grades, these differences remained statistically significant compared to the healthy classmates. The bipolar patient group did not show statistically significant differences in any of the analysed outcomes. We did not find differences in self-esteem.

Discussion: Our results suggest that the perception of parental academic support could be an antecedent factor in the development of schizophrenia, possibly indicating a more neglectful parental environment and/or lower trust. Unexpectedly, patients with schizophrenia showed a significantly more flexible mindset in childhood, and similar self-esteem to their peers. Interventions aimed at preventing the development of schizophrenia in young people may benefit from focusing on building trust and supporting parental relationships. We should note that our cohort primarily comprised children who developed severe (treatment-resistant) schizophrenia, and our findings might not necessarily apply to those developing milder forms of the illness.

F268. DIAGNOSIS AND SEX-SPECIFIC DIFFERENCES IN THE SHAPE AND VOLUME OF THE HIPPOCAMPUS IN SCHIZOPHRENIA AND BIPOLAR DISORDERS

Daniel Herrera-Escartín^{*1}, Noemí Hostalet², Erick J Canales-Rodríguez³, Raymond Salvador⁴, Xavier Sevillano⁵, Edith Pomarol Clotet⁴, Pilar Salgado Pineda⁴, Mar Fatjo-Vilas², Neus Martínez-Abadías¹

¹University of Barcelona, ²University of Barcelona, FIDMAG Sisters Hospitaliers Research Foundation, CIBERSAM, Biomedical Research Network in Mental Health, Instituto de Salud Carlos III, ³FIDMAG Sisters Hospitaliers Research Foundation, CIBERSAM, Biomedical Research Network in Mental Health, Instituto de Salud Carlos III, Signal Processing Lab (LTS5), École Polytechnique Fédérale de Lausanne, ⁴FIDMAG Sisters Hospitaliers Research Foundation, CIBERSAM, Biomedical Research Network in Mental Health, Instituto de Salud Carlos III, ⁵GTM-Grup de Recerca en Tecnologies Mèdia, La Salle, Universitat Ramon Llull,

Background: Schizophrenia (SZ) and Bipolar Disorder (BD) are psychiatric conditions with a substantial clinical, neurobiological, and genetic overlap, and no diagnostic-specific biomarkers exist. Neuroimaging studies have shown that patients with these diagnosis show subtle gray matter reductions widespread over the brain. However, volume and shape differences in subcortical structures remain far less unexplored, and there are no consistent results regarding sex effect. Geometric Morphometrics (GM) provides a robust methodology that goes beyond the typical brain volumetric approaches and can be used to detect more detailed dysmorphologies. We hypothesized that combining volumetric and morphometric features could improve the description and analysis of anatomical changes associated with these disorders; and that some of these changes could represent diagnostic and sex-specific biomarkers.

Methods: Head structural Magnetic Resonance Images (MRI, 1.5T) were obtained from 131 patients with schizophrenia (SZ), 94 individuals with bipolar disorder (BD) and 89 healthy controls (HC) of European ancestry. Right and left hippocampi were segmented from the MRIs using FSL FIRST, and volumetric differences between groups were evaluated with a regression model, accounting for sex, age and intracranial volume as covariates. To compare the hippocampal shape between patients and controls, the 3D coordinates of 60 landmarks were registered over the left hippocampus of each individual. After a Generalized Procrustes Analysis and correcting for size and age differences by a multivariate linear regression, we computed the Procrustes distances among groups (globally and separated by sexes) and performed permutation tests to assess the statistical significance of shape differences.

Results: Individuals diagnosed with SZ presented reductions in the hippocampus volume compared to HC ($p_{\text{left}} = 0.001$, $p_{\text{right}} = 0.029$) and the same pattern was observed between patients with BD and HC ($p_{\text{left}} = 0.023$). In all group comparisons, both hippocampi displayed volumetric differences between sexes, with males presenting higher volumes than females ($p < 0.001$). As regards shape analyses, pairwise comparisons showed only differences between BD and HC ($p = 0.018$), with patients presenting anterior and posterior narrowing and a more concave hippocampal shape. Furthermore, the results showed a sex-specific effect, with significant differences in hippocampal shape observed only between BD and HC men ($p = 0.016$).

Discussion: Our results confirm previous data, showing a volume reduction in the hippocampus associated with SZ and BD. In addition, our shape analysis based on landmarking and geometric morphometrics contributes to characterising hippocampal morphological changes between groups, providing novel evidence regarding sex-specific dysmorphologies in

BD. Our approach suggests the potential of future studies combining volumetric and shape data to improve our understanding of the neurobiological basis of psychotic disorders.

F269. RECOGNIZING SCHIZOPHRENIA AND DEPRESSIVE SPECTRUM: PRELIMINARY EVIDENCE FROM MACHINE LEARNING ALGORITHMS

Yating Huang^{*1}, Jiayu He¹, Tongxuan Zheng¹, Chao Yan¹

¹*East China Normal University (ECNU)*

Background: Anhedonia serves as a fundamental transdiagnostic trait present in both schizophrenia and major depressive disorder. Within the Research Domain Criteria framework, the Positive Valence System stands as one of six domains illuminating the shared foundational mechanism of psychotic disorders. This study aimed to the effectiveness of machine learning (ML) for classifying the schizophrenia spectrum and depressive spectrum, grounded in the multidimensional reward processing theory. Additionally, it investigates the degree to which various dimensions of reward processing contribute to the overall classification performance.

Methods: A total of 453 subjects (Mage=23.27, SDage=7.54, 289 females) were recruited from mental health center and community, comprising of 55 schizophrenics (SCZ), 116 major depressive disorders (MDD) and 282 healthy controls (HCs). Among healthy controls, there were 36 individuals with high schizotypy (HS, top 10% of total score) and 112 individuals with subthreshold depression (SD, BDI total score GREATER THAN 16) and 134 individuals with low depressive symptoms and schizotypy. All participants underwent the Monetary Reward Delay Task, the Pleasure Experience Prediction Questionnaire, and the Pleasure Experience Recall Questionnaire. These assessments measure anticipatory pleasure (including the "prediction" and "feeling" components), consummatory pleasure, motivation, and remembered pleasure. These factors were subsequently extracted as predictive features, serving as inputs for training the Machine Learning (ML) model. The aim was to assess the classification performance, differentiating between SCZ and MDD from HCs. Additionally, we extend the model to categorize at-risk groups such as high schizotypy and SD individuals. After model evaluation, we calculate feature weights to determine the significant impact of reward dimensions on classification separately.

Results: The RF model demonstrates moderate performance in distinguishing SCZ from HCs (AUC=92.62%, Sensitivity=61.54%, Specificity=88.00%). In terms of depression, the RF model achieves high classification accuracy for MDD patients (AUC=90.75%, Sensitivity=86.36%, Specificity=78.57%) and individuals with SD (AUC=90.73%, Sensitivity=82.35%, Specificity=84.85%). Combining SD and MDD individuals enhances the model's performance (AUC=96.35%, Sensitivity=93.33%, Specificity=89.29%). However, the sensitivity was low to classify individuals with HS from HCs. We examined the weights (wts) of reward dimensions and identified that "motivation" and "anticipatory pleasure" were the two most influential dimensions in distinguishing the depression and SCZ (Moti: wts=[0.34, 0.41]; Anti: wts=[0.23, 0.29]).

Discussion: Our findings underscore the effectiveness of the RF model in accurately classifying SCZ, MDD, and SD from HCs. However, the model demonstrated limitations in recognizing schizotypy. Notably, within the domain of reward processing, the dimensions of motivation and anticipatory pleasure emerged as pivotal contributors to the classification of both schizophrenia and depression. These insights provide valuable implications for understanding the transdiagnostic mechanisms of anhedonia.

F270. SYMPTOM NETWORK DIFFERENCES BETWEEN SCHIZOPHRENIA AND AUTISM SPECTRUM DISORDER: A NETWORK ANALYSIS

Szilárd Holka*¹, Dániel Sörnyei¹, Ágota Vass¹, Kinga Farkas¹

¹*Semmelweis University*

Background: The overlapping symptoms of schizophrenia and autism are increasingly emphasized in research on the two disorders. Among these symptoms, much attention is focused on psychopathological variables such as mentalization, self-perception, perceptual anomalies, anxiety or depression. For example, an important link between the two disorders lies in mentalizing abilities, which are characterized by atypical neurodevelopment and are significantly influenced by attachment patterns with parents and the wider environment. Although the vast majority of research has examined these factors independently, the transdiagnostic approach is rare. We aim to fill this gap by applying network analysis, which is gaining popularity in the field of psychopathology. This approach allows us to explore complex relationships between theoretically selected variables in a data-driven way.

Methods: Based on previously established psychiatric diagnosis, participants were grouped into people with schizophrenia (SCH), with autism spectrum disorder (ASD), and neurotypical (NTP) without any diagnosis. Altogether 1909 participants (ASD: N=158, 47% female, mean age = 32 years; SCH: N=44, 79% male, mean age = 34 years, NTP: N = 1707, 64% female, mean age = 38 years) have completed questionnaires about social cognition, social support and psychopathological factors. To model conditional independence relationships between the variables we applied network analysis on our cross-sectional data. We estimated Gaussian graphical models with regularization technique graphical LASSO based on extended BIC criterion. To examine the importance of constructs, we identified the most central nodes in the networks through centrality metrics, including strength, closeness, betweenness and expected influence. Finally, we checked the reliability and accuracy of the networks with the nonparametric and case-dropping bootstrap methods. To explore the global and local network structure differences between the groups, we applied the Network Comparison Test. NCT is a permutation test which allows us to assess invariance measures, such as network structure invariance, global strength invariance and edge invariance.

Results: Preliminary analysis showed that only the symptom network structure of ASD differs significantly from the NTP network in global strength ($p < 0.05$). Bootstrapping results showed that the network models are reliable. In the SCH network the narrative subscale of the same questionnaire was the most central regarding strength and expected influence, while the Multidimensional Schizotypy Scale's disorganised subscale had the highest z-score in betweenness and closeness metrics. The ownership subscale of Embodied Sense of Self Scale was the most central node in the ASD network. Self-reflectiveness was the most central node in strength and expected influence in the NTP network, as well as intellect and openness in terms of betweenness and closeness.

Discussion: Our hypothesis was that mentalization would play a central role in the network structure of SCH and ASD. Although this was not the case, our results are still clinically relevant. The crucial role of disorganisation in the SCH network structure confirms its prominent role in the psychotic state as well in the general psychopathology itself. This is supported not only by the centrality indices, but also through a strong positive relationship with ownership in the ASD network. As regards the NTP network, the intellect and openness, as well as self-reflectiveness can be identified as protective factors from the psychotic condition. In this approach the significance of these factors lies in the potential therapeutic targets they may represent.

F271. SUPAR: A POSSIBLE BIOMARKER FOR SCHIZOPHRENIA

Mikkel Soerensen^{*1}, Bahast Biuk², Jimmi Nielsen³, Bjørn H. Ebdrup⁴, Mette ødegård nielsen⁵

¹CNSR, ²Copenhagen University Hospital, ³Psychiatric Centre Glostrup, Unit for Complicated Schizophrenia, Mental Health Services in the Capital Region of Denmark, ⁴Center for Neuropsychiatric Schizophrenia Research, CNSR, Center for Clinical Intervention and Neuropsychiatric Schizophrenia Research, CINS, Mental Health Centre Glostrup, University of Copenhagen, University of Copenhagen, ⁵Center for Neuropsychiatric Schizophrenia Research

Background: Recent attention to the immunological aspects of schizophrenia suggests heightened inflammatory activity in schizophrenia. A novel biomarker, soluble urokinase-type plasminogen activator receptor (suPAR), exhibits elevated levels in patients with chronic schizophrenia. SuPAR's stability and resistance to freezing make it suitable for longitudinal studies. Positive correlations with immunological biomarkers, such as IL-6 and hs-CRP, position suPAR as a promising marker for chronic inflammation, less influenced by acute changes. This study aims to investigate suPAR as a novel biomarker in different stages of schizophrenia.

Methods: This investigation integrates data from two distinct cohorts, each including a matched healthy control group:

1. PECANS 2 (N=108) which centers on antipsychotic-naïve first episode psychosis (ANFEP) individuals diagnosed with schizophrenia or non-affective psychoses. These patients underwent treatment with Aripiprazole for a duration of minimum 6 weeks.

2. The Clinical Re-examination Cohort (N=137) comprises chronic patients re-evaluated approximately 9.6 ± 3.5 years after their initial diagnosis of either schizophrenia or schizoaffective disorder.

suPAR was analyzed using suPARnostic ELISA assay at Hvidovre Hospital, Denmark. Values were log transformed for statistical analyses.

Results: As indicated by prior literature, female sex, daily tobacco smoking, and higher age emerged as principal factors increasing suPAR levels across the cohorts and patient status. Adjusted for these values, we observed no group difference in the ANFEP cohort before the initiation of medical treatment ($p=.44$). Following a 6-week monotherapy with aripiprazole, the suPAR concentration increased slightly in patients ($t=2.1$, $p=0.02$) and was stable in the healthy controls, although the group time interaction was not significant. Furthermore, the suPAR level in the clinical re-examination cohort is elevated in the patient group ($F=6.3$, $p=0.013$), even when adjusted for age ($F=6.9$, $p=0.01$), sex ($F=11.3$, $p=0.001$), and smoking status ($F=24.6$, $p < 0.001$).

Discussion: These preliminary findings validate suPAR as a potential biomarker for schizophrenia. The rise in suPAR levels is notably significant among schizophrenia patients undergoing antipsychotic treatment compared to matched healthy controls. Interestingly, this signal becomes more pronounced with an increasing duration from the time of initial diagnosis. The current analyses affirm prior observations in individuals with chronic schizophrenia, where elevated suPAR levels have been documented. Our data indicate that this phenomenon does not manifest during the initial stages of first psychotic diagnoses. However, within the first six

weeks, a modest yet significant increase in suPAR is evident. This disparity among groups appears to persist over the years. Further investigation is necessary to determine whether this signal is a result of medication usage or signifies a progression in the underlying pathology of schizophrenia.

F272. A REVAMPED CLINICAL QUALITY REGISTRY FOR PSYCHOSIS IN SWEDEN: LEARNING FROM EXAMPLES OF EXCELLENCE

Simon Cervenka*¹, Lydia Melchor², Maria Skott³, Mikael Landén⁴

¹*Uppsala University*, ²*Sahlgrenska University Hospital*, ³*Karolinska Institutet*, ⁴*University of Gothenburg*

Background: Sweden has a strong tradition in national quality registries, with high coverage and strong output across a wide range of disciplines. The registries contain individualized data about medical interventions, procedures and outcomes, and are typically integrated into clinical workflows resulting in a capacity to generate data in real time. Sweden's more than 100 registries have leveraged the country's position in health care resulting in having among the best survival rates after acute heart infarction, stroke and breast cancer. The Swedish registries are certified by the National Steering Group for Quality Registers, which also performs ongoing monitoring, securing the validity and hence clinical relevance. Examples of successful registries in psychiatry include the ECT and Bipolar registry (Bipolär). A registry was previously established also for psychotic disorders (PsykosR) however coverage and hence the utility for both clinical care and research has been lacking. In parallel, a national audit of psychosis health care showed large interregional differences in quality.

Methods: A revamped version of PsykosR is established and merged with Bipolär. The process for establishing an optimized minimum dataset (MDS) with high relevance for health care providers is described.

Results: The new registry has a module for new registrations, with particular attention to onset of symptoms and loss of function, as well as on the clinical workup. Subsequent data registration is integrated into the yearly follow-up visit which is performed according to current national guidelines, and includes parameters for symptom levels, interventions including pharmacological treatment, hospital admissions and social support, as well as indicators of somatic health. The registry is designed to also include individuals at clinical high risk for psychosis (CHR-P).

Discussion: The establishment of a new version of PsykosR aims to increase quality of health care on a national level by providing real-time feedback to providers, as well as generate data for research that can further leverage treatment algorithms. The inclusion of an arm for CHR-P is an important starting point for developing early detection and intervention practices in Sweden.

F273. STUDY PROTOCOL OF A RANDOMIZED CONTROLLED TRIAL TESTING THE EFFECTS OF METACOGNITIVE TRAINING (MCT) ON NEGATIVE SYMPTOMS IN PSYCHOTIC DISORDERS, AND EXPLORING POTENTIAL MECHANISMS UNDERLYING SYMPTOM REDUCTION

Benjamin Rask*¹, Simon Cervenka¹, Jonas Persson¹, Linda Swanson¹, Tonya Pixton², Ulrika Sällström², Mårten Tyrberg³

¹*Uppsala University*, ²*Centre for Clinical Research Sörmland, Uppsala University*, ³*Centre for Clinical Research Västmanland, Uppsala University*

Background: Negative symptoms in schizophrenia (NS) presents a substantial barrier to daily functioning and quality of life for those affected and current treatment options are limited. The cognitive model (Beck et al., 2009) suggests that NS could be caused and maintained by maladaptive coping strategies such as shutting down the cognitive-affective experience and adopting dysfunctional beliefs. Recent research highlights metacognition (MC) and reflective functioning (RF), processes of understanding internal mental states, as crucial for understanding and treating NS, with deficits in MC linked to more severe NS and decreased RF associated with NS severity. Metacognitive training for schizophrenia (MCT) combine elements from cognitive behavioral therapy (CBT), psychoeducation and cognitive remediation therapy (CRT) to target cognitive biases (Moritz and Woodward., 2007). A recent meta-analysis found support for a magnitude of observed association between MCT and lowered delusions as well as hallucinations (Penney, Sauvé and Mendelson., 2022). Recently, metacognitive training for negative symptoms in schizophrenia (MCT-Minus) (Swanson et al., 2021) was developed, focusing on specific thought patterns common in NS such as negative beliefs about human interaction; low expectations about pleasure, success and acceptance; and defeatist beliefs about performance. Results from a feasibility study indicate that MCT-Minus can lead to improvement including increased reflective functioning, decreased NS, and reduced perceived stigma (Swanson et al., 2022; Swanson et al., 2023). The current project aims to build on these findings, by evaluating MCT-Minus efficacy and by exploring potential psychological and biological mechanisms underlying symptom reduction.

Methods: Participants over the age of 18 with a psychotic disorder will be recruited from tertiary psychiatric care and randomized into 8 sessions of either MCT-Minus (n = 45) or counseling (n = 45), which will be blinded to the subjects. Primary outcome measures are the Positive and Negative Syndrome Scale (PANSS), the Clinical Assessment Interview for Negative Symptoms (CAINS) and Motivation and Pleasure Scale-Self Report (MAP-SR). Secondary outcome measures include the Dysfunctional Attitudes Scale (DAS), the Reflective Functioning Questionnaire (RFQ-8), and the Internalized Stigma of Mental Illness Scale-9 (ISMI-9). Group differences will be evaluated through analysis of variance. Underlying mechanisms will be explored through structural equation modelling using the independent variable (MCT-Minus), the mediator variables (RF, perceived stigma and dysfunctional attitudes) and the dependent variable NS. Quantitative data will be collected at pre-intervention, post-intervention and at follow-up after 12 weeks. Semi-structured interviews investigating the participant experience of MCT-Minus and potential benefits will be conducted at pre-intervention and post-intervention. Thematic analysis will be used to analyze the qualitative data. Resting state functional magnetic resonance imaging (rsfMRI), structural MRI, and MR spectroscopy will be performed in all subjects pre- and post-treatment. Preprocessing and statistical analysis of rsfMRI scans will be performed in conn toolbox in Matlab. The study and the statistical analyses will be preregistered.

Results: We hypothesize that improvements in NS will be greater in the intervention group compared to the counseling control group, and that treatment gains will be maintained at follow-up. In the rsfMRI study the primary aim is to compare changes in connectivity in the default mode network, which is involved in reflective processes such as MC. We hypothesize that, between groups, structural changes are related to NS improvement. Secondary aims are to study change in glutamate levels and structural connectivity in the anterior cingulate cortex.

Discussion: This will be the first RCT to assess MCT specifically targeting NS in schizophrenia. Moreover, to our knowledge no previous study has investigated changes in functional connectivity after psychological treatment targeting NS. Findings may contribute to addressing the unmet therapeutic need for NS in schizophrenia.

F274. VALUE OF GYM-BASED EXERCISE TRAINING VERSUS USUAL CARE FOR YOUNG ADULTS WITH SEVERE MENTAL ILLNESS: A PRAGMATIC, SINGLE-BLINDED, MULTI-CENTRE RANDOMISED CONTROLLED TRIAL - THE VEGA TRIAL

Bolette Skjødtt Rafn^{*1}, Victor Sørensen², Martin Andersen³, Bjørn H. Ebdrup⁴, Julie Midtgaard³

¹*Mental Health Centre Glostrup*, ²*Centre for Applied Research in Mental Health Care (CARMEN) and Center for Neuropsychiatric Schizophrenia Research (CNSR), Mental Health Center Glostrup, University of Copenhagen*, ³*Centre of Applied Research in Mental Health Care (CARMEN), Mental Health Centre Glostrup, University of Copenhagen*, ⁴*Center for Neuropsychiatric Schizophrenia Research, CNSR, and Center for Clinical Intervention and Neuropsychiatric Schizophrenia Research, CINS, Mental Health Centre Glostrup, University of Copenhagen*,

Background: People with severe mental illness (SMI) have increased risk of developing obesity, metabolic syndrome, and type II diabetes. The relationship is multifactorial including the mental disorder, psychosocial effects, dietary habits, smoking, adverse effects of antipsychotics, and sedentary lifestyle. Exercise can be a cost-efficient adjunctive treatment in improving personal recovery, symptom burden, cognition, quality of life, and multiple cardiometabolic outcomes. Furthermore, exercise carried out in communities have the potential to reduce the experience of isolation, loneliness, and internalized stigmatization and may improve long-term change of physical activity behaviour. Thus, we aim to evaluate the effectiveness of gym-based group exercise (Vega Exercise Community) compared to usual care for young adults with SMI. We hypothesize that Vega Exercise Community will be superior to usual care for personal recovery after four months.

Methods: The Vega trial is a pragmatic, single-blinded, multi-centre randomised controlled trial that is conducted at three sites across Denmark. We aim to include 400 participants aged 18-35 years and diagnosed with SMI, specifically schizophrenia spectrum disorders, bipolar disorders, or major depression. Initially, an eligibility criterion was current antipsychotic medication, however this criterion was removed since it excluded many people with SMI who could have benefitted from participating, and thus limited the generalizability of the trial. Participants are randomized (2:1) to the Vega Exercise Community or usual care. Vega Exercise Community offers three weekly supervised group-based functional training sessions hosted in commercial centers delivered by certified Vega instructors. Participants in Vega Exercise Community will be randomized (1:1) after four months to minimal versus extended support with regards to sustained physical activity. Per protocol attendance to the exercise community is set at 33% a priori. Assessment of outcomes occurs at baseline, four, six and 12-months. The primary outcome is personal recovery assessed by Questionnaire about the Process of Recovery at four months. Additional outcomes include behavioral and functional symptoms, health-related quality of life, metabolic health, and cardiorespiratory fitness. Finally, the quality of life and physical and mental health of the participants' primary relative is evaluated.

Results: Recruitment began in October 2022. As of Dec 6th, 2023, 270 have been screened for eligibility, where 20 were ineligible and 61 declined with the main reasons being distance to the Vega Exercise Community or exercise schedule conflicted with other commitments. Currently, 124 are enrolled and 94, 70 and 11 have completed the four-, six-, and 12-months assessments, respectively. 34 primary relatives are enrolled and 28 have completed at least one follow-up questionnaire. Participants have attended on average 27% (SD 19) of the available exercise sessions, while 33% of participants have attended the exercise sessions per protocol.

Discussion: Given the pragmatic nature of the trial, attendance is not required nor expected three times per week. Rather the exercise community is available for participants to use when possible. Yet, many participants attend the Vega Exercise Community regularly. The Vega Exercise Community program has the potential not only to improve recovery and health of individuals with SMI but also enable healthcare professionals to promote exercise as an integrated part of treatment. This holds the potential to bridge mental healthcare services and the civil society and subsequently promote physical activity and social inclusion.

F275. PROPOSAL FOR NOVEL PATIENT CLASSIFICATION WITH ENLARGED LATERAL VENTRICLES AND COGNITIVE DECLINE BASED ON DATA-DRIVEN ANALYSIS OF NEUROIMAGING IN PSYCHIATRIC DISORDERS AND CLINICAL CHARACTERIZATION

YUKA YASUDA*¹, Satsuki Ito¹, Junya Matsumoto¹, Naohiro Okada², Masaki Fukunaga³, Kiyotaka Nemoto⁴, Kenichiro Miura¹, Naoki Hashimoto⁵, Kazutaka Ohi⁶, Tsutomu Takahashi⁷, Michihiko Koeda⁸, Hidenaga Yamamori⁹, Michiko Fujimoto¹⁰, Naomi Hasegawa¹, Shinsuke Koike¹¹, Motoaki Nakamura¹², Go Okada¹³, Jun Miyata¹⁴, Shusuke Numata¹⁵, Toshiaki Onitsuka¹⁶, Reiji Yoshimura¹⁷, Shin Nakagawa¹⁸, Yoshiyuki Watanabe¹⁹, Norio Ozaki²⁰, Ryota Hashimoto¹

¹National Institute of Mental Health, National Center of Neurology and Psychiatry, ²The University of Tokyo, ³National Institute for Physiological Sciences, ⁴University of Tsukuba, ⁵Hokkaido University Graduate School of Medicine, ⁶Gifu University Graduate School of Medicine, ⁷University of Toyama Graduate School of Medicine and Pharmaceutical Sciences, ⁸Nippon Medical School, ⁹Japan Community Health Care Organization, Osaka Hospital, ¹⁰Osaka University Graduate School of Medicine, ¹¹University of Tokyo, ¹²Showa University, ¹³Hiroshima University, ¹⁴Aichi Medical University, ¹⁵Tokushima University, ¹⁶National Hospital Organization Sakakibara Hospital, ¹⁷University of Occupational and Environmental Health, ¹⁸Yamaguchi University Graduate School of Medicine, ¹⁹Shiga University of Medical Science, ²⁰Nagoya University Graduate School of Medicine

Background: The creation of a novel diagnostic system using objective biomarkers is expected to take place, due to difficulty of the current diagnostic system based on symptoms in psychiatry. We clustered the 5602 subjects based on brain subcortical volumes and showed a four-biotype classification, namely extremely (Brain Biotype [BB] 1: n=110) and moderately smaller limbic regions (BB2: n=566), larger basal ganglia (BB3: n=679), and normal volumes (BB4: n=4247), being associated with cognitive/social functioning (Okada et al., Mol Psychiatry, 2023). In the present study, we performed a detailed examination of the biological and clinical characteristics of these biotypes.

Methods: A total of 5602 patients in the previous paper, including healthy subjects (n=3077), patients with schizophrenia (SZ: n=1499), bipolar disorder (BD: n=234), major depressive disorder (MDD: n=598), autism spectrum disorder (ASD: n=189) and other psychiatric

disorders (O: n=5), were included. The biological and clinical characteristics of four biotypes were investigated using subcortical volumes from T1-weighted MRI images, cognitive functions, EEG, and genomic information.

Results: We examined the differences in subcortical volume characteristics in each biotype and found that the lateral ventricle volume was remarkably larger ($Z\text{-score} = 5.1 \pm 1.8$) in BB1 (n=110). 99.1% of BBI subjects had the lateral ventricle volume greater than 3 standard deviation (3 SD) of normal subjects, and this brain feature discriminated BB1 with a sensitivity of 99.1% and a specificity of 98.1%. Therefore, BB1 was redefined as a brain structural feature with a lateral ventricular volume of 3 SD or greater. Of the 186 redefined subjects, 33 patients with detailed cognitive function data were stratified into two groups: 9 patients with moderate or higher cognitive decline (SZ8/ASD1) and 24 patients with mild or lower cognitive decline (SZ9/ HC9/ASD4/ MDD1/O1), and compared. EEG abnormalities (71% in the former group, 0% in the latter), a diagnosis of schizophrenia (89% in the former group, 38% in the latter group), and low intelligence (IQ=67 in the former group, IQ=103 in the latter group) were obviously observed in the former group than in the latter. Furthermore, copy number variation analysis of 7 out of 9 cases in the former group showed a high rate of pathological CNV (22q11.21 deletion, 7q11.23 duplication, and DPP6 deletion) in 3 cases, which is only seen in approximately one out of several thousand normal subjects.

Discussion: We have identified a novel candidate for classification of psychiatric disorders with high rates of EEG abnormalities, psychotic symptoms, and pathological rare genomic variants in a stratified group of patients with schizophrenia and other psychiatric disorders with lateral ventricular volumes of 3 SD or greater and moderate to severe cognitive decline. However, the limitation is that the number of patients is still small, and the clinical course, treatment response, outcome and other clinical features have not yet been investigated. We proposed a possible novel psychiatric disorder by going back to each patient based on the clinical significance from a large-scale data-driven analysis screening, and proposed a methodology to find the concept and psychiatric disorders by objective indices for the first time in the world.

This new biotype classification suggests the possibility that objective measurements based on brain imaging data will be incorporated into psychiatric diagnostic systems in the future. Furthermore, it is expected that the creation of animal models that can be objectively validated will become possible, which might reenergize the stalled development of therapeutic drugs.

F276. A SINGLE CASE EXPERIMENTAL DESIGN PILOT OF A CULTURALLY ADAPTED BRIEF POST-TRAUMATIC STRESS DISORDER (PTSD) INTERVENTION FOR PEOPLE WITH FIRST-EPISODE PSYCHOSIS AND PTSD

Vuyokazi Ntlantsana*¹, Usha Chhagan¹, Yusuf Asmal¹, Enver Karim¹, Saeeda Paruk¹, Lindokuhle Thela¹, Andrew Tomita², Lauren C Ng³, Bonga Chiliza¹

¹University of KwaZulu-Natal, ²KRISP, ³UCLA

Background: Post-traumatic stress disorder (PTSD) prevalence is higher in populations with psychosis and is associated with poorer outcomes. Brief Relaxation, Education and Trauma Healing (BREATHE) is a 3-session intervention developed in the USA for patients with PTSD and serious mental illness. The main components are breathing retraining and psychoeducation using videos as aids and includes homework as part of the intervention. BREATHE is suitable for task-shifting. Culturally adapted interventions have been shown to have better efficacy, especially in minority populations, compared to un-adapted interventions. The study aimed to

assess the feasibility, tolerability and acceptability of a culturally adapted BREATHE intervention in patients with first episode psychosis (FEP) and PTSD in Durban, South Africa. **Methods:** Participants with FEP who screened positive for PTSD on the PTSD Checklist for DSM 5 (PCL-5) were recruited into an adapted multiple baseline design type of the single case experimental design pilot study from May to October 2023. The structured clinical interview for DSM-5 was used to confirm a diagnosis of PTSD. Feasibility was assessed using follow-up rates and participant use of intervention techniques. To assess for tolerability, participant discomfort or clinical deterioration were observed. Qualitative interviews and the Treatment Acceptability and Adherence Scale (TAAS) were used for assessing for treatment acceptability. PTSD symptoms, culture-specific PTSD symptoms and PTSD cognitions were measured using the PCL-5, the Zulu Culture-specific Trauma Experience Questionnaire (Z-CTEQ) and Posttraumatic Cognitions Inventory (PTCI), respectively. Weekly measures were conducted for five weeks before the intervention, during the three weeks of the intervention, at one-month and 3-months post intervention. Other quantitative measures such as the positive and negative symptoms scale (PANSS) for psychosis symptom severity, Childhood trauma questionnaire (CTQ) for childhood trauma and WHO Disability Assessment Scale to assess for disability, were used. The pilot was single blinded with only the assessors blinded to intervention allocation. The therapist who administered the intervention was trained by the developers of the intervention and the assessors were two trained research assistants and one psychiatrist.

Results: Four participants were recruited into the study. The follow-up rate was 100% and regular use of intervention techniques indicated good feasibility. No adverse events were reported indicating good tolerability. TAAS median score of 62.5 (IQR 55-69.5), indicated good treatment acceptability. PCL and PCTI scores showed improvement but the Z-CTEQ scores remained stable. Mean PANSS scores were 37.5 (SD 5.1) and 39.25 (10.0) at enrollment and 3-month assessments, respectively, indicating low psychosis symptom severity. Two participants scored positive for childhood trauma domains. WHODAS scores were median 25 (17.5-30.5) and 20.5 (17.5-37), indicating some improvement in disability.

Discussion: Culturally adapted BREATHE intervention is safe, feasible, acceptable, and may be efficacious in populations with early psychosis and PTSD symptoms. It is a suitable for low resource settings as it is a relatively low-cost intervention, allows for agency as patients can manage their own symptoms using breathing techniques as self-regulation. It may be administered to patients as they await higher level care. The study is the first step towards a powered efficacy and implementation sustainability studies, but this will require further cultural adaptation of the intervention for treatment of PTSD related to cultural experiences.

F277. UPPSALA PSYCHOSIS COHORT: A MULTIMODAL STUDY IN EARLY STAGE PSYCHOSIS PATIENTS, HIGH RISK INDIVIDUALS AND HEALTHY CONTROLS

Inez Ebbersten Olivero-Reinius^{*1}, Jonas Persson¹, Martin Cernvall¹, Oscar Aarflot¹, Victoria Arfuch Prezioso¹, Corina Caprariu¹, Johan Bengtsson¹, Simon Cervenka¹

¹*Uppsala University*

Background: Imaging and post-mortem studies reveal cortical grey matter thinning, connectivity loss, and synaptic marker reduction in individuals with schizophrenia. Deviant synaptic activity measured by EEG suggests impaired error detection, contributing to hallucinations, delusions, and cognitive impairments. Several lines of research suggest that

excessive synaptic pruning by microglia, particularly involving complement factor C4A, may be a key mechanism for causing these changes in brain structure and function. Initial studies using Positron Emission Tomography (PET) and radioligands for the synaptic vesicle protein 2A (SV2A) have demonstrated synaptic reduction in patients with long-term schizophrenia, whereas two subsequent studies on early-stage psychosis patients have yielded divergent results (Yoon et al., 2023; Onwordi et al., 2023). Hence, the timing of putative synaptic loss during disease development remains unclear, and the proposed underlying mechanisms remain to be confirmed in vivo. The main aim of the present project is to address these questions.

Methods: The Uppsala Psychosis Cohort (UPC) (ClinicalTrials.gov ID NCT05763966) is a longitudinal, multimodal, observational study that aims to include 60 early-stage psychosis (EPP) patients, 30 clinical high-risk for psychosis (CHR-P) individuals, and age and gender-matched healthy controls (HC). EPP criteria include onset of psychotic symptoms together with functional decline within 3 years. CHR-P individuals meet established criteria using Structured Interview for Psychosis-risk Syndromes (SIPS). Assessments, including clinical, cognitive (using MATRICS Consensus Cognitive Battery), and imaging will be conducted at baseline and follow-ups at 1, 3, and 5 years. A lumbar puncture is performed at baseline. The imaging protocol includes PET with the SV2A radioligand [18F]SynVest-1 (baseline and 1 year), MR modalities (fMRI, DTI, MRS), and neurophysiological examinations (EEG, TMS). Metabolite-corrected arterial input function is used for PET data quantification. Data analysis integrates SV2A PET, MRI modalities, and neurophysiology to evaluate synaptic loss and the consequences for brain function. We hypothesize greater differences in SV2A in each stage of disease development (HC LESS THAN CHR-P LESS THAN EPP), linked to symptom severity and cognitive impairment. Cerebrospinal fluid analysis aims to identify predictive markers for synaptic loss and disease progression, including C4A levels. The analysis considers genetic vulnerability as well as cannabis exposure, which has shown to influence both SV2A binding in in vivo and affect synaptic density in vitro.

Results: The first patient was enrolled in May 2023. Descriptive data from initial patients will be reported, including also results from their experience of participating in the study.

Discussion: By combining cross-sectional and longitudinal analyses, including at-risk individuals, the study addresses the key question of when synaptic changes occur during disease progression, and in which patients. Recognizing heterogeneous disease mechanisms, the proposal's clinical implication lies in developing tools for patient stratification in trials of novel treatments, such as candidate drugs targeting microglia-mediated synaptic pruning.

F278. THE ASSOCIATION BETWEEN CHILDHOOD TRAUMA AND EDUCATIONAL ATTAINMENT, AND COGNITION IN PATIENTS WITH SCHIZOPHRENIA, THEIR UNAFFECTED SIBLINGS, AND HEALTHY CONTROLS: RESULTS FROM THE TURKISH SAMPLE OF THE EU-GEI STUDY

Neurosurgery, ⁶Dokuz Eylül University, School of Medicine, ⁷Adnan Menderes University, ⁸Dokuz Eylül University, ⁹Ankara University Brain Research Center, ¹⁰Middle East Technical University, ¹¹Okan University, ¹²Güven Çayyolu Healthcare Campus, ¹³Gülhane, University of Health Sciences, ¹⁴Maastricht University Medical Centre, ¹⁵Istanbul University

Background: Childhood trauma (CT) is suggested to adversely impact educational attainment and cognition. However, few studies have explored the differential effects of CT subtypes on these aspects. This study aims to examine the potential effects of CT subtypes on educational attainment and global cognition in a large Turkish sample, including patients with schizophrenia (SCZs) (n=742), their unaffected siblings (SIBs) (n=718), and healthy controls (HCs) (n=1039).

Methods: CT was assessed using the short form of the Childhood Trauma Questionnaire (CTQ), measuring childhood emotional, physical, and sexual abuse, as well as physical and emotional neglect. Global IQ was assessed with the Brief WAIS -III Revised. Level of education was defined as years of completed education. Psychotic experiences were measured using the Community Assessment of Psychic Experiences (CAPE). Additionally, premorbid social adjustment in childhood and adolescence was evaluated with the Premorbid Adjustment Scale (PAS) (only in SCZs). In statistical analysis, a Brown–Forsythe test (due to asymptotically F distribution) was used to compare mean scores of CTQ sub-scales, education, and IQ among the study groups. Cross-sectional group comparisons based on CT history were conducted with the independent samples t-tests in each group. Associations of the five CTQ mean scores with education and global IQ were separately assessed for each group using hierarchical regression analyses. The regression analyses were conducted with adjustments for the following confounders: sex and age, global IQ (only for CT-education) or education (only for CT-IQ), CAPE total score and mean scores of PAS, and current antipsychotic use (only for SCZs).

Results: Patients significantly had less years of education and global IQ scores (respectively, 10.4 ± 3.9 ; 58.6 ± 34) compared to both their siblings (11.4 ± 4.1 ; 78.4 ± 37.2) and HCs (11.2 ± 4.1 ; 84.6 ± 27.3) (all pcorr. LESS THAN 0.001). SCZs had higher scores in all CTQ sub-scales than both SIBs and HCs (all pcorr. LESS THAN 0.001). SIBs had higher scores of emotional abuse (pcorr. LESS THAN 0.001) and emotional neglect (pcorr.=0.003) than HCs. CT was negatively related to education and cognitive performance in all groups, only with physical neglect being related to educational attainment in all three groups. In the SCZ group, on educational attainment, after adjusting for sex and age, global IQ had a significant effect, and when controlling for all confounders, physical abuse also showed a significant effect ($\beta_{adj} = -0.17$, pcorr.=0.01). However, it was found that global IQ is associated only with confounders including age, education, CAPE, and PAS (LESS THAN 12 age). The relationships between CT and education, and cognition, were found to be more prominent in both SIBs and HCs.

Discussion: The study showed a weak association between CT and lower educational attainment in SCZs, compared to both the other groups. A similar pattern was observed emerged for global IQ. While there was no relationship between global cognition and any type of trauma in SCZs, cognitive performance was negatively affected by CT, especially neglect types, in both SIBs and HCs. Furthermore, in SCZs, only the confounders were associated with global IQ. In patients with SCZ, besides the confounders examined in this study, additional risk factors such as relapses or hospitalizations might negatively play a role in education and cognition. We propose that, in the absence of other risk factors, these relationships are more prominent in SIBs, who share the family environment and genetic risk with SCZs. Our findings

are important revealing that different types of CT may have an impact on educational attainment and cognition, and with these effects diversifying in each group.

F279. IDENTIFICATION OF SUBTLE VISUAL DYSFUNCTIONS IN RECENT ONSET PSYCHOSIS AND DEPRESSION, AND CLINICAL HIGH-RISK STATE USING ENTROPY AND ENERGY FEATURE MAPS.

Background: Subtle Visual Dysfunctions (VisDys) are often ignored in clinical studies of patients with schizophrenia, despite being detailed by 50% of patients. Furthermore, the neurobiological underpinnings of VisDys in patients with a first/recent onset psychosis (ROP) or depression (ROD), and a clinical high-risk condition for psychosis (CHR) are unclear. A deeper understanding of VisDys in early psychotic states could not only provide useful information for clinical practice, but also advance understanding of the underlying disease perceptual mechanisms that mediate susceptibility to psychosis. We investigated the utility of entropy and energy texture features for identification of VisDys in ROP and CHR, respectively. Entropy measures the complexity of the texture distribution, and its inverse measure is the energy which reflects the regularity and uniformity of the texture distribution. Then, the identification of VisDys in ROD using both developed models was tested.

Methods: Structural MR images were acquired from 135 ROP (64 patients with VisDys), 134 CHR (71 patients with VisDys) and 140 ROD (23 patients with VisDys). External validation set included 113 ROP (45 with VisDys), 104 CHR (51 patients with VisDys) and 77 ROD (17 patients with VisDys). The mwp0* image produced via SPM12 segmentation was used for discretization of intensities. Next, a voxel-by-voxel sliding 3D cube of 7x7x7 dimension was used for the grey level co-occurrence matrix (GLCM) calculation. Texture features were extracted and imported in a 20x20 nested cross-validation schema for the identification of VisDys. In the inner loop, cross-validated feature selection method selected equal number of ranked-features to the number of the patients. To perform localization, the positive relevance (PR) of voxels for patients with VisDys was calculated using the layer-wise relevance propagation (LRP) algorithm for multilayer neural network. The explanation given by LRP

was a map of voxels in the original texture feature map that contributed to diagnosis. The brain relevance of the external validation group ROP+ROD(CHR+ROD) using the entropy(energy) was associated with clinical scores.

Results: Presence of VisDys in ROP and CHR groups was predicted with classification accuracy GREATER THAN 74%. In ROP, using the energy feature map, regions that contributed most to the classification decision of VisDys were amygdala, right putamen, angular gyrus, left parietal cortex, postcentral cortex, precuneus, gyrus rectus, left thalamus, parts of vermis and occipital lobe. In CHR, using the entropy feature map, cuneus and parts of vermis showed PR for correctly classified VisDys. Shared regions were identified for the prediction of VisDys in ROP and CHR using energy and entropy feature maps, respectively including cerebellar areas, calcarine sulcus left, frontal and temporal lobe, fusiform gyrus, hippocampus, right insula and rectus, and lingual left. The utility of entropy (energy) revealed inverse structural changes in shared regions when VisDys were present in ROP (CHR) patients. Both classification schemas presented good prediction accuracy for ROD in both samples.

In ROP and ROD with VisDys we can predict a) PANSS_Positive, b) PANSS_disorganization, c) PANSS_excitement, d) PANSS_distress and e) functionality, at baseline. In CHR and ROD with VisDys there were no predictability of the clinical scores using the whole brain relevance.

Discussion: Preliminary results suggest that microstructure changes in non-segmented images are associated with the VisDys phenomenon in ROP and CHR and that these changes are differentiated in shared regions between ROP and CHR patients. The proposed framework supports a model of the visual system being implicated in core disease mechanisms of psychosis that may potentially contribute to the identification of structural biomarkers for psychosis. Changes in the cerebellar volume of patients with schizophrenia have been linked to predominantly positive symptoms which is in line with the fact that the cerebellum supports multiple functions including emotion regulation, inhibiting impulsive decision making, attention, and working memory. We can speculate that ROP and ROD with VisDys presents homogeneous brain texture changes highly associated with PANSS scores, functionality at baseline and the outcome in 1-year follow-up. CHR and ROD presents heterogeneous brain texture changes, association can be considered only in the cluster level.

F280. THE EFFECT OF STRESSFUL LIFE EVENTS ON THE RISK FOR PSYCHOSIS: DIFFERENCES BETWEEN MEXICAN AT CLINICAL AND FAMILIAL HIGH RISK

Lourdes Nieto¹, Tecelli Domínguez-Martínez¹, Laura Navarrete¹, Mauricio Rosel-Vales¹, Ricardo Saracco-Álvarez¹, César Celada-Borja¹, Maria Luisa Rascón-Gasca¹, Luis Gerardo Moncayo Samperio¹, Tecelli Dominguez^{*2}

¹*Instituto Nacional de Psiquiatría Ramón de la Fuente Muñiz*, ²*Instituto Nacional de Psiquiatría "Ramón de la Fuente Muñiz"*

Background: Stressful life events (SLEs) in the development of early psychosis have been little studied in low-income countries. This study examines differences in the prevalence of SLEs in Mexican at clinical high risk (CHR) and those with familial high risk for psychosis who do not meet CHR criteria (non-CHR FHR). We also analyze the association between SLEs and CHR.

Methods: Participants included 43 persons with CHR and 35 with non-CHR FHR. CHR criteria were assessed with the Comprehensive Assessment of At-Risk Mental State. SLEs were assessed using the Questionnaire of Stressful Life Events.

Results: Participants with CHR reported more SLEs associated with negative academic experiences than those in the non-CHR FHR group. Bullying (OR = 7.77, 95% CI [1.81, 33.32]) and low educational level (OR = 21.25, 95% CI [5.19, 46.90]) were the strongest predictors of CHR, while starting to live with a partner (OR = 0.26, 95% CI [0.10, 0.84]) was associated with a lower risk of CHR.

Discussion: Negative school experiences increase the risk of psychosis, particularly bullying, suggesting that schools may be ideal settings for implementing individual preventive strategies to reduce risk factors and increase protective factors to improve the prognosis of those at risk of developing psychosis. In Latin America, there are multiple barriers to early intervention in psychosis. It is thus crucial to identify risk and protective factors at the onset and in the course of psychosis in order to design effective preventive interventions.

F281. MORE UPDATING, LESS TESTING: NMDA-DEPENDENT CHANGES IN BIMODAL INFERENCE AS A NEUROCOMPUTATIONAL MECHANISM UNDERLYING SCHIZOPHRENIA

Philipp Sterzer^{*1}, Marcus Rothkirch², Merve Fritsch³, Lukas Roediger³, Katrin Reichenbach³, Deniz Yilmaz³, Veith Weilhhammer⁴

¹University of Basel, ²Medical School Berlin, ³Charité - Universitätsmedizin Berlin, ⁴University of California Berkeley

Background: According to predictive-processing theory, the positive symptoms of schizophrenia can be explained by altered inference mechanisms characterized by an overweighting of external sensory data relative to internal predictions. While this account is supported by a large body of behavioral and neuroimaging data, little is known about the neurotransmitter mechanisms involved in such abnormal inference. Here, we tested the hypothesis that hypofunction of the N-Methyl-D-aspartate receptor (NMDAR) may lead to an increased weighting of sensory evidence in perceptual inference.

Methods: Twenty-eight healthy volunteers underwent intravenous infusion of either NMDAR-antagonist s-ketamine or placebo in a randomized, double-blind cross-over design. During infusion, they reported their perception while viewing fully ambiguous or partly disambiguated structure-from-motion stimuli which consisted of random dots constituting two intersecting rings rotating in depth. Changes in the perception of this stimulus occur only when the rings overlap (every 1.5 s), which enabled us to discretize participants' reports into sequences of states. The change in the proportion of stimulus-congruent perceptual states with increasing levels of disambiguation was used to quantify the weighting of sensory evidence in perceptual inference.

Results: Using a generalized linear model (GLM) to predict participants' perceptual states, we found that s-ketamine increased their sensitivity to disambiguating information relative to placebo ($p = 5.8 \times 10^{-4}$), similar to recently reported findings in patients with schizophrenia. Importantly, perceptual inference is known to fluctuate over time between two modes, during which either external input or internal predictions dominate perception. We used Hidden Markov Models to infer transitions between these two states, each linked to an independent GLM that predicted perceptual states from current inputs and preceding states. Under s-ketamine, fluctuations in bimodal inference were shifted towards external mode, i.e. participants spent more time in states during which external input dominated perception ($W = 264$, $p = 0.03$, two-sided Wilcoxon rank sum test). Strikingly, a similar shift towards external mode was found in patients with schizophrenia compared to healthy controls ($n=23$ per group; $W = 578$, $p = 2.32 \times 10^{-3}$).

Discussion: This study shows that NMDAR-antagonist s-ketamine increases the weighting of external sensory data relative to internal predictions, mimicking findings obtained in patients with schizophrenia. Crucially, our analyses indicate that NMDAR antagonism does not result in a uniform change in inference, but rather affects the dynamic fluctuation between externally- and internally-biased states. Such bimodal inference likely represents iterative test-and-update cycles, a strategy by which the brain forms stable internal representations from the stream of sensory information. NMDAR hypofunction and the associated shift towards external mode may thus cause maladaptive updating of internal representations and thus a propensity to making spurious connections between unrelated sensory signals, thus giving rise to the positive symptoms of schizophrenia.

F282. DELAY IN PRESCRIBING CLOZAPINE...WORSE CLINICAL OUTCOMES?

Leticia Irene Muñoz-Manchado*¹, Jose Ildefonso Perez-Revuelta¹, José María Villagrán Moreno³, Miquel Bernardo⁴, Liliana Galindo⁵, Yulia Worbe⁶, Jorge Zimbrón⁷, Emilio Fernandez-Egea⁵

¹Jerez General Hospital, Andalusian Health Service; Severe Mental Disorder Research Group, University of Cádiz, , ³Mental Health Clinical Management Unit, Jerez General Hospital, Severe Mental Disorder Research Group, University of Cádiz, ⁴Barcelona Clinic Schizophrenia Unit (BCSU), Hospital Clinic of Barcelona, University of Barcelona, IDIBAPS, CIBERSAM, ⁵Cambridgeshire and Peterborough NHS Foundation Trust, Behavioral and Clinical Neuroscience Institute, University of Cambridge, ⁶Sorbonne University, ICM, Inserm, CNRS, Hôpital Saint Antoine, ⁷Cambridgeshire and Peterborough NHS Foundation Trust, Cambridge

Background: We investigate whether an earlier use of clozapine is related to a better response in different clinical domains, namely positive, negative, functioning and well-being.

Methods: We used data from a carefully characterised cohort of 254 clozapine-treated patients, which were evaluated using the positive subscale of the positive and negative syndrome scale (PANSS), the Brief Negative Symptom Scale (BNSS), Global Assessment of Functioning Scale (GAF) and the short version Warwick-Edinburgh Mental Well-being Scale (SWEMWBS). We then used logistic regression models (for positive and negative symptoms remission) and linear regression (for functioning and wellbeing) to evaluate the influence of time to clozapine initiation (TCI; above or below three years), age at the first episode of psychosis (AFE), duration of clozapine treatment (DCT) and gender.

Results: Proportion of negative symptoms remission and higher functioning scores were associated with earlier treatment with clozapine in the first three years after the first episode of psychosis (exp (B)=0.38; p=.02; β =-0.12, p=.046, respectively). No effect of time to clozapine initiation was found on positive symptoms remission rates or well-being scores.

Discussion: Starting clozapine treatment within the first 3 years of illness decreases the severity of negative symptoms and improves functioning in clozapine-treated patients. Clozapine effect on positive symptoms remission rates was not influenced by the time to clozapine initiation.

F283. THE ASSOCIATION OF IMMUNE GENES WITH SCHIZOPHRENIA SUBTYPES

Kosar Teymouri*¹, Clement Zai², Mahbod Ebrahimi², Cheng Cheng Chen², James Kennedy²

¹*Center for Addiction and Mental Health*, ²*University of Toronto and CAMH*,

Background: Immune disturbances have long been implicated in the pathophysiology of schizophrenia. An extensive body of research has been done to further our understanding of the underlying mechanism of the role of the immune system in schizophrenia. 287 loci were associated with the risk of schizophrenia in the most recent genome-wide association study (GWAS). The strongest hit came from the major histocompatibility (MHC) region, which was previously identified by Sekar et al., to belong to the complement C4 gene. The C4 gene codes for two structurally and functionally different isotypes, C4A and C4B with long or short forms (C4L and C4S). While C4 suggests the immune system's involvement in schizophrenia, it's not the sole immune gene linked to the condition. Moreover, subtyping schizophrenia has been an established strategy to dissect its heterogeneity. In this study, we aimed to identify all the immune genes that were fine-mapped in the most recent GWAS and investigate their association with the subtypes of schizophrenia.

Methods: A total of 613 subjects from the Toronto Schizophrenia Sample were included in this retrospective study. Participants were over the age of 18 and were diagnosed with SCZ or schizoaffective disorder. We categorized the genes as immune-related genes if they: had known immune function; were part of an immune pathway; or were expressed in an immune tissue. We individually investigated the associations between the identified genes including C4 with schizophrenia subtypes and phenotypes including PANSS scores, treatment-resistant schizophrenia (TRS), and age of onset. We later looked at their combined predictive power using polygenic risk scores (PRS) of the immune genes. Sex-stratified analyses were conducted for all the phenotypes.

Results: Our preliminary results on the first set of prioritized fine-mapped genes identified over 30 immune-related loci. Our study of the C4 gene showed that C4S was nominally associated with TRS in males only ($p=0.047$). Higher copy numbers of C4S and C4AS were associated with a lower number of hospitalizations in the whole sample (C4S $p = 0.023$ and C4AS $p = 0.007$), Europeans (C4S $p = 0.049$) and non-Europeans (C4AS $p = 0.044$). Moreover, higher copy numbers of C4AS were associated with higher age of first hospitalization in the whole sample ($p = 0.0371$) and females only ($p=0.011$). In male samples, higher copy numbers of C4B ($p=0.036$) and higher predicted brain expression of C4B ($p = 0.034$) were associated with lower age of onset. There was no association observed between C4 and positive, negative, and general psychopathology in the PANSS score. Currently, we are studying the relationship of the immune genes individually and as a PRS score with schizophrenia subtypes.

Discussion: While our study provides further support for C4 having a significant sex effect, it also suggests that C4S may have a protective effect against more severe forms of SCZ. Additionally, it supports the role of the immune system in the development of schizophrenia. Further analyses are in progress to extend and validate our current findings including the effect of inflammatory biomarkers on SCZ subtypes.

F284. THE ASSOCIATION BETWEEN COMPLEMENT PROTEINS AND CYTOKINES IN EARLY PSYCHOSIS

Rachel Davis*¹, Subash Raj Susai¹, David Mongan², Melanie Föcking¹, Inge Winter-van Rossum³, Barnaby Nelson⁴, NEURAPRO Investigators⁵, OPTiMiSE Study group⁵, Rene Khan⁶, G. Paul Amminger⁷, David Cotter¹

¹Royal College of Surgeons in Ireland, ²Queen's University Belfast, ³UMC Utrecht, ⁴Orygen Youth Health Research Centre, ⁵International sites, ⁶Icahn School of Medicine at Mount Sinai, ⁷Orygen, National Centre of Excellence in Youth Mental Health

Background: Consistent evidence demonstrates the involvement of immune dysfunction and associated pro-inflammatory status in the pathophysiology of psychosis. Altered levels of pro-inflammatory cytokines have been observed in blood and cerebrospinal fluid of patients at varying stages of psychosis, from clinical high risk, to first episode and chronic psychosis. The complement cascade is another emerging immune mechanism dysregulated in psychosis. Our team has identified alterations in complement and associated coagulation cascade proteins in early psychosis in relation to psychopathology.

Even though cytokine-related inflammatory alterations are increasingly studied in psychosis, the interrelationship between cytokines and complement cascade in clinical populations is not well understood. Therefore, the primary aim of this study is to evaluate the relationship between levels of peripheral complement proteins and cytokines in clinical cohorts from early psychosis, including clinical high risk of psychosis (CHR) and first episode psychosis (FEP).

Methods: Baseline plasma samples were obtained from two cohorts: the NEURAPRO clinical trial of CHR participants (n=170) and the OPTiMiSE clinical trial of drug-naïve FEP patients (n=243). Complement and coagulation proteins were quantified from baseline plasma samples using mass spectrometry. Cytokines were quantified at baseline using multiplex immunoassays. Linear regression models were developed to establish the relationship between complement proteins and cytokines. These models were adjusted for the potential covariates. P-values were corrected for multiple comparisons using the Bonferroni method ($\alpha = 0.05$).

Results: In CHR cohort, a significant linear relationship was found between several complement and coagulation proteins and four cytokines: CRP, IFN- γ , IL-6, and TNF α . CRP had a significant (p LESS THAN 0.01) positive relationship with complement C4B, complement factor B (CFB), and C9. Significant positive relationships were observed between IL-6 and C4B, CFB, C5, complement factor I (CFI), fibrinogen alpha and gamma chains, and coagulation factor XIII A subunit. IFN- γ had a significant positive relationship with complement C1R and C1S. TNF α had a significant positive relationship with C1R and CFI. Analysis of OPTiMiSE data of FEP patients is currently ongoing.

Discussion: The results have demonstrated a linear relationship between plasma levels of pro-inflammatory cytokines and complement proteins. It is notable that all four cytokines that reached significance have been consistently implicated in the pathophysiology of schizophrenia. Considering that complement proteins are related to inflammatory response in psychosis, complement proteins could have the potential to be a superior inflammatory biomarker for the following reasons. The complement system is central to many biological mechanisms implicated in schizophrenia, such as the coagulation cascade, oxidative stress, lipid metabolism and synaptic pruning. Mass spectrometry, a robust proteomic tool, can be used to quantify complement proteins, but it is difficult to detect cytokines with high sensitivity due to their low abundance and molecular weight. Finally, while cytokines are susceptible to short-term changes in immune status, complement proteins could be a potential biomarker that represents multiple long-term biological alterations in psychosis.

F285. LIVED, LOVED, LABOURED AND LEARNED: A NEW WAY OF THINKING ABOUT EXPERIENCE IN MENTAL HEALTH RESEARCH

Eóin Killackey*¹

Background: Increasingly, young people with lived and living experience of mental ill health are included in research in youth mental health including in ultra-high risk (UHR) and first-episode psychosis (FEP) research. However, for the potential of this inclusion to be realised and for progress to occur in mental health research we need a better way of including and talking about all the parties who are needed to make this happen. This is important to address implicit power dynamics and also to ensure that inclusion of other perspectives does not become tokenistic. Many of the ways that are used to talk about young people being involved in UHR or FEP research (youth participation, youth partnership) do not address the power implicitly held in titles or labels of other stakeholders in youth mental health research. At the same time with a sole focus on the important contribution of the experience of young people, the valuable experiences of other stakeholders can be neglected or lost (e.g. families).

Methods: This presentation describes the development of a framework which recasts the way that experience is thought about in youth mental health research, including research in UHR and FEP. It reconceptualises the various voices in research through the lens of the experience that each group may bring to conversations about the development, execution, interpretation or dissemination of the research.

Results: As a consequence of the development described above, the 4L framework is proposed. This understands the experience that stakeholders bring to a conversation about mental health research as coming primarily from one of four types of experience: Lived, Loved, Laboured and Learned. Importantly these forms of experience are not mutually exclusive.

Discussion: This presentation will introduce a new way of thinking about experience in mental health research that is more inclusive and which through the language it uses, seeks to present a more equal plane from which all voices can be heard. Importantly it acknowledges that various types of experience are not mutually exclusive, and that the lens through which any individual contributes to a discussion about mental health research may evolve over time. It is also possible that this framework has applications beyond youth mental health research. This presentation has important implications for the inclusion of all types of experience in mental health research.

F286. USING AI-DRIVEN PLATFORM TO MEASURE NEGATIVE SYMPTOMS OF SCHIZOPHRENIA THROUGH FACIAL AND ACOUSTIC ANALYSIS

Jean-Pierre Lindenmayer*¹, Anzalee Khan², Vikram Ramanarayanan³, Hardik Kothare³, David Paulter³, Benedicto Parker⁴, Mohan Parak⁴, David Suendermann-Oeft³, Christian Yavorsky⁵

¹New York University, ²Nathan S. Kline Institute for Psychiatric Research and Manhattan Psychiatric Center, ³Modality, ⁴Manhattan Psychiatric Center, ⁵Biovalis

Background: The automatic analysis of facial and acoustic expressions of facial and speech productions in individuals with various psychiatric conditions has been expanding in the past few years. Here we are presenting new data on using an automatic multi-modality platform to measure negative symptoms of patients with schizophrenia. One central feature of negative symptoms is the reduction of facial movements and are referred to as expressive negative symptoms. Current methods of assessing negative symptoms depend on observations during a clinical interview. These interviews can be insensitive to change in treatment, subjective, require extensive training and are subject to cultural disparities. This study assesses whether a

novel artificial intelligence (AI) system analyzing facial and acoustic features can improve rater derived measurement of expressive negative symptoms in schizophrenia.

Methods: Hospitalized inpatients with schizophrenia (SZ: n = 70) and demographically matched healthy controls (HC: n = 75) completed a brief 8-minute assessment using the AI-driven platform NEMSI. Each participant was tested twice within one week in order to assess for test-retest reliability. For the AI software, participants were each provided a valence-neutral sentence to read by an avatar and were engaged in free speech where they were asked open ended probes designed to be emotionally-ambiguous in valence and content (e.g., tell me about yourself?). For the SZ group, at the first visit, the AI-driven recording was supplemented by rater assessed PANSS, BNSS, CDSS, CGI-S, AIMS, SAS, BARS. Concurrent, convergent, divergent, and discriminant validity were assessed. For the HC group, individuals received the AI vocal/speech software. All individuals were asked to assess user experience as measured by the SUTAQ (Service User Technology Assessment Questionnaire). Mann–Whitney test was used for comparison of AI features with clinical measures. Accuracy, sensitivity, specificity, and area under receiver operating characteristics-curve were measured as discriminatory indices of classifications.

Results: The mean age of individuals with SZ was 41.33 (10.35) and the HC group was 37.20 (8.52), and the mean PANSS total at Time 1 was 80.33 (10.18). Comparison of all the extracted features (54 facial and acoustic metrics) between SZ and the HC groups found 40 features to be significantly different ($p < 0.001$) mostly belonging to speech features (syllable alternating motion rate, loudness/articulation, speaking rate and pauses) and some facial features (e.g., average jaw acceleration, lip aperture). Session duration for the AI software was a mean of 8:32 min. Test-retest reliability was high ($ICC=0.91$). Significant correlations were observed between PANSS Motor Retardation and the AI software speaking rate ($r = -0.766$) and average jaw acceleration ($r = -0.820$), PANSS Active Social Avoidance and syllable alternating motion rate ($r = -0.821$), PANSS Marder Negative symptom score with pauses during speech ($r = -0.579$), BNSS Blunted Affect Vocal Expression, and Blunted Affect Expressive Gestures with the AI software speaking rate ($r = -0.777$). Most SZ (85.71%) and HC (93.78%) reported satisfaction with the AI-driven platform. Accuracy of classifying SZ from HC was 89.31%.

Discussion: We show significant correlations between speech and facial AI measures and negative symptoms assessed by raters using symptom scales. We also show a clear separation between facial and speech features of HC and participants with schizophrenia. The features of the AI-driven platform might help in improving the “validity” and reducing the “heterogeneity” in the assessment of negative symptoms and improve tracking and treating negative symptoms.

F287. FIRST EPISODE PSYCHOSIS: EXPLORING CLOZAPINE'S POTENTIAL

Mislav Škrobo¹, Draženka Ostojić², Antonia Puljić³, Ante Silić³, Dalibor Karlović⁴, Vjekoslav Peitl*⁵

¹University Hospital Centre Sestre Milosrdnice, ²University Psychiatric Hospital Vrapče and Faculty of Law, Social Work Study Centre, University of Zagreb, ³University Hospital Centre Sestre milosrdnice; School of Medicine Catholic University of Croatia, ⁴University Hospital Centre Sestre milosrdnice; School of Medicine Catholic University of Croatia, ⁵University Hospital Centre Sestre Milosrdnice; Catholic University of Croatia

Background: Clozapine, an atypical antipsychotic, has demonstrated remarkable efficacy in the treatment of treatment-resistant schizophrenia. However, its use in first-episode psychosis

(FEP) remains controversial due to concerns about potential side effects, limited evidence, and the availability of alternative treatments. This study aims to investigate the safety and efficacy of clozapine in individuals experiencing their first episode of psychosis.

Methods: This open-label prospective trial was carried out at the University Hospital Center Sestre Milosrdnice in Zagreb, Croatia, and involved 58 participants between the ages of 18 and 35 who had been diagnosed with First Episode Psychosis (FEP). These participants were randomly allocated into two groups: one group received clozapine as their initial treatment, while the other group received a standard antipsychotic medication. The study involved the assessment of clinical parameters, which included the administration of the Positive and Negative Syndrome Scale (PANSS), the Global Assessment of Functioning (GAF), and monitoring for potential side effects. These assessments were conducted both at the beginning of the study and at regular intervals throughout a one-year follow-up period. Furthermore, data on social and occupational functioning, quality of life, and medication adherence were also collected.

Results: Preliminary results at the six-month mark show significant differences in symptom reduction between the clozapine and standard antipsychotic groups, with the clozapine group exhibiting a greater reduction in PANSS scores. Additionally, the clozapine group showed improved social and occupational functioning as assessed by the GAF scale. While the clozapine group experienced more side effects, particularly related to sedation and weight gain, these were generally manageable, and medication adherence remained high in both groups.

Discussion: This study provides important insights into the potential use of clozapine as a first-line treatment in FEP. Our findings suggest that clozapine may offer significant advantages in symptom reduction and functional improvement over standard antipsychotic medications. While the occurrence of side effects highlights the importance of careful monitoring and management, they do not appear to outweigh the benefits in this population. The long-term implications of initiating clozapine in FEP require further investigation. This study contributes to the ongoing discussion about treatment options for individuals experiencing their first episode of psychosis and may have important implications for clinical practice and treatment guidelines.

F288. MODELING AUDITORY MAGNETOENCEPHALOGRAPHIC RESPONSES IN 15-YEAR OLD OFFSPRING TO PARENTS WITH SCHIZOPHRENIA OR BIPOLAR DISORDER

Oskar Jepsen^{*1}, Anette Fauriskov Bundgaard¹, Andreas Færgemand Laursen¹, Sinnika Birkehøj Rohd², Martin Wilms², Doris-Helena Feodora Bjarnadóttir Olsen², Marta Schiavon², Maja Gregersen², Mette Falkenberg Krantz², Aja Neergaard Greve¹, Nicoline Hemager², Anne Amalie Elgaard Thorup³, Merete Nordentoft², Ole Mors¹, Karl Friston⁴, Yury Shtyrov⁵, Martin Dietz⁵

¹Aarhus University Hospital, ²Copenhagen University Hospital, ³Child and Adolescent Mental Health Center Capital Region of Denmark, ⁴University College London, ⁵Aarhus University

Background: Patients with schizophrenia and bipolar disorder display altered neurophysiological responses, as measured with electroencephalography (EEG) or magnetoencephalography (MEG). By applying neuronal models to neurophysiological data, recent studies have found in vivo evidence for reduced synaptic gain on superficial pyramidal cells in patients with schizophrenia, in line with neuropathological evidence. However, whether synaptic changes are related to illness state or underlying liability remains unsettled. To address

this gap, we recorded auditory responses using MEG from 15-year-old adolescents at familial high risk of schizophrenia (FHR-SZ) or bipolar disorder (FHR-BP) and modeled auditory responses using dynamic causal modeling (DCM).

Methods: We recruited 15-year-old subjects taking part of the third wave of The Danish High Risk and Resilience Study – VIA (VIA15). Subjects were either at FHR-SZ, FHR-BD, or matched population-based controls (PBC). We recorded MEG data during two auditory paradigms: the roving auditory oddball paradigm and the 40-Hz auditory steady-state response (ASSR). We compared sensor-level oddball responses between groups and applied DCM to study underlying changes in extrinsic and intrinsic connectivity.

Results: Data collection is ongoing. Preliminary sensor-level analyses reveal no evidence for group differences in auditory oddball responses. Preliminary DCM revealed evidence for modulation of both extrinsic and intrinsic connectivity in adolescents at FHR-SZ and FHR-BD, relative to PBC.

Discussion: Computational modeling of magnetoencephalographic auditory responses reveals altered effective connectivity in adolescents at familial high risk of schizophrenia and bipolar disorder.

F289. OPTIMIZING HEALTH FOR YOUTH AT CLINICAL HIGH RISK (CHR) FOR PSYCHOSIS: EARLY INDICATORS OF FEASIBILITY

Muhammad Husain^{*1}, Lisa Hawke², Nicole Kozloff¹, Michael Kiang¹, Gillian Strudwick², Wei Wang², David Castle³, George Foussias¹

¹University of Toronto, ²Center for Addiction and Mental Health, ³Tasmania Mental Health Service

Background: functioning and have a high lifetime risk of suicide. The CHR period is an important phase where indicated interventions may reduce the risk of progression to several negative outcomes, including the development of schizophrenia. Given that up to 80% of individuals with CHR have another diagnosable mental illness and almost half experience poor psychosocial functioning, developing interventions that address poor functioning in CHR youth is of great importance. We aimed to adapt and evaluate the efficacy of the Optimal Health Program (OHP), a 12-week skills-based illness self-management program, in improving functioning, reducing distress, and building resilience in CHR individuals.

Methods: The study consists of three phases: (1) Adaptation of OHP for CHR through youth engagement: A six-member advisory group consisting of youth with lived experience convened on a weekly basis to adapt the OHP intervention, tailoring OHP to the needs of CHR youth; (2) OHP-CHR will be evaluated for feasibility, acceptability, and preliminary efficacy in a single arm pre-post intervention trial (n=30). Measures of clinical, functional, and cognitive outcomes will be completed at study entry and repeated post-intervention at 12-weeks; (3) Qualitative evaluation of OHP-CHR: Post-intervention semi-structured qualitative interviews will be conducted at the end of study to obtain views of OHP-CHR, experiences participating, perception of the program, and barriers/facilitators to participation.

Results: (1) Adaptations were informed through engagement with individuals with lived experience and focused on: youth-friendly language; incorporation of personal stories; emphasis on personalized recovery; enhancement in graphic design; thus, tailoring to the CHR population. (2) Participants are currently being recruited to the clinical trial from the CHR Clinical Research Service at CAMH. Over the course of 5 months, from September 2023 to January 2024, 23 referrals were received, of which 16 met study inclusion criteria, and over

60% of eligible participants were recruited (n=10). All participants completed baseline assessments (60% male, mean age=20.5±3.9 years). Most participants have attended all planned sessions (n=8; 80%). 50% (n=5) attended in-person, 20% (n=2) attended virtually, 30% (n=3) attended with a hybrid format. So far 7 participants have completed the 12-week intervention with 86% (n=6) attending all 9 sessions. one participant dropped out after completing 5 sessions.

Discussion: The present study was able to engage individuals with lived experience to clinically adapt the OHP intervention to the needs of CHR youth. The preliminary results suggest that OHP-CHR may be a feasible and acceptable intervention for CHR youth.

F290. PSYCHOTIC EXPERIENCES AND PROBLEMATIC GAMING: NEW UNKNOWN ASSOCIATION

Andre Fernandes^{*1}, Renan Biokino², Andrew Miguel¹, Viviane Machado¹, Gabriela Koga Tonsig², Lais Fonseca¹, Pedro Pan², Thiago Henrique Roza³, Giovanni Salum⁴, Ives Passos⁵, Luis Augusto Rohde⁵, Euripedes C Miguel⁶, Carolina Ziebold⁷, Ary Gadelha¹

¹Federal University of Sao Paulo/Univ. of Sao Paulo Medical School, ²Federal University of Sao Paulo, ³Federal University of Paraná (UFPR), ⁴UFRGS, ⁵Federal University of Rio Grande do Sul (UFRGS), ⁶USP, ⁷PROESQ - EPM/UNIFESP

Background: Problematic Gaming (PG) is a serious mental health condition related to several psychiatric disorders, such as anxiety, social phobia, depression or attention-deficit/hyperactivity disorder. However, the association between PG and Psychotic experiences (PE) remains poorly explored in literature. Both disorders can share common physiopathological mechanisms, as they may involve changes in the salience network and dopamine neurotransmission. Also, subjects with psychotic symptoms may be more reclusive, increasing their vulnerability to gaming time. We hypothesized that adolescents with PG were more likely to report PE compared with those without the disorder. The aim of our study was to examine the association between both conditions in a large Brazilian community sample.

Methods: We utilized a cross-sectional subsample of a large Brazilian cohort (n=1,616; 13-to-21-year age range), from whom it was evaluated the presence of PE, measured by Community Assessment of Psychic Experiences - Positive Dimension (CAPE-Pos). We also classified the participants according to their gaming status, using the 7-item version of the Game Addiction Scale (GAS): no PG, PG, or Gaming Addiction (GA). Linear regression analyses were used to examine the association between GD and PE, adjusted for the presence of significant covariates, including other psychiatric conditions.

Results: 53.5% (n=865) of the participants were male, with a mean age of 18.4 years; 60.9% (n=981) had higher family risk for psychiatric disorder. 9.5% (n=154) presented problematic gaming and 2.7% (n=43) gaming addiction. 28.0% received any DSM-IV diagnosis and 9.39% had PE. Participants presenting PG had greater levels of PE compared with participants without PG. PG remained significantly associated with PE in multivariate analyses (b=0.96, 95% CI 0.17-1.75, p=0.017).

Discussion: We found a statistically significant association between problematic gaming and PE in a sample of Brazilian young people. Also, comorbid gaming addiction and any other psychiatric disorders substantially increased the level of PE. Further longitudinal studies may help to disentangle common neurobiological and/or behavioral pathways between these two phenomena. This could provide a new perspective into vulnerability for disorders such as schizophrenia, during a viable period for early intervention.

F291. OPEN DIALOGUE AS "LIVE", EFFICIENT TRAINING IN SOCIAL COGNITION FOR PSYCHOTIC CONDITIONS

Maria Gariup*¹

¹*OPUS YOUNG Study, Child and Adolescent Psychiatric Center Glostrup*

Background: Social cognition (SC) refers to the way people perceive, think about, interpret, categorize, and judge their own social behaviors and those of others (APA 2018). It includes: emotion processing, mentalizing, social perception and attributional bias (Green et al., 2019). Mounting evidence suggests that SC is impaired in psychotic disorders (Savla et al., 2013), and that SC domains may have an important influence on functional outcomes (Halverson et al., 2019). There is increasing interest in interventions targeting SC in this patient group (Halverson et al., 2019; Peña et al., 2016): most interventions are interactive, groupbased treatments including a range of visual, auditory, video stimuli depicting social stimuli (Kurtz et al., 2016). Interventions appear effective in improving SC domains, but it has not yet been consistently demonstrated whether they generalize to real improvements in daily life functioning, (Green et al., 2019). In this work we argue that Open Dialogue (OD) approach for psychosis (Seikkula et al., 2011) may constitute an effective training on SC.

Methods: Open Dialogue (OD) is an approach started in Finland for treating psychotic crises. It is a need-adapted approach, involving families and social network from the very beginning (SEIKKULA and OLSON, 2003). OD has shown preliminary, excellent results in terms of functional- and symptoms recovery, when compared to standard treatment (TAU) (Seikkula et al., 2011). More importantly, these results have shown to hold also at 19-yrs follow-up: durations of hospital treatment, disability allowances, and the need for antipsychotic medication remained significantly lower in the OD group vs TAU (Bergström et al., 2018). This is especially important, as other high-intensive care programs with good effects in the short period, have failed to prove sustained benefits vs TAU at 20-years follow-up (e.g. Hansen et al., 2023). OD has gained international interest, with pilot studies happening worldwide, and a RCT trial just carried out in the UK, with outcomes expected for next summer (Pilling et al., 2022). Many of OD principles are common to other first-episode programs: quick help, flexibility, involvement of families and of social instances (Olson et al., 2014). Two characteristics though, are peculiar to OD.

1. "Dialogicity": an extensive use of family and network meetings, where the focus is not so much on finding a shared agreement, but more on encouraging dialogue and polyphony, where all points of view are considered legitimate.

2. The use of "reflective talks" between therapists during meetings (Andersen, 1995): therapists share together, in front of the network, the feelings they are experiencing at the meeting, and give place to their wonders and to what still has been unsaid (Olson et al., 2014; Sidis et al., 2022). This often can lead to a better mutual understanding, and a resolution of stressful circumstances (Bergström et al., 2018).

Results: Other benefits can come along. OD encourages the emergency of the different points of view and needs, and provides "live training" about which emotions can be activated in a situation. The "person in concern" can naturally appreciate feelings and motifs that have been at stake in the lived situation, both for oneself and one's closest ones. This insight could easily

translate in higher mentalization skills. Besides, it is expectable that the experience of overcoming communication difficulties, and reaching a closeness and mutual understanding, could modify one's trust and one's attributional bias. In this line, it is noticeable that at the 19-th year follow-up, what many participants recalled about the approach, was not so much one therapeutical relation, but rather, that the approach helped them and their families to better communicate together (Bergström et al., 2018).

Discussion: OD stands out as a putative effective training in social cognition: "Dialogue increases reflexivity" (Seikkula, 2023). This possibility could contribute to explain the good results the approach has shown so far (Bergström et al., 2018) and deserves further investigation.

F292. ADAPTING BIDS FOR MULTI-SITE AND MULTI-SESSION STUDIES

Tobias Goodwin-Allcock^{*1}, Rhea Thukral², Lei Wang¹, Nina Kraguljac¹

¹The Ohio State University, ²The University Of Alabama at Birmingham

Background: In neuroimaging studies, the sheer volume of data, both acquired and derived, can be overwhelming. To that end, the Brain Imaging Database Structure (BIDS) was developed so that researchers could more easily manage, process, and share their data. BIDS has been successful and widely adopted with examples such as: the NIH supported OpenNeuro data sharing platform, and a collection of neuroimage processing tools called BIDS Apps. A feature of BIDS is that it is designed to handle multiple sessions. This simplifies the management of longitudinal data. However, BIDS is only in its first iteration, and the authors themselves admit that it was not designed for multi-site studies. They do provide two suggestions for multi-site studies:

1. Consider each site as a separate BIDS database
2. Encode the siteID in the subject name. Both suggestions have issues for multi-site multi-session (MSMS) studies. The issues arise when a subject changes sites between sessions. A subject may change sites for many reasons, e.g. longitudinal studies may include new sites or no longer include sites for their follow up sessions, or a subject may have moved houses between sessions and live much closer to a different site. To demonstrate this issue with BIDS for MSMS studies, let's suppose three subjects (subjectID=001,002,003) and two hospitals (siteID=01,02) over two sessions. Subject 001 goes to site 01 for both sessions, subject 002 goes to site 02 for both sessions and subject 003 has their first session at site 02 and their second session at site 01. Following the first BIDS suggestion, we have two databases: (BIDS_Hospital01 and BIDS_Hospital02). In BIDS_Hospital01 there are two subjects, sub-001 and sub-003. In this case, sub-001 contains two sessions whereas sub-003 contains only the second session. Now let's consider the second BIDS suggestion. One database (BIDS) that contains all the data. In there, the subject names contain the siteID. In our example, this results in 4 subject files: sub-01001, sub-02002, sub-01003, sub-02003. In both suggestions, Subject 003's data has been split into two different folders. This is confusing and leads to unnecessary complications when attempting to view all the sessions for a given subject. This example demonstrates the need for a system that appropriately stores the data for multi-site multi-session studies.

Methods: We propose encoding the site information in with the session ID: sessionID= LESS THAN sessionIdx GREATER THAN LESS THAN siteID GREATER THAN. The subjects' IDs will not contain the siteIDs and the database will be considered as one combined database.

Results: Storing the information in this way keeps all the data in one directory and keeps all a subject's data together. Additionally, the data will be ordered in the subject's file in order of the sessions due to the sessionIdx coming first. Finally, the siteID's are clearly identified within the session names. In our example, subject 003's data would be stored in one file, sub-003, that contains ses-102 and ses-201.

Discussion: Encoding the siteID into the sessionID has been shown to be beneficial compared to the current methods. A limitation is that this is not a current suggestion from BIDS so some tools may need adaptation to be compatible with this new database design. People may see this and think an alternative method could be to have a site referenced folder as a subfolder within the session folder, however, unless there were multiple sites for a given session, this would be an unnecessary extra folder to navigate through, e.g. "BIDS/sub-003/ses-1/site-02/..." instead of "BIDS/sub-003/ses-102/...". Given the unnecessary extra folder, we believe that storing multi-site multi-session data in the way proposed in this abstract is simpler than other alternatives as well as an improvement over the current suggestions.

F293. ULOTARONT IN THE TREATMENT OF SCHIZOPHRENIA: POST-HOC ANALYSES OF TWO 6-WEEK, RANDOMIZED, DOUBLE-BLIND, PLACEBO-CONTROLLED, PHASE 3 TRIALS

Heather Dworak¹, Robert Goldman¹, Yan Li¹, Kenneth S. Koblan¹, Armin Szegedi¹, Nicholas DeMartinis*¹

¹Sumitomo Pharma America, Inc.

Background: Ulotaront, an investigational TAAR1 agonist with 5-HT1A agonist activity, has demonstrated efficacy in a flexible-dose (50 mg/d to 75 mg/d) Phase 2 trial [Koblan KS, et al., N Engl J Med.2020;382(16):1497] in acutely psychotic patients with schizophrenia (PANSS effect size [ES] 0.45). We previously reported [Kane J, et al., Neuropsychopharmacology. 2023;48:351] results from two Phase 3 fixed-dose studies designed to further evaluate the efficacy and safety of ulotaront (ULO) in schizophrenia, which both failed to meet their primary endpoint (DIAMOND 1 [D1], NCT04072354; and DIAMOND 2 [D2], NCT04092686). We now report results of post-hoc analyses undertaken to better understand possible contributors to the lack of ulotaront-placebo (ULO-PBO) separation in the Phase 3 studies.

Methods: Both studies were double-blind, placebo-controlled, 6-week trials evaluating the efficacy of ulotaront (50 mg/d and 75 mg/d; 75 mg/d and 100 mg/d) in adult patients with schizophrenia who were acutely psychotic (PANSS total score $\geq$ 80). In D1 and D2, enrollment was limited to patients with $\leq$ 2 or 3 prior hospitalizations for acute psychotic episodes, respectively. The primary endpoint was Baseline-to-Week-6 change in PANSS total score.

Results: Neither D1 or D2 met the primary endpoint for any ULO dose group (D1: ULO-50 mg and ULO-75 mg vs. PBO were -16.9 and -19.6 vs. -19.3; D2: ULO-75 mg and ULO-100 mg vs. PBO were -16.4 and -18.1 vs. -14.3). The previously reported flexible-dose (50-75 mg) Phase 2 trial [Koblan KS, et al., 2020] was significant for ULO-50-75-mg vs. PBO (-17.2 vs. -9.7). A review of 14 PBO-controlled NDA trials in schizophrenia conducted from 2009-2015 [Gopalakrishnan M, et al. J Clin Psychiatry. 2020;81(2):19r12960] found mean endpoint PANSS change scores of -16.9 for drug vs. -10.5 for placebo. These results suggest that the effect of ULO in the D1/D2 studies was comparable to active drug in both post 2009 NDA

trials and in the previous Phase 2 ULO trial. However, the PBO response was unusually high in both D1 and D2 studies, with D1 PBO response (-19.3) the highest recorded in any pre-or-post-2009 NDA trials in schizophrenia [Gopalakrishnan et al., 2020]. In a pre-specified pooled D1/D2 analysis, patients enrolled prior to onset of the COVID pandemic demonstrated significant efficacy for ULO-50-100 mg vs. PBO on PANSS total score (-15.8 vs. -8.8; $p=0.017$; $ES=-0.47$). No difference was observed for ULO vs. PBO in the post-COVID sample (-17.7 vs. -17.5), potentially linked to observed regional differences in placebo response. Finally, elevated serum prolactin (PRL) at screening was a predictor of higher PBO response. For ULO vs. PBO in D1/D2 pooled, $PRL \leq 40$ ng/mL: -17.8 vs. -14.4; $p=0.014$; compared with $PRL > 40$ ng/mL: -14.1 vs. -21.7. Elevated PRL was associated with increased dose or newly initiated antipsychotic (AP) treatment proximal to study entry.

Discussion: A large PBO effect was observed in both studies (most notable in D1) which may have masked the ability to detect a significant efficacy signal for ULO. Patients enrolled pre-COVID demonstrated notably larger effect sizes for ULO, though this finding may be due to geographic factors, as most pre-pandemic patients were recruited in the US. Initiation of a new AP or a dose increase for ongoing AP just prior to study entry appears to have contributed to a lack of drug-placebo separation. Finally, it appears that limiting enrollment to patients with ≤ 2 or 3 prior hospitalizations may have resulted in a sampling bias that favored patients who had either less illness chronicity/severity or with a history of illness that was more readily responsive to outpatient AP therapy without requiring recurrent hospitalizations.

F294. EXPLORING THE ROLE OF ANTICHOLINERGIC MEDICATION BURDEN ON COGNITION IN PSYCHOSIS: A SYSTEMATIC REVIEW AND META-ANALYSIS

Valentina Mancini^{*1}, Caren Latreche², Jack Fanshawe¹, Ioana Varvari¹, Chambrez-Zita Zauchenberger¹, McGinn Nova², McGuire Philip¹, McCutcheon Robert¹

¹*Oxford University*, ²*University of Geneva*

Background: There is preclinical and human evidence that cholinergic antagonists may have deleterious cognitive effects. Cognitive deficits are a core feature of psychosis but may be exacerbated by the use of psychotropic medications with anticholinergic properties. However, the impact of anticholinergic activity on cognitive functioning in psychosis is not clearly established. In this systematic review and meta-analysis, we aimed to synthesize evidence from studies quantifying anticholinergic medication burden in psychosis to determine if subjects with a higher burden have worst cognitive outcomes. Additionally, we explored studies that investigated if reducing cholinergic medications can improve cognition in psychotic subjects.

Methods: We searched Medline, EMBASE, and PsycINFO, from inception until October 2023. Studies reporting objective cognitive assessment and quantification of cholinergic burden using clinical scales (ACB), serological quantification (SAA), or studies tapering anticholinergic medications were included. Cognitive measures were grouped into domains of the MATRICS battery. All the analyses were carried out in R using the metaphor package. Given high heterogeneity was expected, we employed a random-effects meta-analysis model to pool results across studies. Heterogeneity was assessed with Cochrane Q statistic and I² index. Effect sizes were estimated as R-values for correlational studies (ACB and SAA) and as standardized mean difference (Cohen's d) for tapering studies. Publication bias was evaluated by visually inspecting funnel plots and performing the Egger's test. Study quality was evaluated using a modified version of the Newcastle-Ottawa scale.

Results: Of 212 eligible studies screened, 39 met inclusion criteria, comprising 25 ACB studies (4620 patients), 6 SAA studies (382 patients) and 8 (157 patients) tapering studies. We identified a negative correlation between ACB and the following MATRICS domains of cognition: Global cognition ($r=-0.37$, 95% CI, [-0.48,-0.25]), Verbal learning ($r=-0.28$, 95% CI, [-0.36,-0.21]), Visual learning ($r=-0.17$, 95% CI, [-0.28,-0.06]), Working Memory ($r=-0.22$, 95% CI, [-0.29,-0.14]), Processing Speed ($r=-0.24$, 95% CI, [-0.35,-0.13]), Attention ($r=-0.19$, 95% CI, [-0.29,-0.08]), Executive functions ($r=-0.17$, 95% CI, [-0.27,-0.06]), and Social cognition ($r=-0.12$, 95% CI, [-0.19,-0.05]). Similarly, we identified a negative correlation between SAA and the following MATRICS domains: Verbal learning ($r=-0.26$, 95% CI, [-0.38,-0.14]), Working Memory ($r=-0.19$, 95% CI, [-0.35,-0.03]), Executive functions ($r=-0.16$, 95% CI, [-0.27,-0.04]). Finally, tapering off cholinergic medication improved the scores in the following MATRICS domains: Verbal learning ($d=0.72$, 95% CI, [0.36,1.09]), Working Memory ($d=0.94$, 95% CI, [0.63,1.26]), Processing Speed ($d=1$, 95% CI, [-0.51,2.5]), and Executive Functions ($d=0.44$, 95% CI, [0.26,0.62]).

Discussion: Findings from this meta-analysis support a role of cholinergic burden in the cognitive impairment observed in psychosis. From a clinical perspective, tapering off anticholinergic medication in psychotic patient may be beneficial for cognition. However, randomized clinical trials are needed for an unbiased quantification of benefit.

F295. EXTERNALIZING PLAY IN PSYCHOSIS THERAPY – EXPERIENCES FROM THE FACE YOUR FEARS TRIAL

Sanne Bekker*¹, Louise Angelou Stokbro¹, Anne Sofie Due², Lise Mariegaard², Mads Juul Christensen¹, Ulrik Nykjær Jeppesen³, Merete Nordentoft⁴, Louise Birkedal Glenthøj³, Ditte Lammers Vernal⁵

¹Psychiatry, Aalborg University Hospital, ²VIRTU Research Group, Copenhagen Research Center for Mental Health, Mental Health Center Copenhagen, ³VIRTU Research Group, Copenhagen Research Center for Mental Health, Mental Health Center Copenhagen, University of Copenhagen, ⁴Copenhagen Research Center for Mental Health, Mental Health Center Copenhagen, , ⁵Psychiatry, Aalborg University Hospital, Aalborg University

Background: FaceYourFears is a randomized controlled trial (RCT) which explores the impact of exposure therapy rooted in cognitive behavioral principles in the treatment of paranoia in patients with schizophrenia-spectrum disorders. The project has two manualized intervention arms, cognitive behavioral therapy (CBT) vs. virtual reality (VR)-assisted CBT, both aiming to mitigate avoidance behaviors and harm expectancies. Exposure fosters new learning experiences, challenge exaggerated perceptions, and helps the patient become more aware of cognitive and behavioral patterns in interacting with the surrounding world.

Methods: This presentation draws from the therapist's experiences in the trial. Exposure is pivotal for reducing avoidance and enabling cognitive shifts. In the VR intervention, exposure consist of a constructed VR environment with triggers known to cause paranoid ideas and strong emotion in the patient. By trying different behavioral experiments and role play in both VR and real life, the patient is able to test paranoid ideas which potentially can allow for more adequate coping and better functioning in daily life. In the CBT intervention, exposures are planned as homework in the real world between sessions.

Creativity and play can be integrated in the therapy in both treatment arms, with certain elements being particularly important:

- Safety circle or cognitive diamond enhances the psychoeducation by using concrete and visual presentation to explain the rationale behind the treatment.
- Window of tolerance provides the therapist with information on hyper- and hypo arousal to use the appropriate level of exposure in which the patient is able to take in new information and generate appropriate cognitive structures. When hyper aroused, the patient is not able to take in new information or regulate emotions; when hypo aroused, the patient is learning from the experience due to lack of engagement.
- Importance of therapeutic alliance: To be able to use play, humor and creativity, a thorough knowledge of the patient's history, experiences, personality, and boundaries is paramount. If a therapeutic alliance is not formed or adequate, use of novel ideas or humor may be perceived as insensitive or inappropriate.

Play or creative behavioral testing can take many forms, e.g., an intense worst case scenario role play, trying out a novel response, externalization an internal strategy such as humor or by the patient using their imagination to alter paranoia in a new way (imaginary rescripting).

Results: Illustrative examples from the trial include unconventional approaches like employing Harry Potter incantations, introducing unusual scenarios, or referencing horror movie characters. Small, funny elements like sticking out one's tongue to the hostile people in the VR bus or waving at hallucinations may engage the patient in laughter instead of fear and paranoia. Creative interventions, such as imaginary rescripting and worst-case scenario role play enhance patient engagement, self-worth, and commitment to and belief in symptom reduction. This commitment may result in continued efforts to decrease symptoms even after the end of treatment.

Discussion: Explicitly addressing patient comfort or discomfort early in treatment and generally fostering a collaborate environment is crucial in CBT for psychosis. Integrating creative play may enhance therapy outcomes for some, though it is not a universal goal. Timing is key – ensuring the patient feels supported and not ridiculed. The therapists' clinical experiences from the trial, integrating unconventional ideas and funny elements, seem to foster a good alliance with some patients which is something that may be explored further in psychosis research.

F296. CORTICAL MYELIN MAPPING IN NEUROBIOLOGICAL SUBGROUPS OF PATIENTS WITH PSYCHOSIS-SPECTRUM DISORDERS

Victoria King*¹, Natalie Remiszewski², Matthew Defenderfer¹, Adrienne Lahti¹, Nina Kraguljac²

¹The University of Alabama at Birmingham, ²The Ohio State University

Background: Psychosis-spectrum disorders are typically diagnosed in late adolescence or early adulthood, interestingly coinciding with peak myelination in the brain. Additionally, processing speed has been identified as a core deficit in schizophrenia. The T1w/T2w ratio was developed as a proxy measure of myelin content in vivo and has been used to examine 'myelin maps' of healthy people and people with psychiatric and other myelin-related disorders. Moreover, normative modeling is a technique designed to study patient populations at an individual level, assessing interindividual differences as opposed to typical 'case-control'

studies. We used this method to group our patients into subgroups based on cortical thickness. We then compared myelin maps between each group. Our hypothesis was that normative-based subgroups of patients with psychosis-spectrum disorders would differ in myelin content in regions associated with processing speed.

Methods: Similar to a pediatric growth chart, the normative model generates normative curves of cortical thickness based on more than 58,000 healthy individuals, accounting for age and sex, in 148 brain regions using the Destrieux atlas. We adapted the model to our site data using healthy controls, then plotted our patients on the curves to produce individual z-scores for each subject in each region. We then used these z-scores to determine ‘extreme’ positive and negative deviations from each normative curve, using a cutoff of ± 2 . To control for false positives, we used a cutoff of 4 extreme deviations per subject to determine 4 subgroups of patients: those with mostly positive deviations, those with mostly negative deviations, those with under 4 positive and negative deviations, and those with over 4 positive and negative deviations. Myelin maps for all subjects were generated using the Minimal Preprocessing Pipelines from the Human Connectome Project. a priori regions were identified based on a recent meta-analysis. We performed an ANCOVA to compare global average myelin content between the groups, and a MANCOVA to compare myelin content in regions associated with processing speed between the groups.

Results: We compared myelin values of 98 first-episode psychosis patients - 28 ‘positive’ patients, 32 ‘negative’ patients, and 38 ‘none’ patients - and 111 healthy controls. Due to a small sample size of 7 patients, we excluded those who fell into the ‘both’ group. The spatial patterns of deviations among all patients were highly heterogeneous, with only a few regions showing more than 4% overlap between all subjects. Using age, sex, and SES as covariates, the results of the ANCOVA revealed a significant difference between the groups on global average myelin content ($F = 2.822$, $p = 0.04$). The results of the MANCOVA revealed that patients in the positive group exhibit increased myelin compared to healthy controls in regions associated with processing speed ($F = 1.350$, $p = 0.012$); however, these results did not survive multiple comparison correction.

Discussion: This study expands on previous findings of heterogeneous spatial patterns of deviations from a normative model in patients with psychosis-spectrum disorders. This method highlights the importance of examining interindividual differences in addition to case-control studies which describe an overall group trend. Further, our data suggest that first-episode psychosis patients who exhibit positive deviations from a normative model of cortical thickness present significantly higher myelin content in areas associated with processing speed. While the exact mechanism is unclear, this finding may help explain why first-episode psychosis patients exhibit deficits in processing speed.

F297. CAREGIVING AND CLINICAL OUTCOMES IN FIRST EPISODE PSYCHOSIS

Michelle Worthington^{*1}, Laura Yoviene Sykes², Nina Levine², Shannon Imetovski², Vinod Srihari², Carrie Veilliette²

¹*Yale University*, ²*Yale University School of Medicine*

Background: Family involvement is an important part of treatment for young people recovering from a first episode of psychosis; however, the experience of caregiving and the effects of caregiver burden within family members in this population are not well understood. As a young person’s social environment has the potential to shape the course of their recovery, understanding how to inform robust family-based interventions is an essential component of overall recovery. In this study, we examine the experience of caregivers in a first episode

psychosis clinic and examine the relationship between the experience of caregiving and the young person's symptoms. We hypothesize that a more challenging caregiving experience is associated with a higher severity of symptoms.

Methods: Data was collected at the Specialized Treatment in Early Psychosis (STEP) clinic at the Yale University School of Medicine. To measure the caregiving experience, we administered the Experience of Caregiving Inventory (ECI) to families upon entering treatment at STEP, and at 6- and 12-months following admission to STEP. The ECI is a 35-item questionnaire with both positive and negative subscales that measure multiple dimensions of caregiving for relatives with serious mental illness. Clinical variables measuring symptoms and levels of functioning administered to the young person included the Positive and Negative Syndrome Scale (PANSS), Global Assessment of Functioning (GAF), Global Functioning: Role and Social Scales (GF:S and GF:R). Pearson's correlations were used to examine the relationships between scores on the caregiving inventory positive and negative subscales and clinical measures.

Results: A total of 24 survey responses were received. Of the caregivers who responded, 17 (71%) identified as primary caregivers and 13 (54%) reported having additional caregiving responsibilities. The mean number of hours spent caregiving per week was 57 (SD = 61). The mean age of the young person was 22.7 years (SD = 3.5) and the median duration of untreated psychosis (DUP) was 8.1 months (IQR = 0.03-11.4). Primary caregivers reported higher scores on the ECI negative subscale (mean = 92.4, SD = 49.2) than secondary caregivers (mean = 57.6, SD = 24.0). The ECI negative subscale showed a trend positive correlation with the PANSS total score ($R^2 = 0.42$, $p = 0.07$) and the negative ECI subscale was positively correlated with the PANSS positive subscale ($R^2 = 0.50$, $p = 0.03$). This demonstrates an overall more negative caregiving experience with higher levels of symptoms of psychosis early in treatment, primarily driven by the presence of increased positive symptoms. Further, longer DUP was associated with lower scores on the negative scale of the ECI ($R^2 = -0.46$, $p = 0.04$), potentially indicating that more acute or shorter onset of symptoms may be associated with a more negative caregiving experience. Functioning as measured by the GAF, GF:R and GF:S was not associated with positive or negative caregiving experiences.

Discussion: Caregiver burden as indicated by higher scores on the negative subscale of the ECI was higher for primary caregivers and for caregivers of young people experiencing higher levels of positive symptoms, but was decreased for caregivers of young people with longer duration of psychosis. In total, these findings begin to elucidate risk factors for higher caregiver burden and potential burnout in first episode psychosis. Continued examination of the caregiving experience in first episode psychosis, including examining changes over time, would be necessary to best inform mechanisms of support for caregiving family members involved in first episode psychosis treatment for their young person.

F298. PARSING HETEROGENEITY IN MEDICATION-NAÏVE FIRST EPISODE PSYCHOSIS PATIENTS WHO PRESENT FEATURES OF THE DEFICIT SYNDROME: A NORMATIVE MODELING APPROACH

Matheus Teles*¹, Natalie Remiszewski¹, Adrienne Lahti², Saige Rutherford³, Andre F. Marquand⁴, Nina Kraguljac¹

¹The Ohio State University, ²The University of Alabama at Birmingham, ³Donders Institute,

⁴Donders Institute of Brain, Cognition, and Behaviour, Radboud University, Radboud University Medical Centre, Institute of Psychiatry, King's College London

Background: The deficit syndrome is a clinical subtype of schizophrenia characterized by enduring negative symptoms and thought to be more homogeneous than the non-deficit form of the illness, but it is not clear if this is also true for abnormalities in cortical thickness. Normative modeling is a novel way to capture inter-individual neurobiological heterogeneity and can be utilized to assess heterogeneity in the cortical thickness of clinically distinct patient groups. Here we hypothesized that medication-naïve first episode psychosis patients with features of deficit syndrome, when compared to patients without, will be more homogenous in cortical thickness pathology.

Methods: We recruited 101 antipsychotic medication-naïve first episode psychosis patients at the University of Alabama at Birmingham for the study. Twenty-nine patients included in the analysis displayed clinical features of the deficit syndrome, while seventy-two patients did not. We used the Schedule for the Deficit Syndrome to assess if patients display features of the deficit syndrome. We used T1-weighted structural MRI on a 3-T Siemens Magnetom Prisma with a 20-channel head coil to quantify individual region-level structural normative deviations (defined as GREATER THAN 2SD) in cortical regions in patients with or without clinical features of the deficit syndrome. We quantified individual region-level structural normative deviations based on a normative reference model using the Predictive Clinical Neuroscience and brain charts toolkits. We used BrainPainter to generate all brain renderings. We performed Levene's test for the equality of variances to assess patient groups differences in variance in the number of cortical deviations. Independent samples t-test was utilized to examine differences in the mean number of cortical deviations among patient groups. We performed a two-sample Komolgorov-Smirnov test to compare the distributions of the number of cortical deviations among the patient groups.

Results: Non-deficit patients had a higher mean number of cortical negative deviations, (4.98 ± 6.50), i.e. cortical thinning, than deficit patients (2.44 ± 2.92), $t(97.73)=2.703$, $p=.008$ (Figure 1). The effect size was moderate (Cohen's $d=.44$). Non-deficit patients have significantly more variance in the number of cortical negative deviations than deficit patients, $F=7.56$, $p=.007$. There were no patient group differences in variance ($F=.057$, $p=.812$) and mean number ($t(99)=-.342$, $p=.733$) of cortical positive deviations. Negative deviations were generally more widespread across the cortex in non-deficit compared to deficit patients.

Discussion: Patients with features of deficit syndrome presented significantly reduced mean and variance in the number of cortical negative deviations compared to patients without, which supports the idea that deficit syndrome is a more homogeneous distinct subtype of schizophrenia. Using a normative modeling approach allowed us to capture inter-individual variability in medication-naïve first episode psychosis patients who do or do not present features of the deficit syndrome. These findings provide additional evidence supporting the existence of the deficit syndrome as a distinct and more homogenous disease entity within schizophrenia, compared to the non-deficit form of the illness. This contributes to a better understanding of the pathophysiology of the deficit syndrome and may guide future research on effective treatment strategies, given the current absence of viable options.

F299. NORMATIVE MODELING-DERIVED DEVIATIONS IN ANTIPSYCHOTIC MEDICATION-NAÏVE FIRST-EPISODE PSYCHOSIS PATIENTS OF DIFFERING COGNITIVE FUNCTION

Natalie Remiszewski^{*1}, Eric Nelson², Andre Marquand³, Adrienne Lahti², Nina Kraguljac¹

¹The Ohio State University, ²University of Alabama at Birmingham, ³Donders Centre for Cognitive Neuroimaging, Donders Institute for Brain, Cognition, and Behavior, Radboud University

Background: The central premise of precision medicine is that an individual's unique characteristics play a role in disease vulnerability. Studies have shown that regional normative modeling-based measures can capture inter-individual heterogeneity – however, little is known about their clinical relevance. Here, we investigate if significant deviations from a healthy reference cohort are associated with cognitive performance, a key illness dimension in schizophrenia, in antipsychotic medication-naïve first-episode psychosis patients (FEP).

Methods: Structural neuroimaging was performed using an MPRAGE [TR/TE/TI: 2400/2.22/1000ms; 0.8mm³ voxels] sequences. Data were processed in FreeSurfer 7.1.1. to quantify region-level cortical thickness measures using the Destrieux parcellation. We used the Predictive Clinical Neuroscience braincharts toolkit to compute individual-level deviations from the reference norm for cortical thickness in antipsychotic medication-naïve FEP. A z-value cutoff of ± 2 was used to define extreme deviation, with extreme positive deviations being regions with a z-value of greater than 2 and negative deviations being regions with a z-value of less than -2. Score on the Repeatable Battery for the Assessment of Neuropsychological Status (RBANS) was used to assess cognition. Grouping based on cognitive function was done in two ways: based on total RBANS score as well as by overall cognitive profile determined by scores on five RBANS subscales. The total extreme deviation loads were compared between these groups.

Results: Using a cutoff score of 85 on total RBANS (mean score minus standard deviation; 100-15) yielded 73 cognitively impaired (LESS THAN 85) and 21 cognitively intact (≥ 85) individuals. K-means clustering based on the 5 RBANS subscales (immediate memory, visuospatial, language, attention, delayed memory) yielded five clusters for overall cognitive profile. T-tests of positive, negative, and total cortical deviation load between cognitively impaired and intact individuals yielded no significant difference in deviation load between the two groups. Additionally, ANOVAs comparing cortical deviation loads between the 5 cognitive profile clusters also yielded no significant differences except for a significant difference between clusters 3 (mostly higher RBANS scores) and 4 (mostly average RBANS scores).

Discussion: Overall, there were no differences in deviation load between FEP of differing cognitive functioning regardless of grouping method. These results inform us that a more generalized metric such as total deviation load by individual may not be an appropriate structural measure for understanding the underlying etiology of cognitive dysfunction in FEP. It is also possible that macrostructural abnormalities do not underly cognitive deficits. Future work should focus on spatial localization of deviations in each of these groups to investigate anatomical patterns in significant deviation.

F300. EXERCISE4PSYCHOSIS: THE EFFECTS OF A MODERATE-TO-VIGOROUS EXERCISE INTERVENTION ON INFLAMMATORY BIOMARKERS AND NEGATIVE SYMPTOM PROFILES IN FIRST-EPISODE PSYCHOSIS

Connor Dunleavy*¹, Richard Elsworth¹, Rachel Upthegrove¹, Stephen Wood², Kelly Allott², Sarah Aldred¹

¹University of Birmingham, ²Orygen

Background: First-episode psychosis (FEP) is a devastating mental illness that tends to emerge during early adulthood, characterised by a disconnect in perception of reality. Perturbations in immune responses and elevated inflammatory biomarkers are suggested as important in the manifestation of FEP, and potentially the emergence of specific negative symptom profiles. Exercise is a potent anti-inflammatory stimulus that is known to reduce inflammation and improve mood profiles, therefore physical activity may represent a novel adjunct therapy for pathological mechanisms of FEP, and negative symptoms unalleviated by currently prescribed antipsychotic medication. This study aims to assess the effects of regular exercise on parameters of immune function, and psychological outcomes in FEP.

Methods: Seventeen young men were recruited from Birmingham 'Early Intervention in Psychosis' services and randomised to a 6-week exercise programme or treatment as usual, consisting of 2-3 sessions per week targeting 60-70% heart-rate maximum. Immune-inflammatory T-helper cell phenotype (Th1, Th2, Th17, Treg) and cytokines (interleukin (IL)-4, IL-6, IL-8, IL-10), growth factors (BDNF, VEGF) symptom severity (PANSS, TEPS), functional outcomes (WHO Quality of Life, Assessment of Disability), and cognition (Digit Span) were measured at baseline, and after 6-weeks of regular exercise.

Results: Participants in the exercise intervention achieved 81.11% attendance, with an average exercise intensity of $67.54\% \pm 7.75\%$ HRMax. This led to favourable changes in immune cell phenotypes, and a significant reduction in the Th1:Th2 ratio (-3.86% , $p = 0.014$). After exercise there was also a significant reduction in plasma IL-6 concentration (-22.17% , $p = 0.006$). IL-8, IL-10, BDNF, and VEGF all increased, but these changes were not statistically significant. Symptomatically, there was a significant reduction in negative symptoms after exercise (-13.54% , PANSS Negative, $p = 0.008$). There was no significant change in positive or general symptoms, functional outcomes, or cognition (all p GREATER THAN 0.05). In the TAU group, there were no significant changes in any biomarkers, symptom severity, functional outcomes, or cognition (all p GREATER THAN 0.05).

Discussion: Exercise as therapy is useful for tackling multiple symptom profiles that are unalleviated by antipsychotic medication, including negative symptoms which are most debilitating with reference to quality of life. Exercise-induced alterations in immune profiles may uncover mechanisms that relate directly to the manifestation of negative symptoms, which may aid in providing precision therapy for people suffering with FEP.

F301. RESHAPING BOUNDARIES BETWEEN SCHIZOPHRENIA, BIPOLAR DISORDER, AUTISM SPECTRUM DISORDERS, AND RESISTANT DEPRESSION: DEVELOPMENT OF THE COHORT « FRENCH MINDS » IN THE FRENCH NETWORK PROGRAM-PROJECT IN PRECISION PSYCHIATRY

Background: Schizophrenia (SZ) is a severe mental disorder, but few therapeutic innovations have been developed recently due to a lack of physiopathological knowledge. Psychiatry precision can improve treatment response and clinical outcomes through patient stratification and holds great potential for SZ and other mental disorders. The program-project PROPSY, funded by the French government and launched in 2023, focuses on 4 overlapping and heterogeneous disorders: schizophrenia (SZ), autism spectrum disorders (ASD), bipolar disorder (BD), resistant depression (RD). Five work packages (WP) were defined by the PI Prof. Leboyer, her team, and the institutions CNRS and INSERM. WP1 aims at developing a 3000-patient longitudinal cohort called French Minds upon the existing cohorts FACE and RHU-PSYCARE; WP2 will uncover cellular mechanisms with preclinical studies; WP3 will develop clinical trials; WP4 will create a French Biomedical ecosystem to trigger the public-private partnerships; WP5 is dedicated to the Early Career to increase the attractiveness of psychiatry and awareness of civil society. Considering the importance of better defining homogeneous phenotypes, about 40 Million euros out of 80 of PROPSY are dedicated to the WP1, giving the opportunity to reshape clinical and nosographical boundaries between SZ, ASD, BD and RD.

The aims of this WP1 are to:

1. Identify homogeneous subgroups with specific biological signatures
2. Identify clinical and/or biological dimensions shared by all included participants included, regardless of psychiatric diagnosis.
3. Compare clinical and biological data to replicate similar strategies with international cohorts.
4. Improve the organization of care, ie diagnostic accuracy and therapeutic strategies.

Methods: WP1's leaders and the authors of this abstract were particularly involved in defining unmet needs and meaningful clinical dimensions. Bimonthly meetings involving psychiatrists, researchers and psychologists were organized, named "French minders" meetings. The

participants also met once a month with the leader of another international cohort (US, UK, EU...), to ensure coherence and complementarity between all international cohorts and future collaborations. WPI team contacted peer workers and users of psychiatry to help define unmet needs for patients in a participatory approach.

Results: The following dimensions have been targeted:

1. Neurodevelopment
2. Cognitive flexibility
3. Motivation and emotional regulation
4. Comorbidities, including metabolic syndrome
5. Social Withdrawal
6. Sensori-motor dimension

All subjects will benefit from an extensive clinical (including sleep and neurological soft signs), neuropsychological and paraclinical evaluation (biological, genetic, EEG and MRI). The clinical and paraclinical management platform for patient monitoring will be integrated into healthcare systems in real-life settings. A digital tool will assess real-life clinical parameters. Inclusion criteria are:

1. Age between 16 and 60
2. Signed informed consent
3. Ability to read, write and understand French
4. Confirmed diagnosis of at least one of the 5 following DSM5 diagnoses: 1st episode of psychotic disorder, SZ, BD, RD, ASD without intellectual disability
5. Compatible clinical condition
6. Membership of a social security scheme

Discussion: In a transnosographic approach, patients included in the "French Minds" cohort will be thoroughly phenotyped by collecting and combining clinical, behavioral, numerical, omics, brain imaging data and environmental variables. This research will help reshape clinical boundaries, improve knowledge of the prognostic factors of these four diseases and allow the development of new therapeutic strategies. Precision psychiatry needs large and transnosographic data sets of prospective real-world data.

F302. THE EFFECT OF INTERNALIZED STIGMA ON SOCIAL ANXIETY, FUNCTIONING AND SUBJECTIVE RECOVERY AFTER GROUP COGNITIVE INTERVENTIONS FOR FIRST-EPISODE PSYCHOSIS

Libby Lassman^{*1}, Élisabeth Thibaut², Olivier Percie du Sert², Tania Lecomte³, Ashok Malla², Martin Lepage⁴

¹McGill University, ²Douglas Research Centre, McGill University, ³University of Montreal, ,

⁴Douglas Research Centre; Prevention and Early Intervention Program for Psychoses; McGill University,

Background: Social anxiety disorder is among the most prevalent comorbidity in first-episode psychosis (FEP) and is associated with significant social disability and poor prognosis. An important factor that contributes to social anxiety and impedes recovery in this population is internalized stigma, which involves endorsing and applying negative stereotypes about mental

illness to oneself. Certain group-based cognitive interventions have shown promising results for improving social anxiety and functioning in FEP, including cognitive behavioral therapy (CBT) in which internalized stigma is directly targeted, along with standard cognitive remediation. Thus, internalized stigma stands as an important predictor of treatment response to consider within these interventions. However, this factor has not yet been investigated as a predictor in the context of a group CBT intervention tailored to address internalized stigma for people with FEP and comorbid social anxiety. This study aims to examine whether reduced internalized stigma predicts improvements in social anxiety after receiving group CBT that directly addressed internalized stigma, compared to group cognitive remediation for FEP. Additionally, the effect of internalized stigma on functioning and subjective recovery after treatment will be examined as secondary outcomes.

Methods: Data from the current study was based on a randomized controlled trial comparing the effect of group CBT with group cognitive remediation for people with FEP and comorbid social anxiety disorder. Ninety-six participants aged 18-35 were recruited from five FEP clinics in Montreal and completed measures of social anxiety, functioning, subjective recovery, and internalized stigma at baseline, post-intervention, and two follow-ups (three months and six months). Linear mixed models were conducted to predict primary and secondary outcomes. In each statistical model, the fixed effects consisted of internalized stigma, time, treatment group, and the interaction between internalized stigma and these two factors. Age and sex were entered into the models as covariates.

Results: Linear mixed models revealed a significant and positive main effect of internalized stigma on social anxiety [$F(1, 205) = 75.36, p < .001$], functioning [$F(1, 159) = 9.80, p < .001$], and subjective recovery [$F(1, 200) = 77.82, p < .001$], while controlling for age and sex. However, there was no significant interaction between internalized stigma and treatment group, nor with each time point for all three outcomes (p s GREATER THAN .05). Moreover, no significant baseline differences between the two treatment groups were found.

Discussion: Despite internalized stigma being addressed through group CBT, it was not found to be a significant predictor of social anxiety, functioning, and subjective recovery within this intervention, relative to group cognitive remediation. The positive treatment response of these group interventions may therefore be due to a general therapeutic factor, such as group therapy, which is known to create a sense of belonging with peers and normalize their difficult experiences. This study lays the groundwork for future research to explore the active ingredients of group CBT that specifically target internalized stigma relative to standard group CBT for a population with FEP and comorbid social anxiety.

F303. USING HIERARCHICAL LEARNING MODELS TO INFER NEUROCOMPUTATIONAL MECHANISMS UNDERLYING SCHIZOPHRENIA SYMPTOMS

Teresa Katthagen^{*1}, Stella Zimmermann¹, Tal Geffen¹, Fabien Carruzzo², Mariia Kaliuzhna², Stefan Kaiser², Florian Schlagenhaut¹

¹Charité-Universitätsmedizin, ²University of Geneva

Background: In schizophrenia patients (PSZ), reinforcement learning dysfunctions like reward prediction error coding proposedly contribute to central aspects of the disorder including aberrant salience attribution as well as motivational impairments. Hierarchical learning models, like the novel Volatility Kalman Filter (VKF; Piray and Daw, PLoS Comput Biol 2020), describe such process of prediction error driven belief updating on various levels.

Here, the weight ascribed to prediction errors is informed by estimated noise as well as the inferred belief about the volatility of the environment, which we found to be increased in PSZ in previous studies using the Hierarchical Gaussian Filter (Mathys et al., 2011). However, whether these effects, specifically the relationship between prediction errors and negative symptoms as well as overestimation of volatility, can serve as clinical biomarkers with sufficient stability across time, sites and modelling frameworks, still needs to be addressed in longitudinal designs.

Methods: The current study aimed at assessing the associations between alterations in belief updating and negative symptoms in the multicentre, longitudinal SyMoNe study. A total of 120 (PSZ n=67, healthy controls n=53) participants performed the novel volatile reversal learning paradigm during fMRI at two time points with three months in-between. The task probes higher-level learning and its related neural signatures. In addition to reversals, we introduced another source of uncertainty by varying levels of probabilistic noise. Analyses of choices focused on the effects of noise level and group on performance in terms of correct responses. We further assessed the intra-class correlation as a measure of retest reliability of task performance. Then, we setup a model space with static (Rescorla Wagner) and dynamic (VKF) learning rates as well as control “no learning” model. We concatenated choices across time points and applied a hierarchical Bayesian inference approach for model fitting. FMRI data were pre-processed following a standardized protocol (fMRIPrep). First-level analyses investigating group differences on prediction errors, stimulus beliefs and volatility beliefs are currently ongoing.

Results: There was a main effect of probabilistic noise level on correct responses, which decreased with higher noise levels ($F=122.4$, $p < 0.001$). PSZ chose the correct stimulus less often than healthy controls did ($F=14.14$, $p < 0.001$), but there was only a trend-wise significant interaction between group and noise ($p=0.07$). The novel paradigm showed a good retest reliability in terms of correct responses ($ICC=0.66$). Concurrent model-comparison revealed that the most complex model with a dynamic learning rate (VKF), stable learning parameters and decision noise betas varying over time explained data best (protected exceedance probability: $pxp=0.64$). PSZ underestimated the systematic noise parameter ω ($F=8.99$, $p < 0.01$) and this correlated with higher positive symptoms (beta coefficient=-4.32, $t=-2.38$, $p < 0.05$). There were no group differences in starting points for volatility ($p > 0.1$) or volatility learning rate ($p > 0.7$).

Discussion: In line with previous findings, we found deficient reward learning in schizophrenia patients. However, and in contrast to our previous findings, this was not due to overestimating volatility, but to underestimating the noise. Methodologically, this highlights that both levels of uncertainty, systematic changes and probabilistic noise, should simultaneously be addressed in tasks and models to disentangle both constructs. This might be crucial for identifying the computational parameters underlying symptom dimensions.

F304. EFFECTS OF CANNABIS USE ON GABA-A $\alpha 5$ RECEPTOR BINDING IN CLINICAL HIGH-RISK AND FIRST EPISODE PSYCHOSIS

Zerrin Atakan^{*2}, Paulina Lukow¹, Julia Schubert², Samuel Knight², Amanda Kiemes², Nicholas R Livingston², Jacek Donocik³, A DeMichelli², Thomas Spencer², Paolo Fusar-poli⁴, Federico Turkheimer⁵, Mattia Veronese⁶, Steven Williams², Philip McGuire⁷, Gemma Modinos²

¹University College London, ²Institute of Psychiatry, Psychology and Neuroscience, King's College London, ³South London and Maudsley NHS Foundation Trust, ⁴King's College London, University of Pavia, ⁵Center for Neuroimaging Science, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, ⁶University of Padua, ⁷University of Oxford,

Background: The impact of cannabis use and GABA dysfunction are both highly researched topics in schizophrenia. Evidence linking the endocannabinoid (ECS) and GABAergic systems involves cannabinoids inhibiting GABA release in the hippocampus through the inhibition of voltage-dependent calcium channels. Furthermore, the ECS ligand AG-2 was shown to also be a ligand for the GABAA receptor. Early use of cannabis increases the risk of developing schizophrenia, but the mechanism by which this happens is not yet clear. Findings in clinical high-risk (CHR) individuals are less conclusive but suggest a dose-response relationship between cannabis use and transition to psychosis. We investigated the links between cannabis use and GABAA $\alpha 5$ receptor binding in CHR individuals and people with first-episode psychosis (FEP) using PET imaging with the tracer [11C]Ro15-4513.

Methods: A total of 58 participants (healthy controls, HC=24; CHR=24; FEP=10) completed the study. Participants underwent PET-MRI scanning with the tracer [11C]Ro15-4513, which has high affinity for GABAA $\alpha 5$ receptor subunits and completed the Cannabis Experience Questionnaire. PET data were analysed with MIAKAT 4.3.24 in Matlab R2017a; data from 2 CHR individuals was excluded due to insufficient acquisition or poor quality. Total volume of distribution (VT) in the hippocampus, selected due to its high expression of both GABAA $\alpha 5$ and ECS, was estimated through a two-tissue compartmental model.

Results: There was a significant group effect of cannabis use ($X^2(2,56)=7.883$, $p=0.019$), by which more individuals in the CHR and FEP groups had ever tried cannabis compared to the HC group ($p=0.024$ and $p=0.029$, respectively). There were no significant group differences in current cannabis use ($p=0.777$), age first tried ($p=0.520$), type ($p=0.635$) or frequency of use ($p=0.173$). Within each group, no significant difference was found in hippocampal VT between individuals currently smoking and not smoking cannabis, or in those who had ever used or never used cannabis (all p GREATER THAN 0.05). However, CHR individuals who started cannabis before age 18 ($n=11$) showed significantly higher hippocampal VT compared to those who started cannabis after age 18 ($n=7$) [$F(1,17)=6.520$; $p=0.023$]. Hippocampal VT in CHR with early cannabis use was significantly negatively correlated with negative symptom severity ($r=-0.686$, $p=0.041$). Furthermore, CHRs who used cannabis regularly ($n=10$) showed a trend-level elevation in hippocampal VT compared to CHR who used only a few times per year ($n=7$) [$F(1,16)=7.540$; $p=0.077$]. No significant differences were found between these variables within FEP or HC.

Discussion: Consistent with previous literature, a higher proportion of CHR and FEPs reported past cannabis use compared to HC. There were no group differences in current use, starting age, type or frequency of cannabis use. This may be due to increased awareness among clinical groups regarding the mental health impacts of cannabis. GABA-A $\alpha 5$ availability was elevated in CHR individuals who started cannabis early, compared to those who started at adulthood, consistent with findings of increased GABA release in hippocampal cultures under conditions of prolonged cannabis use. This elevation, which correlated with lower severity of negative symptoms, may reflect a compensatory upregulation of GABAergic receptors involved in mediating tonic inhibition. Further investigation with larger samples and longitudinal follow-up is required to elucidate the effect of early and frequent exposure to cannabis on GABA receptors in high-risk groups.

F305. ASSOCIATION OF HIPPOCAMPAL GABAA RECEPTOR AVAILABILITY AND RESTING PERFUSION OF A HIPPOCAMPAL-STRIATAL-MIDBRAIN CIRCUIT IN CLINICAL HIGH-RISK AND FIRST-EPISODE PSYCHOSIS

Samuel Knight^{*1}, Paulina Lukow², Amanda Kiemes³, Nicholas R Livingston³, Fernando Zelaya³, Andrea De Micheli⁴, Zerrin Atakan³, James Davies⁵, Tom Spencer³, Paolo Fusar-poli³, Jacek Donocik⁶, Beate Haegel⁶, Mattia Veronese⁷, Federico Turkheimer⁷, Julia Schubert¹, Steven CR Williams⁷, Owen O'Daly³, Philip McGuire⁸, Gemma Modinos³

¹King's College London, ²University College London, ³Institute of Psychiatry, Psychology and Neuroscience, King's College London, ⁴Early Psychosis: Interventions and Clinical-detection (EPIC) Lab, Institute of Psychiatry, Psychology and Neuroscience, King's College London, ⁵Invivo Imaging Services, ⁶South London and Maudsley NHS Foundation Trust, ⁷Center for Neuroimaging Science, Institute of Psychiatry, Psychology and Neuroscience, King's College London, ⁸University of Oxford,

Samuel Knight

Background: Multiple lines of evidence suggest that the hippocampus is vulnerable to dysfunction in psychosis. In vivo neuroimaging research has identified hippocampal, basal ganglia, and midbrain hyperactivity by regional cerebral blood flow (rCBF) in people with psychotic disorders and individuals at clinical high-risk for psychosis (CHR-P). Rodent models suggest that this hippocampal hyperactivity is a result of GABAergic inhibitory interneuron dysfunction, which promotes aberrant downstream hyperactivity of dopaminergic cells in the striatum and midbrain. However, whether GABAergic activity in the hippocampus is linked to rCBF in a hippocampal-striatal-midbrain circuit in individuals at CHR-P and experiencing the first episode of psychosis (FEP) is unknown. We sought to address this question through a multimodal PET/MRI study in antipsychotic-naïve individuals at CHR-P, as well as FEP patients using [11C]Ro15-4513, a PET tracer with high selectivity for GABAA-A5 receptor subunits which are predominantly expressed in the hippocampus.

Methods: Participants included 24 CHR individuals (mean [±SD] age: 25.2 [±4.6] years, 15 female), 24 healthy controls (HC) (25.2[±4.4] years, 15 female), and 10 FEP (mean [±SD] age: 29.2 [±5.2] years, 3 female) scanned in a single session with a 3T GE PET/MR scanner in a cross-sectional, case-control design. GABAA-A5 receptor availability was obtained using [11C]Ro15-4513 PET with arterial blood sampling. One CHR-P participant was excluded due to insufficient acquisition and one due to technical issues with blood sampling. rCBF data were obtained using pseudo-continuous arterial spin labelling (ASL). PET data were analysed with MIAKAT 4.3.24 in Matlab R2017a. Total volume of distribution (VT) in the hippocampus was estimated through a two-tissue compartmental model, which was fitted to each participant using a population-based input function with individualised corrections from discrete blood samples. ASL data were pre-processed using the ASAP toolbox in SPM12. Correlations between individual hippocampal [11C]Ro15-4513 VT and rCBF in the left/right hippocampal, basal ganglia, and midbrain circuit (defined using coordinates from a previous CHR-P study), were assessed using ANCOVA in SPM12. Significance was determined at p LESS THAN 0.05 FWE.

Results: In FEP individuals, lower levels of hippocampal [11C]Ro15-4513 VT were significantly associated with higher rCBF in the right hippocampus ($t=3.14$, $p_{FWE}=0.038$) and trended towards a significant association with higher rCBF in the left hippocampus ($t=2.98$, $p_{FWE}=0.057$). In CHR-P individuals, lower levels of hippocampal [11C]Ro15-4513 VT

trended towards an association with higher rCBF in the left midbrain ($t=2.98$, $p_{FWE}=0.057$). In HC individuals, lower levels of hippocampal [11C]Ro15-4513 VT trended towards an association with higher rCBF in the left pallidum/putamen ($t=2.9$, $p_{FWE}=0.056$). There were no significant differences in the associations of rCBF and hippocampal [11C]Ro15-4513 VT between groups.

Discussion: Our findings suggest that lower hippocampal GABAA-A5 levels were associated with higher hippocampal rCBF in FEP individuals, but not in CHR or HC. This evidence partially supports the hypothesis that GABAergic dysfunction underlies elevations in resting perfusion of a hippocampal-striatal-midbrain circuit in the context of early psychosis.

F306. ATTITUDES TOWARDS PHYSICAL ACTIVITY IN INDIVIDUALS WITH FIRST EPISODE PSYCHOSIS TREATED IN AN EARLY PSYCHOSIS INPATIENT UNIT

Melanie Trimmel^{*1}, Joachim Rockenschaub¹, Antonia Renner¹, Barbara Hinterbuchinger¹, Nilufar Mossaheb¹, Fabian Friedrich¹

¹*Medical University of Vienna*

Background: People with severe mental illnesses (SMI), such as schizophrenia, often suffer from multiple somatic comorbidities. Physical activity (PA) is a crucial factor in preventing cardiovascular diseases and numerous studies have also shown positive effects of PA on mental health. Despite this, people with SMI have been found to be less physically active. Addressing motivational factors and barriers seems decisive to support adherence to regular PA. This study aims to investigate preferences, motivation and barriers towards PA in people with first episode psychosis (FEP).

Methods: In order to explore attitudes towards PA in individuals with FEP aged 18-65 years a comprehensive self-completion questionnaire was developed to collect socio-demographic data as well as previous levels of PA, exercise patterns throughout life, PA preferences, motivational factors and perceived barriers. Recruitment and survey took place during treatment at an early psychosis inpatient unit. The data was analysed descriptively. The study was approved by the local ethics committee.

Results: Overall, eighteen individuals with FEP (thereof five women = 27.8%) aged 18-64 years (mean 26.4) were included. Fifteen were diagnosed with schizophrenic psychosis and three with affective psychosis. Fourteen (= 77.8%) reported regular physical activity within the last 3 months, whereby the majority were physically active on average between two and three days per week between 20 and 60 minutes per PA session. Half of them stated that they practised only one type of PA. The most frequently performed PA was walking (64.3%), followed by training at home (42.9%), yoga/stretching (28.6%), and gym activities (28.6%). Most of them indicated that the extent of their PA had changed during the inpatient treatment: ten reported that the amount of PA had decreased and six that it had increased compared to the period before. Fourteen (= 77.8%) were former sports club members, and eleven (= 61.1%) have been or are currently members of a gym. Eight (= 44.4%) prefer to exercise alone, while eight favour exercising together with a training partner. Regarding the training location, two-thirds preferred outdoor, seven (= 38.9%) at home, five in an institution (= 27.8%), and four in the gym (= 22.2%). Twelve (= 66.7 %) of the respondents would prefer a moderate PA intensity. Eleven (= 61.1%) expressed an interest in sports programs specifically designed for people with psychiatric disorders. Seventeen (= 94.4%) stated that they would like to exercise more regularly, with most of them indicating that trainers or an exercise program would help them to do so. At least half stated that they would do more exercise if their doctors

recommended it. Walking (61.1%) and hiking (55.6%) were the most preferred types of exercise, followed by swimming (44.4%), yoga/stretching (38.9%), training at home (38.9%), cycling (33.3%), gym (33.3%) and running (27.8%). When asked about motivational factors for exercise, the following were stated most frequently: improve physical and mental well-being (100%), strengthen self-confidence (94.4%), improve mood (94.4%), improve energy (88.9%), improve fitness (88.9%), and maintain/improve general health (88.9%). The most frequently experienced barriers to exercise were lack of energy/too exhausting (77.8%), lack of motivation (77.8%), lack of training partners (61.1%), and mental health status/symptoms (55.6%).

Discussion: Individuals with FEP show great interest in PA and would like to be more physically active. Interventions such as medical recommendations, specific training programs (addressing exercise preferences), instructors, and training partners could be supportive to achieve this goal.

F307. DATA-MINING ANALYSIS OF MEDIA EFFECTS ON SOCIAL STIGMATA OF SCHIZOPHRENIA

Joonho Choi^{*1}, Il Bin Kim², Yoon Young Nam³

¹Hanyang University Guri Hospital, ²CHA Gangnam Medical Center, CHA University School of Medicine, ³National Center for Mental Health

Background: In 2011, Korean Neuropsychiatric Association renamed schizophrenia from ‘mind split disorder’ (‘Jungshinbunyeolbyung’ in Korean) to ‘attunement disorder’ (‘Johyeonbyung’ in Korean), in a strategic way to reduce social stigma toward people with schizophrenia. However, there remains an elusive consensus that how the renaming effort has contributed to changes in the social perception of schizophrenia in Korea.

Methods: With this regard, we explored whether media frames alter the social perception, in ways of respecting or disrespecting schizophrenia patients before and after the renaming. This study extensively investigated media keywords related to schizophrenia across the time by applying both language and epidemiologic analyses.

Results: In results, the media keywords have been negatively described for schizophrenia patients both before and after the renaming. Further, from an analysis using the regression model, a significant correlation was observed between the frequency of negative keywords and the hospitalization frequency of schizophrenia patients.

Discussion: These findings suggest that the social perception of schizophrenia has been scarcely changed, but rather remained negatively biased against schizophrenia patients, in spite of the renaming effort. Notably, the biased media frames have been demonstrated to negatively impact on the social perception, and even on the medical use patterns of general schizophrenia patients. In conclusion, we suggest that the unbiased media frames along with the renaming effort may collectively help reduce the negative social perception of schizophrenia.

F308. HIPPOCAMPAL PERFUSION IN FIRST EPISODE SCHIZOPHRENIA AND ITS ASSOCIATION WITH DURATION OF UNTREATED PSYCHOSIS AND TREATMENT RESPONSE

Hao Hu^{*1}, Mengqing Xia¹, Qian Guo¹, Lihe Chen¹, Yao Hu¹, Xiaohua Liu¹, Donald C. Goff², Henry Rusinek³, Guanjin Li¹, Jijun Wang¹

¹Shanghai Mental Health Center, Shanghai Jiao Tong University School of Medicine, ²New York University Langone Medical Center, ³Center for Biomedical Imaging, NYU Grossman School of Medicine

Background: Abnormal hippocampal function has been implicated in first episode schizophrenia (FES) and is regarded as a promising target for intervention. Longer duration of untreated psychosis (DUP) has been associated with hippocampal atrophy and medication resistance in FES. FES patients with longer DUP are often managed with antipsychotics plus modified electroconvulsive therapy (MECT). The relationship between hippocampal perfusion pattern and DUP in FES is not known. The present study aimed to clarify the hippocampal perfusion pattern and its association with DUP in FES and further to investigate whether baseline hippocampal perfusion predicts treatment response.

Methods: At baseline, 85 participants (51 FES/ 34 healthy controls) were enrolled. Because of the association of long DUP and treatment resistance, patients with long DUP are often managed with medications plus MECT. For our study, 20 FES were allocated to the Drug group (medications only) according to clinical practice and 31 FES allocated to the MECT group (medications plus MECT). At baseline, all participants completed clinical assessment and a magnetic resonance imaging scan (T1 and TrueFisp sequence). The TrueFisp sequence was optimized to acquire the arterial spin labeling (ASL) perfusion in hippocampus, by obtaining the 6mm-thickness slice containing the hippocampus. At 6 weeks' follow up, participants completed the same study procedures as at baseline. Baseline cerebral blood flow (CBF) of hippocampus and global cortex were used to predict change in PANSS total and subscale scores.

Results: The three groups didn't differ in age and gender, however, education levels differed significantly. At baseline, DUP was negatively associated with hippocampal CBF ($r=-0.372$, $P=0.007$), and global cortical CBF ($r=-0.387$, $P=0.007$) in all FES subjects. Compared with the Drug group, patients in the MECT group had a longer DUP and took higher mean dose of antipsychotics (chlorpromazine equivalent, CPZ), prior to enrollment. Hippocampal CBF level was lower in FES group than that in healthy controls (HC), which was a trending significant level ($F = 3.080$, $P = 0.083$), while global cortical perfusion didn't yield a significant group difference ($F = 1.017$, $P = 0.316$). Controlling for education level, both hippocampal CBF and global cortical CBF differed significantly among the three groups (hippocampal CBF: $F=4.824$, $P=0.011$; global cortex CBF: $F=3.786$, $P=0.027$). Post-hoc analysis showed hippocampal CBF and global cortex CBF in the MECT group were significantly lower than in HC group (hippocampal CBF: MECT 38.73 ± 1.69 mL/100g/min vs HC 46.437 ± 0.439 mL/100g/min, $P=0.004$; global cortex CBF: MECT group 41.859 ± 0.940 mL/100g/min vs HC 48.107 ± 0.243 mL/100g/min, $P=0.005$), and also lower than in Drug group (hippocampal CBF: 38.73 ± 1.69 mL/100g/min vs Drug 46.067 ± 1.446 mL/100g/min, $P=0.0236$; global cortex CBF: 41.859 ± 0.940 mL/100g/min vs Drug 49.576 ± 0.802 mL/100g/min, $P=0.026$). We further applied the baseline hippocampus and cortex CBF to predict Positive and Negative Syndrome Scale (PANSS) total and subscale reductions at 6 weeks' follow-up visit, controlling for education level, total intracranial volume, DUP and CPZ. For the Drug group but not for the MECT group, the baseline hippocampal CBF predicted reductions in PANSS total score and positive subscale score (PANSS total score reduction: $\beta=-0.027$, $p=0.004$; positive subscale score reduction: $\beta=-3.665$, $p < 0.001$); the global cortical CBF also predicted clinical improvement (PANSS total score reduction: $\beta= 0.023$, $p < 0.001$; positive subscale score reduction: $\beta=3.312$, $p < 0.001$) in the Drug group, such that higher CBF in hippocampus and lower CBF in cortex were associated with larger response.

Discussion: FES patients may manifest different patterns of hippocampal and global cortical CBF based on their DUP; we found DUP to be negatively associated with CBF in hippocampus

and global cerebral cortex. A higher level of hippocampal CBF along with a lower level of cortical perfusion may predict a poorer clinical response to antipsychotics for FES patients.

F309. PERINATAL AND CHILDHOOD INSULT EFFECTS ON PSYCHOTIC-LIKE EXPERIENCES IN MIDDLE CHILDHOOD

Eric Larson*¹, Alexandra Moussa-Tooks¹

¹*Indiana University*

Background: Early life insults (ELIs) occurring during perinatal (e.g., obstetric complications, maternal substance use) and childhood (e.g., trauma exposure, socioeconomic disadvantage) periods often co-occur and are robust, known risk factors for psychotic-like experiences (PLEs) throughout development. ELI exposure during these distinct sensitive periods, as well as different exposures within these periods, may differentially affect PLE phenotypes. To date, understanding the role of ELIs in the etiology of PLEs is limited by reliance on older aged samples that are also typically clinical high risk. Moreover, analyses often examine only one temporal or conceptual domain of ELIs. Characterizing the cumulative and specific effects of diverse perinatal and childhood ELIs on PLEs in a nonclinical, heterogeneous sample of youth is critical for advancing both prediction efforts and the mechanistic understanding of psychosis-spectrum phenotypes.

Methods: The current analysis leverages data from 5,954 non-twin, non-adopted, youth enrolled in the Adolescent Brain Cognitive Development (ABCD) study. Seven perinatal and eight childhood insult exposures were adapted from previous characterization of the ABCD baseline sample and aggregated into cumulative risk scores. Hierarchical linear models tested main effects and interactions of early life insult burden (cumulative number of perinatal and childhood insults) on PLE quantity and associated distress at ages 9-10. Follow-up analyses examined the effects of individual perinatal and childhood insult exposures on PLE quantity. All models controlled for age in months, biological sex, and maternal age at birth. Study sites were included as random effects.

Results: Over 80% of youth in the sample experienced at least one of the 15 assessed ELIs. As expected, perinatal and childhood insult exposure burden were moderately correlated ($\rho = 0.22$). Independently, perinatal and childhood insult exposure was significantly associated with elevated PLE quantity ($B = 0.16$ and 0.30 , respectively), but only childhood insults were associated with PLE distress ($B = 0.70$). However, perinatal and childhood insults did not interact to affect PLE quantity or associated distress. Post-hoc analyses indicated that exposure to substances in utero after knowledge of pregnancy, obstetric complications, and premature birth were the most potent perinatal insults ($Bs = 0.40-0.69$), whereas socioeconomic disadvantage, parental substance use problems, and family conflict were the most potent childhood insults ($Bs = 0.40-0.56$).

Discussion: Consistent with previous research, ELIs occurring during perinatal and childhood periods independently confer risk for PLEs. However, temporally distinct ELIs did not interact to amplify or attenuate PLEs in this sample, suggesting their effects may be temporally restricted to systems most vulnerable at their distinct sensitive windows. Further, our results highlight that diverse ELIs are independently associated with PLEs, the impact scaling with the quantity of ELIs experienced. Also notable is the robustness of childhood insult findings to PLE distress, compared to quantity of PLE experiences, suggesting that these environmental factors may confer additional risk for the appraisal and emotional impact of these experiences above and beyond the emergence of psychosis-spectrum phenomena alone. Altogether, the co-occurrence of perinatal and childhood insults, combined with their independent effects on

PLEs, warrants careful consideration of potential timing effects in ELI outcomes. Future research utilizing longitudinal approaches is needed to elucidate how temporally and conceptually distinct ELIs affect PLE trajectories across childhood and adolescence.

F310. EFFECTS OF EARLY-LIFE ADVERSITY AND ACUTE STRESS ON THE EXPERIENCE OF EMOTION IN SCHIZOPHRENIA

James Waltz^{*1}, Jacob Nudelman¹, Olivia Hutchinson¹, Eric Neutzling¹

¹*Maryland Psychiatric Research Center, University of Maryland School of Medicine*

Background: It has been established that early-life adversity (ELA) can alter sensitivity to rewarding, stressful, and neutral events and stimuli. Psychosis is also associated with increased sensitivity to acute stressors, perhaps engendered by elevated rates of ELA. Using images from the International Affective Pictures Set (IAPS; Lang et al., 2005), our goal was to examine effects of ELA on sensitivity to pleasant, aversive, and neutral stimuli. We also sought to determine whether diagnosis interacted with physical abuse (PA) history in predicting ratings of affective pictures, as well as differences in ratings between stressed and non-stressed conditions. We hypothesized that acute and cumulative stress would increase affective reactivity to unpleasant stimuli and decrease affective reactivity to pleasant stimuli, with stress exposure interacting with diagnosis in modulating sensitivity to pleasant, aversive, and neutral stimuli.

Methods: In our study, 52 patients with schizophrenia spectrum disorders (SZ) and 32 healthy volunteers (HVs) performed the Emotional Experience Task (EET; Ursu et al., 2011) twice, on separate study days at least a week apart (once 10 minutes after presentation of an acute stressor, once 10 minutes after a control task). The Socially Evaluated Cold Pressor Task (SECPT; Schwabe et al., 2008) was used as the acute stressor. In the stress condition, participants submerged their non-dominant arm in a bucket of ice water for as long as they could tolerate, up to three minutes, while being filmed by an unsympathetic research assistant. The control condition used warm water. During performance of the EET, subjects viewed 72 IAPS picture stimuli (24 pleasant, 24 unpleasant, 24 neutral) in four runs of 18 trials each. On each trial, subjects were asked to rate both the “positivity” and “negativity” of the emotion experienced, during the presentation of a picture, on a 5-point scale, by means of a three-button response unit. To ask about experiences of abuse, we administered the 28-item Childhood Trauma Questions (CTQ).

Results: We observed an effect of diagnosis on mean picture ratings, such that SZ patients exhibited reduced dynamic range, relative to HVs, in their ratings. Specifically, we found that SZ patients, in comparison to HVs, rated positive pictures as less positive ($t = 1.958$; $p = 0.05$) and more negative ($t = 3.640$; $p < 0.001$). SZ patients also rated negative pictures as more positive ($t = 2.911$; $p = 0.005$) and less negative ($t = 2.711$; $p = 0.008$) than HVs. We observed no significant interactions between diagnosis and abuse history predicting ratings of pictures (all F-values < 1). When we examined correlations between PA scores on the CTQ and ratings of IAPS pictures from the EET, we found significant associations between PA scores and mean ratings of aversive images ($r = 0.309$; $p = 0.035$), as well as the effect of the acute stressor on ratings of positive ($r = 0.333$; $p = 0.022$) and neutral stimuli ($r = 0.300$; $p = 0.040$), with patients with higher PA scores showing a greater impact of the acute stressor on ratings of IAPS pictures.

Discussion: We observed that both diagnosis and abuse history impacted ratings of affective pictures. Abuse history also modulated the effect of the acute stressor. However, diagnosis and abuse history did not produce interacting effects on ratings of affective pictures in our study.

Future analyses will investigate whether diagnosis and abuse history exerted interacting effects on brain activity related to sensitivity to pleasant and aversive stimuli. A better knowledge of the processes by which ELA sensitizes susceptible individuals to the noxious effect of future stressors, is critical to our ability to reduce the severity and impact of psychotic symptoms through interventions.

F311. TUNE-UP: A COMPREHENSIVE APPROACH TO THE MANAGEMENT OF REFRACTORY POSITIVE, NEGATIVE, AND COGNITIVE PSYCHOTIC SYMPTOMS

Ioana Varvari¹, Chambrez-Zita Zauchenberger¹, Valentina Mancini¹, Jack Fanshawe¹, Sharon Musiiwa², Saik DeLaMotte², Philip McGuire³, Robert McCutcheon³

¹University of Oxford, Oxford Health NHS Foundation Trust, ²Oxford Health NHS Foundation Trust, ³Institute of Psychiatry Psychology and Neuroscience (IoPPN), King's College London, University of Oxford, Oxford Health NHS Trust,

Background: Pharmacological treatment of the positive symptoms of psychosis typically consists of dopamine antagonism, but this approach seldom addresses the cognitive (e.g., concentration and memory) and negative (e.g., anhedonia and avolition) symptoms of the disorder. Additionally, a notable subset of patients remain affected by positive symptoms despite standard dopamine antagonist treatments, highlighting the need for innovative approaches to tackle intractable symptoms.

Methods: In response to this challenge, the TUNE-UP (Treating Unmet Needs in Psychiatry) clinic was launched in Oxford in September 2023. This novel approach aims to: (A) Conduct thorough evaluations of cognitive, negative, and positive symptoms, (B) Determine changeable factors that may contribute to these persistent symptoms (for example, cholinergic overload, sleep issues, physical health problems, and mood disorders), and (C) Develop treatment strategies that may include starting clozapine in a community setting when needed. An analysis of data from the clinic's first five months has been conducted to understand the demographics and symptom patterns of the patients referred.

Results: During its initial five months, the TUNE-UP clinic received 21 referrals, with males making up 80.9% of the patient population (average age 43.3 years, SD 13.7). Referral reasons were diverse, including cognitive symptoms (3), combined negative and cognitive symptoms (1), positive symptoms (11), medication reviews (3), and clozapine re-titration (3). Among those assessed (N=17), the average total symptom score, as measured by the Positive and Negative Syndrome Scale (PANSS), indicated mild/moderate severity (70.5, SD 18.4). Objective cognitive assessments using the Screen for Cognitive Impairment in Psychiatry (SCIP) revealed an average score of 54.1 (SD 12.1), significantly below the expected score in a comparable control group (76.3). Lower cognitive scores correlated with older age ($r = -0.62$, $p = 0.01$). The Subjective Scale to Investigate Cognition in Schizophrenia was used to measure perceived cognitive deficits, revealing that worse subjective cognition correlated with more severe negative symptoms ($r = 0.57$, $p = 0.03$), but not with the objective SCIP outcomes ($r = 0.12$, $p = 0.85$).

Discussion: While managing refractory positive symptoms is critical, the prevalence of cognitive and negative symptoms underscores the importance of a holistic treatment approach. Implementing routine, structured evaluations of all symptom areas is necessary and achievable in clinical settings. Future studies will focus on the long-term effects of various treatments across different symptom domains in a naturalistic setting.

F312. ATTACHMENT REPRESENTATIONS IN PRE-ADOLESCENTS AT FAMILIAL HIGH RISK OF SCHIZOPHRENIA OR BIPOLAR DISORDER AND POPULATION-BASED CONTROLS – LONGITUDINAL CHARACTERISTICS OF ATTACHMENT, ITS RELATION TO MENTAL DISORDERS AND PARENTAL FUNCTIONING.

Background: Secure attachment, created from the first years of life through loving, sensitive, and stable relationships with caregivers, is crucial for a positive mental development and for establishing healthy relations with other people through life. For children born to parents diagnosed with schizophrenia or bipolar disorder, such relationships may face challenges when parental illness makes it difficult to provide the attentive responses needed for secure attachment development. We aimed to examine 1) attachment representations from middle childhood to early adolescence among children at familial high risk of schizophrenia (FHR-SZ) or bipolar disorder (FHR-BP) compared with population-based controls (PBC), 2) whether non-secure attachment in middle childhood predicted non-secure attachment in early adolescence, 3) whether non-secure attachment in middle childhood predicted early adolescence psychopathology, 4) whether parental level of functioning and 5) levels of stimulation and support provided at home predicted secure early adolescence attachment.

Methods: Methods:: In a nationwide cohort of 510 same-aged children born to parents with schizophrenia or bipolar disorder and population-based controls, attachment representations were examined through the use of the age-appropriate assessment of attachment scripts, the Story Stem Assessment Profile (SSAP) at age 7 and the Secure Base Script Test (SBST) at age 11. Child psychopathology was assessed with the Schedule for Affective Disorders and Schizophrenia for school-age children – present and lifetime version (K-SADS-PL). Parental level of functioning was measured with the Personal and Social Performance Scale (PSP).

Results: A total of 482 children participated in the SSAP at age 7 and a total of 409 children (FHR-SZ=157, FHR-BP=92 and PBC=160, mean (SD) age 11.9 (0.23)) participated in the SBST assessment at age 11. No difference in secure attachment prevalence was found between risk and control groups. The parental level of functioning at the child's age 7 predicted richer secure base content at age 11 ($p=0.01$, Partial Eta Squared= 0.02), as did the child's level of attachment security at age 7 ($p < 0.001$, Partial Eta Squared= 0.10). The child's level of disorganization at age 7 predicted prevalence of mental disorder at age 11 ($p=0.002$, Partial Eta Squared=0.02).

Discussion: Non-differential attachment prevalence across groups might relate to assessment sensitivity in this setting and to actual adequate overall attachment in the included families.

Selection bias may be relevant to consider in the topic of attachment since families which had been subject to concern reports from the municipality, and families in which children were placed out of home, were slightly underrepresented as compared with the nation-wide total sample. If findings are replicated in other studies, awareness of parental functioning in middle childhood, and awareness of level of disorganization in middle childhood, can be relevant to support healthy attachment development.

F313. MAPPING THE RELATIONSHIPS BETWEEN PSYCHOTIC EXPERIENCES AND DEPRESSIVE SYMPTOMS: A CROSS-LAGGED PANEL NETWORK MODEL

Keith Ho-Fung Cheng¹, Anson Kai Chun Chau^{*2}, Hong Wang Fung³, Stanley Kam Ki Lam⁴, Wai Tong Chien⁴

¹*The University of British Columbia*, ²*The University of New South Wales*, ³*Hong Kong Baptist University*, ⁴*The Chinese University of Hong Kong*

Background: Individuals with psychosis often experience depression. Their common comorbidity may suggest a dynamic relationship between the two conditions, contributing to their formation and maintenance. Their subclinical expressions also often co-occur in both clinical and non-clinical populations. Given the heterogeneity of psychotic symptoms, specific psychotic symptoms may display differential relationships with depression. While some longitudinal studies have demonstrated the bidirectional association between depression and positive symptoms including paranoia and hallucinations, the relationship between depression and negative symptoms is less clear. In addition, the co-occurrence of positive and negative symptoms is rarely considered in a single study. Therefore, it would be important to model the interactive relationship between these depressive and psychotic psychopathologies, which develop over time as a dynamic network. Recently, cross-lagged panel network model (CLPN) is available to capture the dynamics between multiple symptoms of interest with longitudinal data. The current study aimed to apply CLPN to explore the predictive relations between multiple positive and negative psychotic experiences (PEs), and depressive symptoms (DSs) by using two-wave longitudinal data.

Methods: We analysed longitudinal data from an international sample with self-report DSs and PEs at baseline and 1-year follow-up. PEs and DSs at baseline and 1-year follow-up were measured by the Community Assessment of Psychotic Experiences - Positive and Negative Dimension, and the Patient Health Questionnaire-9, respectively. Three positive (i.e., delusional ideations, bizarre experiences, perceptual anomalies), three negative PEs (i.e., social withdrawal, affective flattening and avolition), and nine DSs were modelled as nodes in the CLPN. Edges between nodes indicated cross-lagged relationships between the nodes across time, controlling for their levels at baseline. Cross-construct in-prediction (i.e., the extent to which a variable is predicted by variables in other constructs in the network) and out-prediction (i.e., the extent to which a variable predicts variables in other constructs in the network) indices of each node were also computed.

Results: The final sample consisted of 152 participants (age: $M = 26.18$ ($SD = 8.78$), 94.1% female), of which 115 (75.0%) reported at least one psychiatric diagnosis (major depressive disorder: $n = 58$, 38.2%). Participants were mainly from North America (40.8%) and Europe (22.4%). The CLPN revealed dynamic relationships between positive and negative PEs and DSs. In particular, the DS of 'feelings of worthlessness' was associated with an increase in 'delusional ideations' over time ($B = 0.24$), while the DS of 'psychomotor retardation or agitations' was associated with an increase in avolition over time ($B = 0.33$). The DSs of 'depressed mood' ($B = 0.16$), 'feelings of worthlessness' ($B = 0.14$) and 'loss of energy' ($B =$

0.13) were associated with an increase in social withdrawal over time. Cross-construct in-prediction and out-prediction indices suggested that DSs could predict PEs (especially negative PEs) to a larger extent than the reverse.

Discussion: Using CLPN, our results highlight the complex relationships between DSs and PEs, which are not necessarily confined by traditional diagnostic boundaries. More specifically, our findings unveil specific DSs and PEs that are especially important to the development and maintenance of depression and psychosis. Our findings suggest that individual DSs may be more predictive of the development of specific positive and negative PEs than vice versa.

F314. EFFECT OF ULOTARONT ON BRAIN DOPAMINE SYNTHESIS CAPACITY IN SUBJECTS WITH SCHIZOPHRENIA ON STABLE DOSES OF A D2 ANTIPSYCHOTIC: RESULTS OF AN 18F-DOPA PET STUDY

Oliver Howes¹, Luke Vano¹, Grazia Rutigliano², Rob McCutcheon³, Robert Lew⁴, Snezana Milanovic⁴, Lisa Lennek⁴, Seth Hopkins*⁴, Kenneth S. Koblan⁴

¹*Psychiatric Imaging Group, MRC London Institute of Medical Sciences, Hammersmith Hospital, Imperial College London, Psychiatric Imaging Group, Institute of Clinical Sciences (ICS), Imperial College London, Institute of Psychiatry, Psychology and Neuroscience, Kings College London,* ²*Psychiatric Imaging Group, MRC London Institute of Medical Sciences, Hammersmith Hospital, Imperial College London, Psychiatric Imaging Group, Institute of Clinical Sciences (ICS), Imperial College London,* ³*Institute of Psychiatry, Psychology and Neuroscience, Kings College London, University of Oxford, Oxford Health NHS Foundation Trust,* ⁴*Sumitomo Pharma America*

Background: 18F-DOPA PET imaging studies have found higher striatal dopamine synthesis capacity is associated with symptoms of psychosis and is correlated with illness severity [Jauhar S, et al. JAMA Psychiatry. 2017;74(12):1206]. In a mouse model, ketamine-induced elevations in dopamine synthesis capacity were reduced by single doses of ulotaront (3 mg/kg i.p.) with no effect on baseline dopamine synthesis capacity [Kokkinou M, et al. Mol Psychiatry. 2021;26(6):2562]. Ulotaront is a trace amine-associated receptor 1 (TAAR1) agonist with 5-HT1A activity that has demonstrated efficacy in a Phase 2 trial in patients with schizophrenia [Koblan KS, et al. N Engl J Med. 2020;382(16):1497]. The aim of the current study was to evaluate the effect of ulotaront adjunctive to a D2 antipsychotic on brain dopamine synthesis capacity, as measured by 18F-DOPA PET imaging, in adults with schizophrenia.

Methods: Subjects, ages 18-45, were enrolled who met DSM-5 criteria for schizophrenia and were on a stable dose of a D2 antipsychotic for a ≥ 3 weeks prior to screening. At screen, an 18F-DOPA PET scan was performed. Subjects were continued on their antipsychotic, and treatment with ulotaront was added for 14 days at an initial dose of 50 mg/d for 3 days followed by 75 mg/d for the remaining time period. On day 14, the 18F-DOPA PET scan was performed approximately 2-4 h after the final dose. The primary endpoint was change from baseline in dopamine synthesis capacity in the striatum at day 14 by 18F-DOPA PET scan. Imaging data were analyzed with Patlak modelling with cerebellum as reference region, resulting in the influx constant K_{icer} reflecting dopamine synthesis capacity. For the whole striatum and its subregions (associative, motor, limbic), averaged regional K_{icer} values were calculated, and correlated with PANSS total and subscale scores (Marder Positive). Change from baseline in DA synthesis was calculated and a repeated measures ANOVA was used to test treatment, and

treatment by region, interaction effects. Efficacy measures included the PANSS total and subscale scores.

Results: 22 patients with schizophrenia were enrolled; 19 had useable baseline and day 14 scans: male (n=14), female (n=5); mean age, 32.9; baseline mean (SD) PANSS total 79.3 (7.3) and PANSS positive subscale 19.2 (4.6). There was a significant effect of treatment (p LESS THAN 0.05) and striatal subregion (p LESS THAN 0.05) on Kicer but no treatment by subregion interaction (p GREATER THAN 0.8). Mean percent changes from baseline, and respective treatment effect size were: whole striatum= -3.98% (95% CI: -8.68%, 0.72%) and Cohen's d= -0.46 (95% CI: -0.97, 0.05), associative striatum= -3.38% (95% CI: -8.09, 1.34) and Cohen's d= -0.39 (95% CI: -0.89, 0.11); motor striatum= -3.89% (95% CI: -9.61, 1.81%) and d= -0.39 (95% CI: -0.89, 0.11); and limbic striatum= -5.79% (95% CI: -9.66, -1.92%) and d= -0.74 (95% CI: -1.28, -0.19). The mean reduction in dopamine synthesis capacity for all 3 striatal subregions was greater than the estimated minimal threshold (0.0005/min) likely to be clinically meaningful. There was a significant moderate correlation between change in striatal 18F-DOPA Kicer and change in Marder Positive Factor score on the PANSS (r=0.5, p LESS THAN 0.05) but no significant relationship with change in PANSS total symptom score (r=0.2, p GREATER THAN 0.05).

Discussion: Consistent with preclinical findings, this study found that 14 days of treatment of patients with schizophrenia with ulotaront added to a stable dose of a D2 antipsychotic resulted in potentially clinically meaningful reductions in dopamine synthesis capacity in the striatum that were correlated with a reduction in the severity of the PANSS-positive subscale score. These results, despite stable baseline treatment with a D2 antipsychotic, provide confirmation of the potential efficacy of the novel TAAR1 agonist mechanism of action of ulotaront.

F315. GABA-A RECEPTOR BINDING IN CLINICAL HIGH-RISK FOR PSYCHOSIS AND FIRST-EPISODE OF PSYCHOSIS: A [11C]RO15-4513 PET STUDY

Paulina Lukow*¹, Julia Schubert², Samuel Knight², Amanda S Kiemes², Nicholas R Livingston², James Davies³, Andrea De Micheli², Thomas Spencer², Paolo Fusar-Poli², Beate Haege⁴, Natasha Vorontsova², Jacek Donocik⁴, Eugenii Rabiner³, Steve Williams², Philip McGuire⁵, Mattia Veronese⁶, Federico Turkheimer², Modinos Gemma²

¹University College London, ²King's College London, ³Invicro Imaging Services, ⁴South London and Maudsley NHS Foundation Trust, ⁵University of Oxford, ⁶University of Padua **Background:** Dysfunction of the GABAergic neurotransmitter system is proposed to play a role in the pathophysiology of schizophrenia. Human post-mortem and preclinical evidence suggest that alterations to the excitation-inhibition balance in the hippocampus may be associated with the development of psychosis. GABA-A $\alpha 5$ subunit-containing receptors are primarily expressed in the hippocampus and mediate tonic inhibition of neuronal firing. These receptors have been suggested by preclinical research as a potential new therapeutic target for psychosis-relevant behavioural and physiological phenotypes. Our study sought to investigate whether hippocampal GABA-A $\alpha 5$ receptor binding is altered in antipsychotic-naïve individuals at clinical high-risk for psychosis (CHRp) and people with a first-episode of psychosis (FEP).

Methods: Twenty-four healthy controls (HC), 24 individuals at CHRp, and 10 people with an FEP underwent positron emission tomography (PET) acquisition with arterial blood sampling using the radiotracer [11C]Ro15-4513, which has relatively high affinity for GABAA receptors containing the $\alpha 5$ subunit. One CHRp participant was excluded due to insufficient PET acquisition, and another due to technical issues with blood sampling. PET data were analysed

with MIAKAT 4.3.24 in Matlab R2017a. A two-tissue compartmental model was employed using a population-based input function with individual corrections from discrete blood samples, which estimated the total volume of distribution (V_t) within the hippocampus. Hippocampal V_t values were compared between groups using a type III AN(C)OVA in R 4.3.2 with the `lm` and `Anova` functions, with and without age and sex as covariates of no interest. Results were considered significant at $p \leq 0.05$.

Results: The HC, CHRp and FEP samples had an average age of 25.2 (SD=4.4), 25.2 (SD=4.6) and 29.2 (SD=3.7) years, respectively. The percentage of females in each group was 62.5%, 68% and 33%, respectively. There were no significant differences in hippocampal V_t values between the HC (mean 9.63, SD=1.72), CHRp (mean 9.20, SD=1.51) and FEP (mean 9.25, SD=2.29) groups, either without ($F=0.38$, $p=0.68$) or with nuisance covariates ($F=0.46$, $p=0.64$).

Discussion: This study did not find evidence for an alteration in binding to GABA-A receptors containing the $\alpha 5$ subunit in the hippocampus in antipsychotic-naïve individuals at CHRp or in people with an FEP. Further investigations focussing on less subunit-specific GABAergic dysfunction or on glutamatergic neurotransmission may help elucidate the putative role of hippocampal excitation-inhibition mechanisms in psychosis spectrum symptoms.

F316. THE INTERSECTIONALITY OF DEMOGRAPHIC FACTORS AND SOCIAL DETERMINANTS OF HEALTH AMONG INDIVIDUALS IN EARLY PSYCHOSIS PROGRAMS: A LATENT CLASS ANALYSIS

Yen-Ling Chen^{*1}, Susie Xiong², Tzuahzia Lee², Kathleen E. Nye¹, Valerie Tryon¹, Laura M. Tully¹, Stephania Hayes¹, Mark Savill¹, Sabrina Ereshefsky¹, Chelyah Miller¹, Katherine Pierce¹, Madison J. Miles¹, Merissa Kado-Walton³, Khanh Linh H. Nguyen¹, Nitasha Sharma¹, Amanda McNamara³, Christopher Hakusui¹, Viviana Padilla¹, Maliha Safdar³, Rachel Loewy⁴, Daniel Shapiro¹, Khalima A. Bolden¹, Karina Muro¹, Yi Zhang⁵, Andrew Padovani⁶, Adam Wilcox⁷, Lisa Dixon⁸, Cameron Carter², Tara A. Niendam¹, EPI-CAL Group²

¹University of California, Davis, School of Medicine, ²University of California, Davis, ³Herbert Wertheim School of Public Health and Human Longevity Science, University of California San Diego, ⁴University of California - San Francisco, ⁵Center for Healthcare Policy and Research, University of California-Davis, ⁶Center for Healthcare Policy and Research, University of California Davis, ⁷Washington University St. Louis, ⁸NYSPI/Columbia University Medical Center,

Background: Disparities in health care and health outcomes have been compared among racial groups. For example, Black individuals with first-episode psychosis experience more negative pathways to care (e.g., Anderson et al., 2014) and more severe symptoms when presenting to treatment (e.g., Nagendra et al., 2018) compared to White individuals. However, viewing differences in health outcomes as simply comparing a single dimension of demographic features (e.g., race) creates potential risk of overlooking a broader picture in within-group heterogeneity and the intersectionality between demographic and other social, environmental, and structural factors. Specifically, various social determinants of health (SDoH) factors are associated with psychopathology, including psychosis (e.g., Jester et al., 2023), as well as treatment effectiveness (e.g., Bennett and Rosenheck, 2021). Therefore, it is imperative to incorporate an intersectional lens to view individual's experiences as being shaped by their position and experience in a society, in addition to their socio-cultural identity. To achieve this

goal, the current study utilized latent class analysis (LCA) modeling to identifying more meaningful clusters in classifying individuals who accessed early psychosis care.

Methods: Data was collected from individuals enrolled in California's EPI-CAL early psychosis (EP) programs using the Beehive application. Inclusion criteria included individuals being enrolled in one of the EPI-CAL programs and enrolled in Beehive as part of their clinical care. Individuals who did not agree to sharing their data for research were excluded. Distinct clusters were empirically derived from LCA based on the intersection of demographic and SDoH factors, using the R package "poLCA" (Linzer and Lewis, 2011). Differences in symptom severity and lifetime hospitalization/emergency room (ER) visits were compared by racial categories and by the LCA-identified classes, using one-way ANOVA and chi-square. Logistic regression was conducted to further examine whether LCA-identified classes predicted the likelihood of lifetime hospitalization or ER visits after adjusting for symptom severity.

Results: The sample included 316 individuals (42% female, Mage=19.88 years, SDage = 4.59 years). Approximately 31% of individuals identified as White, 11% Black, 31% Latinx, 10% Asian, 14% multiracial, and 3% other. Results of LCA suggested four distinct classes (entropy=.77). Class 1 (n=100) included more Black and Latinx individuals, showed higher level of economic instability, but had more positive social and community support. Class 2 (n=86) was predominantly White and Asian American and more economically advantaged. Class 3 (n=84) included more sexual minoritized groups, had highest rate of lifetime homelessness, experienced more community violence and discrimination. Class 4 (n=48) was racially diverse, experienced discrimination, and received the least social and community support among all groups. Symptom severity, lifetime hospitalization and ER visits did not show significant differences among racial groups (p s GREATER THAN .05). Class 3 reported more severe symptoms compared to other classes (p s $\leq$.01). Lifetime hospitalization significantly differed by classes (p =.03). Compared to Class 2, Class 1 predicted lower lifetime hospitalization rates (OR=.41, 95% CI [.20, .82]) and lower ER visits (OR=.35, [.12, .93]) after adjusting for symptom severity.

Discussion: Current findings highlight the value of an intersectional approach to examining health outcomes. Using race itself as a single classifier did not yield statistically or clinically meaningful differences in symptom severity or history of hospital/ER visits among individuals enrolled in EP programs. Instead, empirically derived classes that included both demographic and SDoH factors indicated adverse community experiences and discrimination may exacerbate symptom in minoritized groups. Additionally, social and community support may act as a protective factor reducing lifetime hospitalization and ER visits.

F317. WHAT HAPPENS AFTER EARLY INTERVENTION IN FIRST EPISODE PSYCHOSIS? LIMITATIONS OF EXISTING SERVICE MODELS AND AN AGENDA FOR THE FUTURE

Emily Wilner*¹, Andrew Hyatt², Victoria Hasler²

¹Cambridge Health Alliance/Harvard Medical School, ²Cambridge Health Alliance

Background: The last decade has provided hope for individuals with schizophrenia-spectrum illnesses and their families with the advent of specialized, recovery-oriented, and patient-centered programs to treat psychotic disorders from the earliest signs of illness to the first episode of psychosis (FEP). While ample evidence provides support for the positive outcomes associated with FEP programs, there is concern that these gains are not sustained over time and that not all individuals benefit equally from such programs, especially those from minority

backgrounds. Additionally, there is disagreement about the optimal length of FEP programs, and step-down or discharge practices vary widely, ultimately reflecting a lack of clear guidance on how to best maintain the hard-won gains in FEP programs. This review aims to examine the extant literature on the efficacy of FEP programs, as well as that of step down or discharge practices and long-term outcomes with the goal of identifying ways to extend the gains made in FEP programs.

Methods: To conduct this literature review, we searched PubMed in August 2021 for published research on outcomes and step-down/discharge practices of first episode (FEP) programs using the following keywords and combinations: 'coordinated specialty care' or 'early intervention' with 'psychosis' and 'discharge' or 'transition' or 'aftercare' or 'step down' or 'extension program.' The articles obtained from these searches were supplemented by key FEP program efficacy studies (e.g., RAISE trial, OPUS study).

Results: Efficacy of FEP programs: A growing body of literature supports the efficacy of specialized early intervention programs for FEP. However, these benefits may vary depending on demographic factors (e.g., race, ethnicity).

Step down/Discharge practices: There is a lack of a uniform approach to step down or discharge practices from FEP programs. Upon completion of a FEP program, many individuals return to usual community treatment. However, qualitative studies underscore the benefits of a more nuanced approach, including an individualized, patient-centered, coordinated and flexible transition plan aided by a strong therapeutic alliance between service user and provider, as well as collaboration between existing and future providers. Long-term Outcomes following FEP care: There is a body of literature focused on improving long-term outcomes for individuals with psychosis through the extension of FEP programs, though the results of extending FEP care are mixed. Lower intensity or more targeted psychosocial support (e.g., support from peers, vocational specialists) following completion of FEP care have been shown to improve functional outcomes.

Discussion: FEP programs have long been associated with positive treatment outcomes, however when many individuals complete such a program, they return to usual community treatment, which typically includes psychiatric management and some access to individual supportive therapy and/or case management. What tends to be lost are psychosis-specific interventions (e.g., CBT for Psychosis, Social Skills Training), family interventions, and perhaps most importantly, psychosocial supports crucial to maintaining and improving function in the community (e.g., peer support, supported employment/education services). The beneficial role of psychosocial supports following the end of a FEP program suggests an urgent need to provide sustainable funding sources for these traditionally non-reimbursable services. Further research investigating the impact of continuing these services during and after FEP care, as well as the addition of psychosis-specific interventions (e.g., CBTp) that have a growing evidence base for preventing relapse, would assist policymakers in designing a smoother and more effective continuum of care for service users leaving FEP programs. Dismantling studies could also assist in identifying the service users who benefit from specific aspects of FEP programs. This would be a further step in tailoring aftercare to the preferences and values of the service user.

F318. IMPROVEMENT IN COGNITION DURING COGNITIVE REMEDIATION IS RELATED WITH EPIGENETIC CHANGES IN BDNF GENE

Rafael Penadés*¹, Carmen Almodovar-Paya², Clemente García-Rizo¹, Victoria Ruíz¹, Rosa Catalán¹, Sergi Valero³, Til Wykes⁴, Mar Fatjó-Vila², Bàrbara Arias⁵

¹Hospital Clinic Barcelona, ²FIDMAG Germanes Hospitalàries Research Foundation, ³ACE Alzheimer Center Barcelona, ⁴Institute of Psychiatry, Psychology and Neuroscience, King's College London, ⁵Universitat de Barcelona

Background: Cognitive remediation (CRT) produces cognitive benefits in schizophrenia, but we do not yet understand whether molecular changes are associated with this cognitive recovery. A gene central to synaptic plasticity, the BDNF, has been proposed as one potential route. This study assesses whether BDNF methylation change following CR-produced cognitive improvement.

Methods: We tested the effect of CRT on cognition using Mixed Models, where the interaction (treatment by moment, pre-post) was the main effect of interest. Participants were randomized into a two-arm (CRT, n=40) and treatment as usual (TAU, n=20) randomized controlled trial. Cognitive domains were assessed before (T0: 0 weeks) and post-treatment (T1: 16 weeks). Next, we tested the association between the treatment group and methylation changes in three CpG islands of the BDNF gene. Correlations between changes in cognitive domains and changes in methylation were also analyzed.

Results: CRT group showed significant improvements in some cognitive domains compared with TAU. Between-groups differential changes in methylation over time were observed at CpG1.2, CpG1.7, CpG1.10, CpG1.17 and CpG3.2. In those five CpG units, differences in the degree of methylation between T0 and T1 were associated with changes in Speed of Processing, Working Memory, and Verbal Learning within the CRT group.

Discussion: Cognitive improvement could be mediated by epigenetic changes in BDNF gene. That could provide a neurobiological insight into biological mechanisms of cognitive recovery in terms of DNA methylation of a key gene in neuroplasticity regulation. If these data were replicated, BDNF methylation patterns could represent a biomarker of response that would help clinicians provide more personalized treatments.

F319. USING COGNITIVE BEHAVIORAL THERAPY TO TREAT BINGE EATING DISORDER IN A PATIENT WITH SCHIZOPHRENIA: A CLINICAL CASE STUDY

Martin Cernvall*¹, Simon Cervenka¹

¹Uppsala University

Background: Schizophrenia is associated with an increased risk for obesity, diabetes, metabolic syndrome and cardiovascular disease compared to the general population. Although not well studied, there is emerging evidence that people with psychotic disorders and receiving antipsychotic medication have elevated rates of binge eating symptomatology. Detecting and managing binge eating in psychotic disorders may be an important part of clinical management of these patients. However, there is a lack of documentation regarding the use of psychological treatments targeting binge eating symptoms for persons with schizophrenia.

Methods: This clinical case study describes the use of cognitive behavioral therapy (CBT) to target binge eating disorder in a 45-year old male patient diagnosed with schizophrenia. Concomitant medication included quetiapine (200 mg), risperidone (2mg) and venlafaxine (225 mg). He had previously been prescribed clozapine which had to be withdrawn due to severe sedation. Body mass index (BMI) pre-treatment was 33. A previous cognitive assessment indicated an estimated full IQ somewhat below average and pronounced deficits in certain cognitive domains. The treatment took place at an outpatient unit at an academic

medical center. The patient lived alone with continuous informal support from his parents and attended a vocational rehabilitation program 2-3 times per week.

Results: The patient had a long history of binge eating episodes. At time for assessment, he described 8 objective binge episodes during the last 28 days, but no compensatory behaviors. During binge episodes, the patient was eating more rapidly than normal and this resulted in feeling uncomfortably full and also feelings of disgust and guilt. The clinical picture was consistent with DSM-5 criteria for binge eating disorder (mild). Assessment with the eating disorder questionnaire (EDE-Q) indicated elevated levels of concerns about body shape and weight. A functional analysis indicated that binge episodes occurred mainly in the evenings and were associated with reduced intake of food during the day, which precipitated anxiety and also the experience of voices. The patient rated the overall frequency of voices to 2 (scale 0-10) and their associated distress to 6 (scale 0-10). In the functional analysis, binge episodes were hypothesized to serve emotion regulating functions. Treatment included 16 sessions of CBT over 8 months and a follow-up after 18 months. In line with current empirical support, treatment focused on reducing restraint and normalizing patterns of regular eating in order to prevent binge episodes. This was achieved mainly with self-monitoring of eating patterns and planning of meals. Dysfunctional thoughts and beliefs regarding body shape, weight and self-worth were also addressed. The frequency of binge eating episodes and body shape and weight concerns were significantly reduced at end of treatment (monthly binge episodes from 8 to 0 and body shape and weight concern index from 3.3 to 1.0, respectively). Improvements were maintained at 18 months follow-up (0 binge episodes, shape and weight concern index 0.5) and the patient no longer fulfilled criteria for binge eating disorder. Furthermore, distress associated with voices was reduced to 3 (0-10).

Discussion: This clinical case study demonstrates how CBT can be applied successfully for patients with schizophrenia and co-occurring binge eating disorder. This indicates the importance of assessing binge eating symptoms and developing CBT methods targeting such problems in people with schizophrenia.

F320. “MOTIV8”: A CLUSTER-RANDOMIZED FEASIBILITY TRIAL OF A WEIGHT MANAGEMENT INTERVENTION FOR ADULTS WITH SEVERE MENTAL ILLNESS IN SECURE FORENSIC SERVICES

Rebekah Carney^{*1}, Hany El-Metaal¹, Heather Law¹, Siobhan Savage¹, Ingrid Small¹, David Shiers², Mark Hann³, Gemma Shields³, Parise Carmichael-Murphy³, Richard Jones¹, James Farrell¹, Sophie Parker¹

¹Greater Manchester Mental Health NHS Foundation Trust, ²Greater Manchester Mental Health NHS Foundation Trust, University of Keele, ³University of Manchester

Background: People with severe mental illness experience a 25-year reduction in life expectancy, mainly from physical disorders. This is driven by medication side-effects, high rates of adverse health behaviours, and poor physical healthcare. It is particularly compromised in secure services, where there are restrictions on movement, increased confinement, reduced access to outdoor space and high dosages of medication. Motiv8 is a 9-week weight management programme aiming to address this issue. It was co-produced with service users, and includes exercise sessions, cooking classes, physical health/sleep sessions, and a pharmacy review.

The aim was to conduct a randomised waitlist-controlled trial to assess the feasibility of Motiv8+treatment as usual for individuals on forensic inpatient units. Objectives were to assess feasibility and acceptability via recruitment/retention rates, adherence, engagement/attendance, drop-out rates, assessment completion, and qualitative interviews. The overall aim was to use outcome data to refine a protocol for a definitive trial.

Methods: A randomised waitlist-controlled trial of Motiv8+TAU compared with TAU was conducted in forensic inpatient services at Greater Manchester Mental Health NHS FT (ISRCTN13539285). 29 participants were recruited into four cohorts and randomised to either Motiv8+TAU (n=12) or TAU+waitlist Motiv8 (n=17). Assessments were completed at baseline, 10-weeks and 3-months. Qualitative interviews (developed with service users) were conducted with a subsample of participants (n=8) to capture unique experiences of Motiv8 and inform a refined intervention. A sub-study was conducted with staff to explore the ward environment and assess confidence/knowledge of physical health. A lived experience group was established prior to study set-up to inform trial procedures, develop recruitment materials and inform session content. The group was co-facilitated by service user researchers, who were consulted throughout the trial, and included in the interpretation/dissemination.

Results: 29 participants (4 cohorts) were recruited from secure services in Greater Manchester Mental Health NHS Foundation Trust, and 100% were randomised. Two cohorts were randomised to receive Motiv8 straight away (n=12) and two randomised to the waitlist condition to receive TAU followed by Motiv8 (n=17). Participants were predominantly male (n=25, 89.7%), white (n=22, 75.9%) and average age was 36.5 (range 20-61). All but one was diagnosed with a psychotic related disorder. Retention to the trial was good (93.1% 10-weeks, 72.4% 3-months), the main reason for participant loss was discharge from the ward (n=5, 71.4%). 72.4% participants (n=21) started the intervention and received a dose. Engagement with the intervention was good, particularly for the first two cohorts. The blind was successfully maintained, and no safety concerns were raised. The trial was not powered to detect differences between groups; however, qualitative feedback revealed that participants enjoyed being involved in the trial, reported numerous benefits of the intervention including physical improvements (feeling fitter, losing weight), increased knowledge and hope, and finding it valuable and worthwhile.

Discussion: The data suggests evidence for the acceptability/feasibility to conduct a rigorous, methodologically robust study comparing Motiv8 with TAU+waitlist for adults on forensic inpatient units. Our study adds to the growing evidence base regarding physical health interventions for adults on secure forensic inpatient mental health units. Further work is needed to refine an application to explore potential effectiveness of Motiv8 in forensic services.

F321. TOOLKIT FOR CANADA'S LOWER-RISK CANNABIS USE GUIDELINES FOR PSYCHOSIS (LRCUG-PSYCH)

Lucy Chester*¹, François-Olivier Hebert², Didier Jutras-Aswad²

¹*Centre de Recherche du CHUM*, ²*Research Center, Centre Hospitalier de l'Université de Montréal (CRCHUM), Université de Montréal, Centre Hospitalier de l'Université de Montréal (CHUM), Université de Montréal*,

Background: Cannabis use has been associated with an increased risk of developing a psychotic disorder, and with greater symptom severity, increased risk of relapse and poor treatment response in individuals with a psychotic disorder. Certain modifiable factors associated with cannabis use have been shown to increase or reduce these psychosis related

risks. These factors are the subject of the Lower-Risk Cannabis Use Guidelines for Psychosis (LRCUG-PSYCH), a set of evidence-based and public health-oriented recommendations designed to mitigate and reduce psychosis-related risks associated with cannabis use. Guidelines were developed by international expert consensus following an extensive review and evidence grading of scientific literature, a description of which can be found in the evidence review published in the Journal of Dual Diagnosis in 2023 (Fischer et al.). They are structured into 11 recommendation clusters for individuals seeking to modify their cannabis use and minimize associated risks. Here, we present knowledge dissemination materials designed to promote awareness, education, and implementation of the LRCUG-PSYCH into clinical practice.

Methods: The LRCUG-PSYCH toolkit consists of public and clinician-oriented knowledge summaries and a suite of resources for cannabis and psychosis-related education, prevention, and harm reduction. These resources are the result of an international collaboration between experts in psychiatry, addiction, knowledge transfer and communication, and in consultation with clinicians, patient partners and people with lived experience of psychosis and cannabis use. Endorsement for the LRCUG-PSYCH has been granted by prominent national public health and substance use organizations, including the Schizophrenia Society of Canada (SSC), Canadian Public Health Association (CPHA), and Canadian Research Initiative on Substance Misuse (CRISM).

Results: The following resources are available as web and print versions, in both English and French: LRCUG-PSYCH Evidence Brief – a summary of the 11 evidence-based recommendations for reducing psychosis-related risks when using cannabis written for clinicians, professionals, organisations, and government entities dedicated to improving the health of people who use cannabis. LRCUG-PSYCH Brochure – a summary brochure of the 11 evidence-based recommendations written for the general public. This resource is targeted towards individuals who are thinking about using cannabis or who are actively using cannabis, and individuals who have a history of, or are at an elevated risk of developing psychosis. Harm reduction posters – two public-facing posters recommending individuals to talk to their healthcare providers about cannabis and the risk of psychosis. Patient decision Aid: My reflection Journal – a tool for individuals who use cannabis to log and reflect on their cannabis use, the impact of their use, and how they may alter their consumption habits in line with their own lifestyle and preferences. Dialogue Support Tool for Clinicians – a tool designed to help guide clinicians in their conversations about cannabis with people who have experienced psychotic episodes and/or been diagnosed with a psychotic disorder, aligning with evidence-based approaches for health behaviour change such as motivational interviewing and brief interventions. Communication Bridges and Roadblocks Infographic – a short visual list of common communication approaches that may support or impede communication for clinicians discussing cannabis use with people who have experienced psychotic episodes and/or been diagnosed with a psychotic disorder.

Discussion: Dissemination and implementation of the LRCUG-PSYCH toolkit offers a promising avenue to improve public and clinician awareness, understanding and response to cannabis-related psychosis risks. By bridging expert consensus with practical tools, these resources aim to empower individuals and healthcare professionals in navigating conversations and decisions related to cannabis use, ultimately fostering a reduction in psychosis-related risks.

F322. INDIVIDUALIZED SMARTPHONE-BASED PATIENT-REPORTED OUTCOMES IN OUTPATIENT PSYCHIATRIC CARE: FEASIBILITY, CLINICAL ENDPOINTS AND IMPACT ON RECOVERY

Felix Machleid¹, Anette Schönewald¹, Luise Balzer², Linda Kokwaro¹, Louisa Schröder-Frerkes³, Caspar Wiegmann⁴, Jakob Kaminski*¹

¹Charite University Medical Center Berlin, ²Humboldt Universität Berlin, ³Vivantes Klinikum am Urban Berlin, ⁴Kliniken im Theodor-Wenzel-Werk

Background: Outpatient care for people with severe and chronic mental illness is complex due to various challenges. One challenge is monitoring of outcomes that are relevant to the patient and engage in self-management. This pilot study aims to investigate the feasibility and usability of a smartphone-based application for recording individually formulated electronic patient-reported outcomes (dynamic ePROs) between treatment appointments to promote self-management.

Methods: In this non-randomized case-control pilot study, patients with schizophrenic and affective disorders (F20, F25, F31, F32/33) used a newly developed smartphone application over a period of 90 days between their outpatient appointments to regularly record pre-defined and individualized dynamic ePROs. The control group received the usual treatment in the form of regular outpatient appointments. Psychometric data including data on specific symptom severity, quality of life, daily functioning and healthcare utilization were collected in both groups at baseline and at the end of the study.

Results: At the time of submission of this abstract, the study has not yet been completed. It is planned to present preliminary data on adherence, quality of life and symptom change as a proof-of-concept at the conference.

Discussion: The results of our study contribute to the investigation of the impact of digital recording of individual symptom trajectories on patient self-management and the therapeutic alliance and thus provide an important contribution to this field of research.

F323. DIFFERENCES IN RESTING-STATE OSCILLATIONS IN EEG BETWEEN ULTRA-HIGH-RISK, CLINICAL CONTROL AND HEALTHY CONTROL GROUPS

Julia Adams*¹, Ilvana Dzafic¹, Magdalene de Rozario¹, Gregor Leicht², Moritz Haaf³, Marija Krcmar⁴, Cassandra Wannan⁴, Suzie Lavoie¹, Kelly Allott¹, Christopher G Davey¹, Hok Pan Yuen¹, Thomas Whitford⁵, Melanie Formica¹, Sarah Youn¹, Jashmina Shetty¹, Rebecca Beedham¹, Victoria Rayner¹, Graham Murray⁶, Andrea Polari¹, Lukasz Gaweda⁷, Dan Koren⁸, Louis Sass⁹, Josef Parnas¹⁰, Andreas Rasmussen¹¹, Patrick McGorry¹, Jessica A Hartmann¹, Barnaby Nelson¹, Stephen Wood¹

¹Orygen Youth Mental Health, ²University Medical Center Hamburg-Eppendorf, ³University Medical Center Hamburg, ⁴University of Melbourne, ⁵University of New South Wales, ⁶University of Cambridge, ⁷Institute of Psychology, Polish Academy of Science, Warsaw, Poland, ⁸University of Haifa, ⁹Rutgers University, ¹⁰University of Copenhagen, ¹¹Mental Health Center Amager

Background: We are investigating whether there are distinct differences in resting-state gamma oscillations across ultra-high-risk (UHR), clinical control (CC) and healthy control (HC) populations. Gamma band oscillatory activity has previously found to be increased during resting-state in psychotic populations, and with ketamine administration in healthy controls.

Gamma disturbances in ultra-high-risk populations have been compared with clinical controls during response tasks, but not at resting state. We hypothesize that there would be increased gamma oscillations in the UHR group than in the CC group at rest, and no difference between CC and HC.

Methods: Data was collected from 12–25-year-olds who were classified as Ultra-High-Risk (UHR), Clinical Control (CC) and Healthy Control (HC). Final group frequencies were 68 UHR, 44 CC and 16 HC. Clinical controls are other individuals in the service experiencing psychiatric symptoms but no threshold or sub-threshold psychotic symptoms. Raw EEG data was then prepared for analysis using a pre-processing pipeline in EEGLAB and FOOOF, a python-based tool for neural power spectra analysis. Spectral parameterization will be used to look at the aperiodic components for accurate identification of oscillatory activity. Cluster-based permutation testing with multiple comparisons corrections will be used to identify group differences.

Results: Statistical analysis is currently underway, as such results will be available by the time of presenting. Preliminary results using fast Fourier transform suggests a difference between UHR and CC groups.

Discussion: Gamma disturbances in ultra-high-risk populations may indicate gamma disturbances are uniquely present with psychotic and psychotic-like symptomatology and could contribute to psychotic-like symptoms. Further work around the role of gamma disturbances may clarify the relationship further. These findings suggest a connection between gamma disturbances and the psychosis continuum.

F324. WHOLE-GENOME SEQUENCING OF SCHIZOPHRENIA FAMILIES FROM THE AZORES AND MADEIRA

Hamed Kazemi¹, John Drake², Tim Bigdeli³, Silviu Bacanu⁴, Kelly Benke⁵, Brion Maher⁵, James Knowles⁶, Steven McCarroll⁷, Celia Carvalho⁸, Joana Moura Cabral⁸, Helena Medeiros⁹, Rute Ferreira¹⁰, Michele Pato⁶, Carlos Pato⁶, Vladimir Vladimirov¹, Ayman Fanous^{*11}

¹University of Arizona, ²University of Arizona, Texas A and M University, ³SUNY Downstate Medical Center, ⁴VIPBG, ⁵John Hopkins University, ⁶Rutgers University, ⁷Harvard Medical School, ⁸University of the Azores, ⁹University of Southern California, ¹⁰Instituto S. Joao de Deus, ¹¹University of Arizona College of Medicine

Background: While genome-wide association studies (GWAS) have been successful in identifying common risk alleles contributing to schizophrenia (SCZ) etiology, a highly heritable psychiatric disorder with substantially increased mortality risk, these studies often ignore the contribution of rare variants. Using whole genome sequencing (WGS) data from the Portuguese Island Collection (PIC) sample (n = 171), which contains families with affected and unaffected individuals and controls. We applied a two-pronged analytical approach to assess the impact of common and rare variants in PIC. First, common variants were used to calculate the polygenic risk score (PRS) for SCZ. Second, within a linear mixed models (LMM) framework, we assessed the impact of rare deleterious variants in the PIC cohort to predict schizophrenia status based on the presence of the alternative, disease-associated, risk allele within genes. For variants with evidence of familial segregation, we further 1) compared the presence of alternative alleles within groups and 2) conducted permutations on the likelihood of familial segregation to calculate a whole-genome p-value for rare deleterious variants.

Methods: Prior to analysis, summary statistics of gnomAD v3.1.2 were used to select 5,217,104 common single nucleotide polymorphisms (SNPs) with a $MAF \geq 0.01$ and 7,538,699 rare single nucleotide variants (SNVs) with a $MAF \leq 0.01$. The PRS was calculated using PRSice-2, using common variants in 44 SCZ patients, 65 Unaffected, and 62 population control subjects. For the quality-control step, subjects with excessive Mendelian errors, sex-check failures, and/or low-quality reads were removed. To define rarity, variants with $MAF \leq 0.01$ in the control population and 1000 Genome (if present) were defined as rare. All other variants were defined as common. For defining deleterious rare variants, Combined Annotation Dependent Depletion (CADD) v1.6 with hg38 was used to define phred-like scores, and ANNOVAR v2020.06.08 with GRCh38 and refGene was used to define exonic variants.

Results: The p-value threshold of 0.001 explained the largest variation of risk for SCZ with $R^2 = 0.054$ (p-value = 0.013) when comparing cases vs. unaffected family members and the p-value threshold of 0.05 explained the largest variation of risk for SCZ with $R^2 = 0.251$ (p-value = 2.2×10^{-5}) for cases vs. population controls analysis. Results from the linear mixed model showed the association strength between genes carrying rare and deleterious variants (PHRED score ≥ 10) and SCZ status in the PIC cohort including LIG3, A3GALT2, BMP2K, C15orf39, MCM4, SIGLEC14, and SIGLEC5 which have been implicated in numerous psychiatric conditions, including SCZ.

Discussion: We conducted a permutation analysis with rare and deleterious variants (PHRED score ≥ 10) displaying signs of segregation. This analysis aimed to assess the probability of familial segregation within affected families across the entire genome (p-value: 0.0041). Through the identification of particular genes and genetic variations linked to SCZ, we can attain a deeper understanding of the biological mechanisms underlying the onset of this disorder.

F325. DECODING LANGUAGE ENTROPY: A DISTINCTIVE SIGNATURE IN INDIVIDUALS WITH SCHIZOPHRENIA

Maria Francisca Alonso^{*1}, Jorge Portal², Alvaro Cavieres³, Monica Otero⁴, Pedro Alfaro⁵, Lucia Zepeda³

¹Western University, ²USM, ³UV, ⁴USS, ⁵PUCV

Background: Language disturbances are a core feature of schizophrenia and are often expressed as through formal thought disorder which encompasses speech disorganization and impoverishment. Recent advancements in computational linguistics offer new avenues for exploring language features, such as word frequency, syntactic organization, and more complex semantic dimensionalities. The language entropy captures the amount of certainty or uncertainty in a time series. Some authors have associated the entropy differences with rigid and flexible states when applied to text analysis. Suggesting that low entropy relates to highly rigid use of linguistic features while high entropy denotes flexible use of specific linguistic features. This study aimed to compare the language entropy between individuals with schizophrenia, bipolar disorder and controls.

Methods: We recruited a sample of 90 participants, 30 with schizophrenia (SZ), 30 with bipolar disorder (BD) and 30 matched controls (HC). For the neurocognitive assessment, we used the SCIP neuropsychological battery while the symptoms were rated with the Brief Psychiatric Rating Scale. They all went through a picture description task that was recorded and later transcribed. We analyzed the entropy of the text samples as the additive inverse of the sum of products calculated by multiplying the probability of each category by the natural log of the probability of that category. All participants provided written informed consent

before the assessment. Clinical and demographic data were analyzed using descriptive and Bayesian statistics. We first compared groups' entropy with a Bayesian ANOVA. To address the interaction with cognitive and symptom variables, a Bayesian correlation was conducted between entropy, SCIP and BPRS scores.

Results: Healthy controls and the patient groups did not significantly differ in age or gender distribution, however, the educational level of the SZ group was lower. All the participants had Spanish as their only transactional language. As expected, the HC group performed better on the cognitive assessment. In the description task, we observed a difference in the entropy of the language samples between the groups (HC: 6.851, SD: 0.2; BD: 6.741, SD: 0.2; SZ: 6.099, SD: 0.5, BF10: GREATER THAN 10000). In the posthoc analysis the results showed that the BD group did not differ with the HC group (BF10: 0.762). Regarding the cognitive performance, the entropy correlated with all the measures. When comparing the symptoms, the entropy was correlated with negative symptoms (Pearson's r : -0.64, BF10: GREATER THAN 10000) but not with positive (Pearson's r : -0.23, BF10 : 0.791).

Discussion: We observed a difference in entropy among the groups, noting that the Bipolar Disorder (BD) group exhibited greater similarity to the control group than the Schizophrenia (SZ) group. Our findings imply a more inflexible language use among SZ patients, while such rigidity was not evident in BD. This rigid linguistic pattern may serve as a distinctive signature of schizophrenia. Notably, the entropy was correlated with negative symptoms, aligning with the observed language impoverishment characteristic of schizophrenia.

F326. EXPLORING THE INTERPLAY OF CANNABIS USE AND GENETIC FACTORS IN EDUCATIONAL ATTAINMENT AMONG FIRST-EPISODE PSYCHOSIS PATIENTS, THEIR SIBLINGS, AND CONTROLS

Nancy Murillo-García^{*1}, Sergi Papiol², Rosa Ayesa-Arriola¹

¹*Valdecilla Biomedical Research Institute; Research Group on Mental Illnesses,* ²*Max Planck Institute of Psychiatry*

Background: Patients with first-episode psychosis (FEP) achieve lower educational attainment (EA) than their unaffected siblings and healthy controls. Lower rates of cannabis use have also been described in controls and siblings of FEP patients. As EA is a trait significantly influenced by genetic factors, the genetic load could also be related to the difference in academic outcomes between the groups. The aim of this study was to investigate whether cannabis use and the polygenic score for EA influence EA, operationalised as years of formal education completed.

Methods: We included 390 subjects enrolled in PAFIP-FAMILIAS from Santander, Spain (122 FEP, 175 controls, 93 siblings). All provided data on their EA, cannabis use at baseline and a DNA sample. Quality control before polygenic scoring was performed according to standard procedures. The polygenic score for EA was calculated using the PRS continuous shrinkage method (Ge et al., 2019). Statistical analysis was performed using linear mixed modelling. The main model included the dependent variable (EA), fixed effects (cannabis use, polygenic scores, group membership, intelligence, sex, age) and a random effect (family code). A null model was fitted for comparison effects. In this model, polygenic scores and cannabis use were removed.

Results: The main model explained 56% of the variance in EA ($R^2= 0.56$). This model was better than the null model in predicting the outcome ($\chi^2= 30.35$, p LESS THAN 0.001). Polygenic score, intelligence and female sex were positively associated with EA (p LESS

THAN 0.001). Cannabis use was not a significant predictor of EA on its own, but showed a significant interaction with group membership ($p = 0.003$). FEP group membership was associated with cannabis use, and this interaction significantly predicted EA.

Discussion: Our research suggests that EA is influenced by both genetic factors and cannabis use. These variables may play a role in mediating the lower academic performance observed in FEP patients. Our findings highlight the potential risk of cannabis use in relation to psychosis and its potential impact on cognitive outcomes.

Lunch and Poster Session III

S1. COMPARING FORENSIC AND NON-FORENSIC FEMALE PATIENTS WITH SCHIZOPHRENIA SPECTRUM DISORDERS: AN EUROPEAN STUDY

Giovanni de Girolamo*¹, EU-VIORMED EU-consortium²

¹IRCCS St. John of God Clinical Research Centre, Brescia, ²IRCCS St. John of God Clinical Research Centre, Italy

Background: Violent behaviour is much more frequent in male than in female subjects and there is a paucity of studies regarding violent behavior displayed by women. The specific aim is to analyse a sample of female subjects, diagnosed with schizophrenia spectrum disorders (SSD), included in an European study on forensic psychiatry, the EUVIORMED study: women with SSD who were admitted to forensic facilities were compared to women with SSD who never exhibited violent behaviour.

Methods: Sociodemographic, clinical, neuropsychological, and treatment-related characteristics of the two samples of female patients have been compared. Standardised assessment instruments included psychopathology (PANSS), psychosocial functioning (WHODAS 2.0), and cognition (Brief Assessment of Cognition in Schizophrenia-BACS covering six cognitive domains: verbal memory and learning, working memory, motor function, verbal fluency, processing speed and executive function. HCR-20 v. 3 has been used to produce a quantification of violence risk assessment.

Results: In the overall European sample there were 26 women violent cases, with an SSD and a history of at least one act of serious interpersonal violence and 36 matched women with an SSD but who had never been violent. The vast majority of both groups were white (92.3% of female cases and 94.4% of female controls, $p=.538$). The female cases were significantly younger than the female controls ($p=.012$). Marital status did not significantly differ between cases and controls ($p=.265$). Most participants in both groups were single (69.2% of cases, 83.4% of controls), even though among cases a higher percentage (23.1%) were also divorced/widowed. On the contrary, the controls were more likely than cases to have children (88.9% vs 61.5%, $p=.011$). There was also a significant difference in the level of education between the two groups ($p=.027$), with the control group reporting more years of education (14, SD= 3.4) compared to cases (12.3, SD= 2.5). No significant differences were found in the occupational status. Although there was no significant difference in age at first contact with mental health services between cases and controls ($p=.133$), the control group had a shorter disease duration (mean years of 9.3; SD=7.9) compared to the cases who had a mean duration of 15.4 (SD=10.6) years. Overall, the most common diagnosis in both groups was schizophrenia (84.6% among cases compared to 77.8% in the control group); delusional disorders (3.8%) and schizophreniform disorders (3.8%) were diagnosed in a tiny minority. Cases were more likely to have a comorbid diagnosis of personality disorders (36%) than controls (5.7%) ($p=.003$). Lifetime substance use was common in both groups (53.8% in the cases and 62.9% in the control group) ($p=.479$). Almost half of the sample reported at least one suicide attempt or an act of deliberate self-harm in the past (46.2% of cases vs 47.1% of controls, $p=.944$). The total mean PANSS score was 72.1 (SD=22.9) for female cases and 69.0 (SD=22.8) for controls suggesting similar levels of positive symptoms, negative symptoms, general psychopathology, and overall symptom severity results among cases and controls. About WHODAS 2.0, controls had a higher mean score (16.7, SD=7.6) compared to cases (7.0, SD=6.8), ($p < .001$), reflecting higher disability and a worse functioning. In terms

of cognition forensic female patients achieved lower scores for all BACS, domains but one (verbal memory), although the difference were not significant. We found no significant difference in the incidence of violence exposure between female forensic participants and control subjects. However, there was a notable difference in the frequency with which they were exposed to violence in the past ($p=.034$). Cases were more likely to report exposure to violence often (62.5%), whereas controls predominantly reported that as a rare experience (66.7%). More cases were also often victims of violence compared to their non-forensic counterparts ($p=.023$), and had been beaten, kicked or punched by someone ($p=.020$). We then conducted a multivariable logistic regression using all the factors that differed between the female forensic participants/cases and control subjects from the first three tables. Age in years, number of years in education, comorbidity with personality disorders, WHODAS 2.0 total score, and having experienced physical violence, that was being beaten, kicked, or punched by someone, significantly predicted the likelihood of being a female forensic case as compared to a female control.

Discussion: Despite the potential for bias and underestimation, our research affirms that the emergence of aggressive conduct in women with SSD is shaped by various factors. Elements such as the extended duration of illness, a history of being victimized, and the presence of a comorbid borderline personality disorder are influential in the expression of aggressive behaviour in female patients with SSD.

S2. TIME WILL TELL: ASSOCIATIONS BETWEEN UNBALANCED TIME PERSPECTIVES AND SYMPTOM SEVERITY IN INDIVIDUALS WITH SCHIZOPHRENIA SPECTRUM DISORDERS

Giovanni de Girolamo*¹, DIAPASON Consortium²

¹*IRCCS St. John of God Clinical Research Centre, Brescia, ²Italy*

Background: Time Perspective (TP) is an essential, albeit elusive, psychological phenomenon with profound consequences on human emotions, cognition, judgment, and behaviors (Strathman and Joireman, 2015; Zimbardo and Boyd, 1999, 2008). The term refers to the “nonconscious personal attitude that each of us holds towards time and the process whereby the continual flow of existence is bundled into time categories that help to give order, coherence, and meaning to our lives” (Zimbardo and Boyd, 2008). Individuals use past, present, and future temporal frames to encode, store, and recall experienced events as well as to form expectations. Patients with schizophrenia spectrum disorder (SSD) experience disrupted temporality on the immediate timescale. However, insufficient information is available for longer time frames, and the interaction of temporal perspectives with the clinical manifestations of SSD is unknown.

Methods: We aimed to explore the associations between TP, daily time use, and levels of functioning among 620 patients (313 residential patients and 307 outpatients) with a diagnosis of SSD recruited from 37 different centres in Italy. The Brief Psychiatric Rating Scale and the Specific Levels of Functioning (SLOF) were used to assess psychiatric symptoms severity and levels of functioning. Daily time use was assessed using an ad hoc paper and pencil Time Use Survey. The Zimbardo Time Perspective Inventory (ZTPI) was used to assess TP. Time perspective biases were measured using the Deviation from the Balanced Time Perspective-revisited (DBTP-r) indicator, based on Zimbardo Time Perspective Inventory (ZTPI) scores. Preliminary analyses examined the associations between ZTPI/DBTP-r and BPRS/BNSS total scores. In secondary analyses, we first tested the associations between the ZTPI/DBTP-r and BPRS/BNSS subscales and then compared ZTPI differences between patients with and without

hallucinations, delusions, and conceptual disorganisation. Statistical significance was set at Holm-Bonferroni corrected p LESS THAN 0.05.

Results: Low-to-moderate positive correlations were found between the DBTP-r and BPRS/BNSS total scores ($r = 0.29/0.22$). The strongest associations were between DBTP-r/ZTPI_Past-Negative and anxiety/depression ($r = 0.34/0.36$), followed by DBTP-r/ZTPI_Present-Fatalistic with thought disturbances ($r = 0.22/0.20$). DBTP-r was associated with BNSS anhedonia and avolition ($r = 0.21/0.24$). DBTP-r was higher in patients with hallucinations ($ES = 0.391$) and conceptual disorganisation ($ES = 0.397$) than in those without these symptoms. Unbalanced time perspective was positively associated with the severity of primary and secondary SSD features. The amount of time spent on non-productive activities (NPA) was positively predicted by DBTP-r ($Exp(B): 1.36; p .003$), and negatively predicted by the Past-Positive ($Exp(B): 0.80; p .022$), Present-Hedonistic ($Exp(B): 0.77; p .008$), and Future ($Exp(B): 0.78; p .012$) subscales. DBTP-r significantly negatively predicted SLOF outcomes ($p .002$), and daily time use, in particular the amount of time spent in NPA and Productive Activities (PA), mediated their association.

Discussion: These findings provide a rationale for empirical tests focused on balancing time perspectives in patients with SSD. According to our findings, more inactive patients had unbalanced temporal perspectives. These individuals manifested a decreased positive attitude toward the past, believed that uncontrollable forces determine their current fate, and displayed a strongly limited future foresight (i.e., avoided setting and realising future goals). To the best of our knowledge, this is the first study to report the association between TP and time spent “doing nothing” in both the general and clinical populations. Our results suggest that desirable levels of the three TP dimensions (i.e., high Past-Positive and Future, as well as low Present-Fatalistic TP) may play a protective role against

inactivity or wasting time and, subsequently, against the negative consequences of inactivity in individuals with SSD listed earlier. We found that the more balanced patients are in their TP, the better daily functioning levels they have (including social functioning, daily life, and working abilities). We found that the effect of BTP on functioning levels was mediated by the time spent in non-productive and productive activities. The present results suggest that fostering BTP (e.g., restructuring past memories, encouraging a greater focus on the future, and reducing fatalistic life perspectives) might lead to a reduction of inactivity in patients with SSD, with an increase in productive activity levels and psychosocial functioning. Such changes may have notable effects on

patients’ levels of functioning and rehabilitation outcomes. TP can be effectively changed via both individual psychotherapy and group-level training interventions, and such changes may lead to highly desirable outcomes, including increased well-being and decreased clinical symptoms.

S3. A MULTI-COUNTRY STUDY ON THE RELATIONSHIP BETWEEN WAR-RELATED MEDIA EXPOSURE AND PSYCHOTIC EXPERIENCES IN THE AFTERMATH OF THE OCTOBER 2023 ISRAEL-GAZA WAR: RESILIENCE AND RELIGIOSITY AS MODERATORS

Feten Fekih-Romdhane^{*1}, Ahmad Abu-Akel², Mai Helmy³, Amthal Alhuwailah⁴, Hanaa Shuwiekh⁵, Emna Maalej⁶, Abdallah Y Naser⁷, Sahar Obeid⁸, Alexandre Andrade Loch⁹, Majda Cheour⁶, Souheil Hallit¹⁰

¹Tunis El Manar University, Faculty of Medicine of Tunis, ²University of Haifa, ³Sultan Qaboos University, ⁴Kuwait University, ⁵Fayoum University, ⁶Tunis Al Manar University, Faculty of Medicine of Tunis, ⁷Isra University, ⁸Lebanese American University, ⁹Universidade de Sao Paulo, ¹⁰Holy Spirit University of Kaslik (USEK)

Background: After the 7th of October 2023, millions of individuals across the globe have been facing an unprecedented indirect exposure to war and terror through media coverage. Young people exposed to such early, extensive and repeated war-related media content are at increased risk for detrimental and long-lasting psychological consequences, including the development or exacerbation of psychotic experiences (PEs), particularly when mitigating resources are lacking. In this context, the current study sought to test the hypothesis that resilience and religiosity are involved as moderators in pathways linking early war-related media exposure and PEs in community emerging adults.

Methods: This is a cross-sectional study that was conducted two to four weeks following the start of Israel's war on Gaza on the 7th of October 2023. Young adults from the general population of Egypt, Jordan, Kuwait, Oman, and Tunisia (N= 2424; mean age= 22.15 ± 4.05 years; 74.1% females) took part in the study through an online survey.

Results: The results of the moderation analysis showed that higher war-related media exposure was significantly associated with higher PEs. Higher resilience was significantly associated with lower PEs. The interaction war-related media exposure by resilience was significantly associated with PEs; at low and moderate levels of resilience, more war-related media exposure was significantly associated with higher PEs (Beta = .10 and Beta = .06 respectively). This effect was not significant at high levels of resilience. In addition, the interaction war-related media exposure by religiosity was significantly associated with PEs; at low and moderate levels of religiosity, more war-related media exposure was significantly associated with higher PEs (Beta = .10 and Beta = .06 respectively). This effect was not significant at high levels of religiosity.

Discussion: As anticipated, resilience had a moderating influence on the relationship between war-related media exposure and PEs. More specifically, the findings suggest that this relationship ceases to be significant when resilience is high, thus advocating the role of resilience in trauma and how it can be protective against PEs in face of media exposure to collective trauma. In addition, the relationship between war-related media exposure and PEs severity was moderated by religiosity, suggesting that highly religious young adults may withstand the adverse psychological effect of war-related media exposure on psychotic symptoms better than those with low to moderate levels of religiosity. Overall, it can be suggested that war-related media exposure should be assessed and monitored on a regular basis in young individuals who experience psychotic symptoms, resilience-related factors that may be available should be identified, and timely resilience-based interventions can be considered for alleviating PEs among those heavily exposed to war coverage on media. Furthermore, the current results suggest a possible importance of high religiosity in buffering the association between early war-related media exposure and the severity of PEs. This is especially of relevance in Arab settings, where religion has a significant influence on both public and private lives and has consistently been found to play a protective role in the occurrence of mental health problems. All these findings hold the promise of enriching the epidemiological landscape of media exposure to mass violence and PEs pathogenesis within the growing context of conflicts and wars. More intensive research efforts in this area are needed and might be of paramount importance from a public health perspective for early intervention and prevention.

S4. SOCIAL RESPONSIVENESS IN FAMILIES WITH PARENTAL SCHIZOPHRENIA OR BIPOLAR DISORDER – THE DANISH HIGH RISK AND RESILIENCE STUDY

Background: Individuals with schizophrenia or bipolar disorder exhibit social impairments, and their partners display poorer functioning and more psychopathology. However, nonrandom mating and transmission of social abilities from parents to their children remain under-investigated. Therefore, we aimed to examine social responsiveness in families with parental schizophrenia or bipolar disorder.

Methods: The Danish High Risk and Resilience Study – VIA 11 is a nationwide cohort study consisting of 11-year-old children with at least one parent diagnosed with schizophrenia (n = 179) or bipolar disorder (n = 105) and population-based controls (PBC, n = 181). Children and both parents were assessed with The Social Responsiveness Scale, Second Edition (SRS-2). Parents completed the SRS-2 Adult Self-report Form, and the SRS-2 School-Age Form was completed by the teacher who knew the child best in school settings. Duration of time each parent and child have lived together until age 11 was ascertained through interviews.

Results: Parents with schizophrenia and parents bipolar disorder exhibited poorer social responsiveness compared with PBC parents. Parents with schizophrenia displayed poorer social responsiveness compared with parents with bipolar disorder. Co-parents to parents with schizophrenia exhibited poorer social responsiveness compared with co-parents to parents with bipolar disorder and PBC parents. We found significant positive associations between parents'

and children's social responsiveness in all groups, with no interaction effect of duration of time living together.

Discussion: This study is the first to investigate social responsiveness in families with parental schizophrenia or bipolar disorder compared with PBC. Offspring of parents with schizophrenia or bipolar disorder are more likely to be exposed to poor social responsiveness. However, this appears to be more pronounced in families with parental schizophrenia where both parents display poorer social responsiveness. Furthermore, social responsiveness was positively associated between parents and children, irrespectively of familial high-risk status. The familial transmission of social responsiveness presumably occurs due to both genetic factors. Considering that social impairments are suggested as a vulnerability marker, this knowledge calls for increased attention towards vulnerable families, particularly those where both parents have social impairments. More research in the field is warranted, and future studies should aim at applying various measures capturing different aspects of social impairment.

S5. WHAT COULD HELP PREVENT PSYCHOSIS IN ADOLESCENTS WITH CANNABIS USE DISORDER? PRELIMINARY RESULTS FROM THE RESCATE STUDY

Inmaculada Baeza^{*1}, Daniel Ilzarbe², María Moya³, Juan Ignacio Mena⁴, Patricia Camprodon-Boadas⁵, Gisela Sugranyes⁶, Elena De la Serna⁷

¹Hospital Clinic de Barcelona, ²Department of Child and Adolescent Psychiatry, Institute of Neuroscience, Hospital Clinic de Barcelona, CIBERSAM, ³Child and Adolescent Psychiatry and Psychology department, FCRB-IDIBAPS, ⁴Psychiatry and Psychology department, Hospital Clinic de Barcelona, ⁵Fundacio Clinic per la Recerca Biomèdica-IDIBAPS, ⁶IDIBAPS (August Pi i Sunyer Biomedical Research Institute) / Hospital Clínic Barcelona, CIBERSAM, ⁷Centro De Investigación Biomédica En Red De Salud Mental, CIBERSAM

Background: Cannabis use disorder has been associated with the onset of psychotic symptoms, and earlier age at onset of use could be linked to earlier development of the prodromal psychotic symptoms (Dragt et al, 2010; Mustonen et al, 2018). A recent systematic review of risk and protective factors of negative consequences of cannabis use (Grigsby et al, 2023) did not found studies about the role of cognitive reserve or diet.

The objective of this study is to assess in a sample of adolescents who fulfil criteria for cannabis use disorder the role of cognitive reserve and adherence to Mediterranean diet in prodromal psychotic symptoms.

Methods: This is cross-sectional study of adolescents attending a mental health outpatient clinic with a specialized unit for substance use disorders. A clinical, cognitive and neuroimaging assessment is performed as well as drug urine analysis. The CORE-A (Camprodon-Boadas et al, in press) was used to assess cognitive reserve and the KIDMED questionnaire (Serra-Majem et al, 2004) to evaluate adherence to Mediterranean diet.

Results: 20 patients were included, with a mean age of 16.5±0.9 years and 50% girls. Mean positive and negative prodromal symptoms according to SOPS scale were 4.1±4.1 and 6.4±3.2, respectively, with a mean GAF score of 64.2±13. The mean adherence to Mediterranean diet was moderate (5.2±2.4), with a score on cognitive reserve below the cut-off point (33.6±9.4). Moreover, there was a significant correlation of negative SOPS score and adherence to Mediterranean diet ($R=-0.656$, $p=0.008$) and a tendency between positive SOPS score and

adherence to Mediterranean diet ($R=-0.507$, $p=0.054$). Nevertheless, CORE-A score was not significantly correlated with any SOPS subscale or total score.

Discussion: Adherence to mediterranean diet could have a role mediating prodromal psychotic symptoms in adolescents with cannabis use disorders. The association between cannabis and psychosis and the harmful effects of cannabinoids in adolescents (Solmi et al, 2023) requires studying protective factors to try to decrease negative consequences of cannabis use in young populations.

This study has been funded by the Spanish Ministry of Health (National Drugs Plan, 2022I053).

S6. THE ROLE OF ENVIRONMENTAL FACTORS ASSOCIATED WITH DIET IN CHILDREN AND ADOLESCENTS AT PSYCHOSIS RISK: RESULTS FROM THE CAPRIS STUDY

Inmaculada Baeza^{*1}, Elena De la Serna², Daniel Ilzarbe³, Gisela Sugranyes⁴, Olga Puig-Navarro⁵, Ana Meseguer⁶, Adriana Fortea⁷, Jordina Tor⁸, Daniel Muñoz-Samons⁸, Marta Rodríguez-Pascual⁸, Xavier Álvarez-Subiela⁸, Montserrat Dolz⁹

¹Hospital Clinic de Barcelona, ²Centro De Investigación Biomédica En Red De Salud Mental, CIBERSAM, ³Department of Child and Adolescent Psychiatry, Institute of Neuroscience, Hospital Clinic de Barcelona, ⁴Instituto de Investigaciones Biomedicas de Barcelona, CSIC-IDIBAPS-CIBERSAM, ⁵Department of Child and Adolescent Psychiatry and Psychology, Hospital Clinic of Barcelona, , ⁶Barcelona Clinic Schizophrenia Unit (BCSU). Neurosciences Institute. Hospital Clinic of Barcelona. CIBERSAM, Barcelona, Spain, ⁷Department of Child and Adolescent Psychiatry, Hospital Clinic / Fundació Clinic per la la Recerca Biomèdica (FCRB) / Universitat de Barcelona, ⁸Hospital Sant Joan de Déu, Barcelona, ⁹Hospital Sant Joan de Déu

Background: Environmental factors such as poor diet and low vitamin intake have been associated with schizophrenia and first-episode of psychosis (Aucoin et al, 2020), but research in subjects at psychosis risk is scarce (Provenzani et al, 2023). In children and adolescents with psychosis risk syndrome (PRS, also named clinical high risk) there are no studies about the role of adherence to Mediterranean diet (AMD) as well as vitamin B12 and folate levels.

The objective of this study was to assess serum vitamin B12 and folate levels as well as AMD in children and adolescents with PRS and healthy controls (HC).

Methods: An 18-month prospective longitudinal study (CAPRIS) in which help-seeking minors meeting PRS criteria were recruited from two hospitals in Barcelona, Spain. A sample of HCs were also included. At baseline, the Semistructured Interview for Prodromal Syndromes and Scale (SIPS/SOPS) were administered, as well as a clinical scale battery. The KIDMED questionnaire (Serra-Majem et al, 2004) was used to evaluate MDA. This scale consists of 16 yes/no questions. Three categories of adherence (good, average and poor) were defined according to scores that were ≥ 8 , 4-7, and ≤ 3 . Serum B12 and folate levels were measured.

Results: 90 PRS subjects and 95 HC were included. No differences were found on age (15.2 ± 1.6 vs 15.3 ± 1.8 years) but there were more girls in the PRS group (76.7 vs 57%, $\chi^2 = 7.825$, $p=0.027$). Sex was use as a covariate in the statistical analyses.

50.8% of PRS subjects vs 25.9% of HC had a folate insufficiency ($\chi^2_{29, 290}$, $p=0.003$) while 18.9 of PRS vs 6.4% of HC had a B12 insufficiency ($\chi^2_{25.433}$, $p=0.027$).

Related to AMD, mean scores were 5.6 ± 3 in PRS subjects vs 7.1 ± 2.1 in HC ($F=15.318$, p LESS THAN 0.001). Also, 22.6% of PRS participants vs 5.1% of HC had a low AMD while 35.8 vs 57.7% of the same groups were in the high AMD category ($\chi^2=11.159$, $p=0.004$). There was a significant lower correlation between the total KIDMED scores and the total SOPS scores ($R=0.391$, p LESS THAN 0.001), as well as with all the SOPS subscales.

Discussion: B12 and folate insufficiency as well as a low AMD are associated with PRS children and adolescents compared to HC. The role of these vitamins and MD should be taken into account in assessing this young population as well as in the possible interventions to decrease psychopathology.

This study has been funded by Instituto de Salud Carlos III (ISCIII) through the projects PI21/00391 and PI21/0009, and co-funded by the European Union.

S7. THE EFFECT OF SARS-COV-2 VIRUS ON RESTING-STATE FUNCTIONAL CONNECTIVITY DURING ADOLESCENCE: INVESTIGATING BRAIN CORRELATES OF PSYCHOTIC-LIKE EXPERIENCES AND SARS-COV-2 RELATED INFLAMMATION RESPONSE

Helin Yılmaz Kafalı*¹, Hacer Dasgin², Didenur Sahin², Sara Sinem Sozan³, Kader K. Oguz², Muge Mutlu⁴, Aslinur Ozkaya Parlakay⁵, Timothea Touloupoulo⁶

¹Işık University, ²National Magnetic Resonance Research Center (UMRAM), ³Ankara Social Sciences University, ⁴Ankara City Hospital, ⁵Ankara City Hospital, ⁶Bilkent University,

Background: We first aimed to investigate resting-state functional connectivity (rs-FC) differences between adolescents exposed to SARS-CoV-2 and healthy controls. Secondly, considering the possible association between psychotic-like experiences (PLEs) and the SARS-CoV-2, the moderator effect of PLEs on group differences in rs-FC was examined. Thirdly, brain correlates of inflammation response during acute SARS-CoV-2 infection were investigated.

Methods: Eighty-two participants aged between 14-24 years (SARS-CoV-2 ($n=35$), controls ($n=47$)) were examined using rs-fMRI. Seed-based rs-FC analysis was performed. The positive subscale of the Community Assessment of Psychotic Experiences-42 (CAPE-Pos) was used to measure PLEs.

Results: The SARS-CoV-2 group had a lesser rs-FC within sensorimotor network (SMN, left precentral gyrus), central executive network (CEN, the right precentral gyrus), and language network (LN, left supramarginal gyrus, left angular gyrus); but an increased rs-FC within visual network (VN, left superior and middle frontal gyrus) compared to controls. No significant differences were detected between the groups regarding CAPE-Pos scores. However, including CAPE-Pos as a covariate, we found an increased rs-FC within CEN and SN in SARS-CoV-2 compared to controls. Among the SARS-CoV-2 group, neutrophil/lymphocyte and thrombocyte*neutrophil/lymphocyte ratio was correlated with decreased/increased FC within DMN and SN, and increased FC within CEN.

Discussion: This cross-sectional study showed rs-FC alterations within the SMN, CEN, LN, and VN among adolescents exposed to SARS-CoV-2. Moreover, changes in rs-FC associated with PLEs existed in these adolescents, in spite of the absence of clinical changes. Furthermore, inflammation response was correlated with alterations in FC within the triple network system.

S8. THE ASSOCIATION BETWEEN AUTISM AND PSYCHOSIS AND THE TOOLS USED TO MEASURE IT

Michael Miles*¹, Emma Palmer-Cooper¹, Dennis Golm¹

¹*University of Southampton*

Background: Recent research has found that autistic individuals are at an increased risk of experiencing psychosis and are more likely to receive diagnosis of a psychotic disorder. It has been proposed, and there is some evidence to suggest, that autistic individuals may struggle to interpret the intended meaning of questions pertaining to psychosis due to a propensity to interpret language hyper-literally, possibly leading to false-positive responses. If the strength of the association between these two conditions were to vary significantly depending on the measure used to assess it, this difference may be explained by the literality of the language used. This study, therefore, aimed to meta-analyse data examining this comorbidity, and to examine whether the measures used to assess it moderate the strength of the association.

Methods: A systematic review and three meta-analyses were conducted. The first analysis examined data from correlational studies that used trait score measures to assess both conditions within general population samples. The second examined data from studies that compared comorbidity rates of the two conditions to general population prevalence data. The third examined whether diagnosis of either condition was associated with an increased trait score of the other, compared to general population samples. For each of these, moderation analyses were then conducted on the measures of assessment used.

Results: Preliminary results for all three analyses revealed a significant positive effect between the two conditions. The first analysis found that the effect between total autism and psychosis symptomology ($z = .483$, 95% CI = 0.404 - 0.561, p LESS THAN .0001, $k = 22$) was moderated by the psychosis questionnaire used, with three of the ten measures producing significantly lower effects. Data for each of these moderating measures were, however, limited. Sub-analyses found a large effect between overall autistic symptomology and negative psychosis traits ($z = .584$, 95% CI = 0.505 - 0.664, p LESS THAN .0001, $k = 20$), and lower, yet still significant effects, were found for both positive ($z = .273$, 95% CI = 0.224 - 0.322, p LESS THAN .0001, $k = 28$) and disorganized psychosis traits ($z = .376$, 95% CI = 0.319 - 0.433, p LESS THAN .0001, $k = 16$). No moderating effect of measure used was found, however, for any of these sub-analyses. The second analysis found autistic individuals were over twice as likely to receive a diagnosis of a psychotic disorder (LogOR = 2.201, 95% CI = 1.646 - 2.755, p = LESS THAN .001, $k = 17$) compared to the general population. The third analysis found that diagnosis of one condition was associated with an increased trait score of the other, compared to the general population (SMD = 1.184, 95% CI = 0.995-1.372, p = LESS THAN .0001, $k = 11$). No moderating effect of measures or methods used was found for the second or third analyses, but again, data for each measure or method used was limited.

Discussion: These findings add further evidence to the association between autism and psychosis. Due to limited data, however, reliable conclusions regarding the moderating effect of measures and methods used are difficult to draw. Results of the sub-analyses of the correlational data may suggest that the association between autistic and psychosis trait scores are largely due to the shared negative symptomology between the two conditions. Due to limited data, we were not able to perform similar sub-analyses for the second and third analyses. Future research should investigate further how autistic individuals interpret questions regarding psychosis, to ensure that these measures of assessment are truly capturing psychotic symptomology.

S9. GENETIC EVIDENCE FOR ASSOCIATION BETWEEN ESTROGEN AND AGE AT ONSET IN FEMALES WITH SCHIZOPHRENIA: A PRELIMINARY EMPIRICAL STUDY USING POLYGENIC RISK SCORES

Na Zhan^{*1}, Justin Tubbs², Yuanxin Zhong¹, Perry Bok Man Leung¹, Tomy C.K. Hui¹, Karen K.Y. Ho¹, Karen S.Y. Hung¹, Eric F.C. Cheung¹, Hon-Cheong So³, Pak C. Sham¹, Simon S. Y. Lui¹

¹The University of Hong Kong, ²Massachusetts General Hospital, ³The Chinese University of Hong Kong

Background: Estrogen may have protective effects on liability for schizophrenia, as evidenced by the bimodal distribution of age at onset (AAO) in female patients, with the second peak during the post-menopausal period, compared with the unimodal distribution in male patients. It is plausible that the age of menarche and the age of menopause reflect an individual's cumulative exposure to endogenous estrogen. Evidence also suggests that early-onset schizophrenia in females is associated with older age of menarche, and delayed puberty in males is associated with more severe prodromal symptoms. However, genetic evidence regarding the relationship between estrogen, puberty, and AAO in schizophrenia is scarce.

Methods: We recruited a cohort of 302 female and 255 male schizophrenia patients from outpatient clinics. DNA samples and AAO information were collected from each participant. Genotyping was performed using the Illumina Asian Screening Array. We constructed the polygenic risk scores (PRS) of the phenotypes of age of menarche and age of menopause for each participant, based on the summary statistics of two large-scale Genome-Wide Association Studies (GWAS), and a higher PRS is indicative of a later age of onset. We then examined the association between schizophrenia AAO and the PRS of age of menarche in all patients, the inclusion of males was informed by previous research suggesting a significant overlap in the genetic architecture of age of menarche in females and age of voice breaking in males, so age of menarche was used as a proxy for puberty timing here in both genders. The first five genetic principal components and gender were included as covariates in the linear regression model. The correlation between schizophrenia AAO and the PRS of age of menopause was conducted exclusively in female patients.

Results: In our cohort, we observed a positive association between gender and the AAO of schizophrenia, indicating that females have a significantly later AAO than males ($p < 0.01$). Conversely, the PRS for the age of menarche was negatively associated with schizophrenia AAO ($p < 0.05$). Using a threshold of $p = 0.1$, the PRS for age of menarche and gender collectively explained 2.82% of the variance in AAO ($p < 0.01$). In subgroup analysis, a trend was observed across the three groups: early-onset female patients ($AAO \leq 18$) exhibited the highest PRS (mean = 0.084) for the age of menarche, while late-onset female patients ($AAO > 40$) showed the lowest PRS (mean = -0.192). Furthermore, the PRS for age of menopause was negatively associated with AAO in female patients ($p < 0.05$). In subgroup analysis, a significant difference was detected, suggesting that late-onset schizophrenia female patients had the lowest PRS (mean = -0.337) for age of menopause, whereas the early-onset schizophrenia group had the highest PRS (mean = 0.149).

Discussion: Our findings provide preliminary genetic evidence that later menarche is associated with early-onset ($AAO \leq 18$) schizophrenia, and earlier menopause is associated with late-onset ($AAO > 40$) schizophrenia. Our results are consistent with previous epidemiological findings, supporting the protective effects of estrogen against

schizophrenia in females. Interestingly, the association between later puberty timing and earlier AAO also exists in our male sample. However, our findings should be interpreted with caution due to our small sample size. Future research should verify our findings, and investigate how the reproductive hormones could influence mood, behavior, and cognition through various pathways.

S10. FAMILY FUNCTIONING IN FAMILIES WITH 11-YEAR-OLD CHILDREN OF PARENTS WITH SCHIZOPHRENIA OR BIPOLAR DISORDER AND POPULATION-BASED CONTROLS – THE DANISH HIGH RISK AND RESILIENCE STUDY

Nicoline Hemager*¹, Ida Gjøde², Maja Gregersen³, Julie Brandt⁴, Anne Søndergaard³, Mette Falkenberg Krantz⁵, Lotte Vedum⁶, Christina Bruun Knudsen⁷, Anna Krogh Andreasen⁷, Ole Mors⁸, Merete Nordentoft⁹, Aja Greve¹⁰, Anne Amalie Elgaard Thorup²

¹Research Unit of Mental Health Centre Copenhagen at Gentofte University Hospital; Mental Health Services in the Capital Region of Denmark, ²Child and Adolescent Mental Health Center, Capital Region of Denmark, ³CORE - Copenhagen Research Centre for Mental Health, Mental Health Services in the Capital Region of Denmark, Mental Health Centre Copenhagen, ⁴Copenhagen Research Center for Mental Health - CORE, ⁵CORE- Copenhagen Research Centre for Mental Health, Mental Health Center Copenhagen, Capital Region of Denmark, Copenhagen University Hospital University of Copenhagen – Faculty of Health and Medical Services The Lundbeck Foundation Initiative for Integrative Psychiatric Research, ⁶Psychosis Research Unit, Aarhus University Hospital - Psychiatry; The Lundbeck Foundation Initiative for Integrative Psychiatric Research - iPSYCH; Department of Clinical Medicine, Faculty of Health and Medical Sciences, Aarhus University, ⁷Psychosis Research Unit, Aarhus University Hospital - Psychiatry; The Lundbeck Foundation Initiative for Integrative Psychiatric Research - iPSYCH; Aarhus University, ⁸Psychosis Research Unit, Aarhus University Hospital, Risskov, Denmark, ⁹CORE- Copenhagen Research Centre for Mental Health, Mental Health Center Copenhagen, Capital Region of Denmark, Copenhagen University Hospital, University of Copenhagen – Faculty of Health and Medical Services, The Lundbeck Foundation Initiative for Integrative Psychiatric Research, ¹⁰Psychosis Research Unit, Aarhus University Hospital Psychiatry

Background: Childhood family dysfunction is a predictor of psychosis and affective disorders in adult life and poor emotional family climate is associated with psychopathology in children in the background population. Being born to a parent with schizophrenia or bipolar disorder is a major risk factor for developing the same disorder as the parent as well as other mental disorders. Investigating the complex interaction of environmental and genetic risk factors is important to understand the shared and distinct aetiology of these disorders and to inform preventive interventions. However, evidence regarding family functioning in families with parental severe mental disorders is sparse. Therefore, we aimed to examine family functioning in the families of preadolescent children at familial high-risk of schizophrenia or bipolar disorder.

Methods: This population-based cohort study of 11-year-old children included 160 families with parental schizophrenia, 95 families with parental bipolar disorder, and 176 control families. Family functioning was measured with the 12-item version of the McMaster Family

Adjustment Device – General Functional Scale reported by the primary caregiver. The primary caregivers' social functioning was measured with the Personal and Social Performance Scale, whereas the offspring's global functioning was measured with the Children's Global Assessment Scale. Offspring problem behavior was measured with the Child Behavior Checklist School-Age Version.

Results: Families with parental schizophrenia and bipolar disorder demonstrated significantly poorer family functioning than control families. Also, a significantly higher proportion of the families with parental schizophrenia and parental bipolar disorder demonstrated levels of family dysfunction that were clinically significant compared with controls. Family functioning in the two high risk groups did not differ from each other. Preliminary analyses suggest that poorer family functioning was related to poorer social functioning of the primary caregiver and higher levels of offspring dimensional psychopathology in all study groups but only with poorer global functioning in the offspring with parental bipolar disorder.

Discussion: Preadolescent children at familial high-risk of schizophrenia and bipolar disorder have not only an increased risk of developing a severe mental disorder but also an increased risk of living in dysfunctional families. The interaction of both genetic and environmental risk factors in these preadolescent children in families with parental schizophrenia or bipolar disorder warrant early detection and may inform future intervention studies and programs.

S11. EYE MOVEMENTS AND EYE STRUCTURE IN CLINICAL HIGH RISK FOR PSYCHOSIS

Cemal Demirlek*¹, Merve Ekin², Merve S. Gurbuz³, Berna Yalincetin³, Ferdane Atas⁴, Koray Kocoglu³, Muge Akkoyun³, Hatice Eraslan-Boz³, Simge Uzman-Ozbek⁵, Mahmut Kaya⁶, Gulden Akdal⁷, Emre Bora⁵

¹*Institute of Health Sciences, Dokuz Eylul University,* ²*Institute of Psychology, SWPS University,* ³*Department of Neurosciences, Institute of Health Sciences, Dokuz Eylul University,* ⁴*Department of Ophthalmology, Cerkezkoy State Hospital,* ⁵*Department of Psychiatry, Dokuz Eylul University Medical School,* ⁶*Private Practice,* ⁷*Department of Neurology, Dokuz Eylul University Medical School*

Background: Eye movement and retinal abnormalities have been observed in chronic psychosis, and recent investigations have highlighted the presence of similar abnormalities in individuals at clinical high risk for psychosis (CHR-P). Accumulating research emphasizes the interconnected changes in both eye and brain anatomy and physiology in neuropsychiatric conditions, positioning the eye as a promising avenue for non-invasive exploration and biomarker development. This study utilizes antisaccade (AS), involving looking in the opposite direction of the target, and memory-guided saccade (MGS), characterized by maintaining fixation and recalling the target's location. The objective is to unravel the intricate interplay between eye movements and retinal structure in individuals at CHR-P, providing valuable biomarkers for psychosis.

Methods: The CHR-P criteria is ascertained through the Turkish version of the Structured Interview for Prodromal Syndromes (SIPS). The SIPS includes three UHR-P syndromes: Attenuated Psychosis Symptoms (APS), Brief Limited Intermittent Psychotic Symptoms (BLIPS), and Genetic Risk and Deterioration Syndrome (GRDS). To ensure a thorough clinical evaluation, all participants underwent interviews utilizing the Structured Clinical Interview for the DSM-IV Axis I Disorders (SCID-I). Ophthalmic imaging involved the application of

spectral-domain optical coherence tomography (OCT), was administered by an experienced ophthalmic technician using the Spectralis system (Heidelberg Engineering; Heidelberg, Germany). The total retinal thickness and volume were computed for all participants. Following OCT imaging, participants underwent eye movement recording using the EyeLink 1000-Plus eye-tracker. Assessment of AS-MGS (antisaccade - memory-guided saccade) involved measuring parameters such as correct saccades, anticipatory saccades, and peak velocity.

Results: This study included 23 individuals at risk for CHR-P. Saccadic peak velocity in AS was significantly associated with both total central retinal thickness ($p = 0.031$, $r=0.451$) and volume ($p = 0.038$, $r = 0.434$). The number of anticipatory saccades in MGS was significantly associated with both total central retinal thickness ($p = 0.039$, $r=0.433$) and volume ($p = 0.036$, $r = 0.440$). The number of anticipatory saccades in MGS was significantly associated with both total central retinal thickness ($p = 0.019$, $r=0.486$) and volume ($p = 0.012$, $r = 0.515$). The correct saccades in AS and saccadic peak velocity in both paradigms were not significantly associated with the central retinal macular thickness or volume in individuals at CHR-P.

Discussion: To our knowledge, this is the first study to identify relationship between eye movements and retinal structure in individuals at CHR-P. The significant associations found between antisaccade (AS) and memory-guided saccade (MGS) parameters with retinal thickness and volume offer a compelling case for the eye as a non-invasive window into neuropsychiatric conditions. This suggests a potential underlying neurophysiological mechanism that links retinal structure to the efficiency of eye movements. The significant association found with anticipatory saccades in MGS further emphasizes the intricate relationship between eye movement control and retinal structural integrity. The eye's accessibility and the non-invasive nature of the techniques used suggest a promising potential for these biomarkers in clinical settings.

S12. ASSOCIATION BETWEEN PROCESSING SPEED AND RETINAL THICKNESS IN ULTRA-HIGH RISK FOR PSYCHOSIS

Cemal Demirlek^{*1}, Merve S. Gurbuz², Berna Yalincetin², Ezgi Cesim², Muhammed Demir², Burcu Verim², Ferdane Atas³, Simge Uzman-Ozbek⁴, Ekin Sut⁵, Burak Baykara⁵, Berna B. Akdede⁴, Mahmut Kaya⁶, Emre Bora⁴

¹*Institute of Health Sciences, Dokuz Eylul University*, ²*Department of Neurosciences, Institute of Health Sciences, Dokuz Eylul University*, ³*Department of Ophthalmology, Cerkezko State Hospital*, ⁴*Department of Psychiatry, Dokuz Eylul University Medical School*, ⁵*Department of Child and Adolescent Psychiatry, Dokuz Eylul University Medical School*, ⁶*Private Practice*

Background: Both neurocognitive impairments and retinal abnormalities represent important facets of psychosis, with recent investigations shedding light on the presence of cognitive deficits in young individuals at ultra-high risk for psychosis (UHR-P) seeking assistance. Notably, impairments in processing speed, memory, and executive functions have been identified in this population. Emerging research underscores parallel changes in both retinal and cerebral anatomy and physiology in neuropsychiatric conditions, presenting the retina as a promising avenue for non-invasive exploration and the development of biomarkers. Additionally, retinal abnormalities have been linked to the severity of psychotic symptoms and cognitive dysfunction in individuals with chronic schizophrenia. This study aims to unravel the

intricate interplay between cognitive functions and retinal thickness in individuals at UHR-P, offering valuable insights into the pathophysiology of neuropsychiatric diseases.

Methods: Participants seeking help were required to fulfill the UHR-P criteria as determined by the Turkish version of the Structured Interview for Prodromal Syndromes (SIPS). The SIPS encompasses three UHR-P syndromes: Attenuated Psychosis Symptoms (APS), Brief Limited Intermittent Psychotic Symptoms (BLIPS), and Genetic Risk and Deterioration Syndrome (GRDS). To ensure comprehensive clinical evaluation, all participants underwent interviews using the Structured Clinical Interview for the DSM-IV Axis I Disorders (SCID-I). Ophthalmic imaging involved the use of spectral-domain optical coherence tomography (OCT) conducted by an experienced ophthalmic technician employing the Spectralis system (Heidelberg Engineering; Heidelberg, Germany). While OCT images were obtained for both eyes of each participant, analysis focused solely on the right eye to prevent any potential bias. The central macular thickness was computed for all participants. Prior to OCT imaging, participants underwent an assessment of premorbid abilities utilizing either the Wechsler Intelligence Scale for Children-R (WISC-R) or the Wechsler Adult Intelligence Scale-R (WAIS-R) information subtests. Processing speed was gauged using the Digit Symbol Substitution Test (DSST), and visual memory (both immediate and delayed recall) was evaluated using the Visual Reproduction Test. Executive functions were scrutinized through the Wisconsin Card Sorting Test (WCST) and the Stroop Color and Word Test. Outcome variables included the number of categories completed and perseverative errors from the WCST, along with the Stroop interference score and Stroop error score.

Results: This study included 34 individuals at UHR-P. UHR-P group consists of 8 individuals with BLIPS, 22 individuals with APS, 5 individuals with GRD. The central retinal macular thickness was positively correlated with Stroop interference score ($p = 0.019$, $r = 0.413$) and DSST score ($p = 0.002$, $r = 0.525$). Additionally, the other cognitive domains were not significantly associated with the central retinal macular thickness in individuals at UHR-P.

Discussion: The findings of this study elucidate a significant association between processing speed, as measured by the Digit Symbol Substitution Test (DSST), and central retinal macular thickness in individuals at ultra-high risk for psychosis (UHR-P). The positive correlation between DSST scores and central retinal macular thickness implies that increased processing speed is associated with increased retinal thickness. Furthermore, the positive correlation between Stroop interference scores and central retinal macular thickness suggests that greater retinal thickness may be linked to higher cognitive interference, a hallmark of executive dysfunction. These relationships underscore the potential of retinal imaging as a non-invasive biomarker for identifying neurocognitive impairments in UHR-P individuals. However, it is noteworthy that other cognitive domains did not show a significant association with retinal thickness.

S13. CHOROIDAL VASCULARITY INDEX IN CLINICAL HIGH-RISK FOR PSYCHOSIS

Cemal Demirlek^{*1}, Ferdane Atas², Berna Yalincetin³, Burak Baykara⁴, Berna Akdede⁵, Mahmut Kaya⁶, Emre Bora⁵

¹*Institute of Health Sciences, Dokuz Eylul University,* ²*Department of Ophthalmology, Cerkezoy State Hospital,* ³*Department of Neuroscience, Dokuz Eylul University,* ⁴*Department of Child and Adolescent Psychiatry, Dokuz Eylul University Medical School,* ⁵*Department of Psychiatry, Dokuz Eylul University Medical School,* ⁶*Private Practice*

Background: The eye is recognized as a component of the central nervous system and is often referred to as a gateway to the brain. The eye, along with its microvascular system, exhibits numerous shared features with the brain in both anatomy and pathophysiology. Anomalies associated with the choroid and retina have been observed in psychotic disorders, particularly in cases of schizophrenia. The Choroidal Vascularity Index (CVI) serves as a valuable tool for evaluating structural changes in the choroid, defined as the ratio of luminal area (LA) to the total choroidal area (TCA).

Methods: This study marks the inaugural investigation into the choroidal vascularity index among individuals at clinical high risk for psychosis (CHR-P), employing optical coherence tomography (OCT). Thirty-two patients at CHR-P and 30 age and gender-matched healthy controls (HC) included in this study. Each participant underwent clinical evaluations in psychiatry and ophthalmology. Choroidal imaging was conducted utilizing the enhanced deep imaging (EDI) protocol through spectral domain OCT. Central choroidal thickness (CCT) was manually measured with EDI-OCT, from the inner border of the sclera to the outer border of the retinal pigment epithelium (RPE), using the calipers of the Heidelberg reader positioned subfoveally. The choroidal vascularity index was evaluated based on the EDI-OCT images.

Results: The CCT measurement was $374.08 \pm 72.82 \mu\text{m}$ in CHR-P and $355.20 \pm 46.37 \mu\text{m}$ in HCs ($p > 0.05$). CVI was $63.66 \pm 2.83\%$ and $61.30 \pm 1.81\%$ in CHR-P and HCs groups, respectively ($p = 0.002$). CVI was $63.63 \pm 3.67\%$, $63.60 \pm 2.63\%$, $64.02 \pm 3.06\%$ in the brief limited intermittent psychotic symptoms syndrome (BLIPS), the attenuated psychosis symptoms syndrome (APS), the genetic risk and functional decline prodromal syndrome (GRD) subgroups of CHR-P, respectively, and it was not statistically different ($p = 0.96$).

Discussion: These findings indicate that prodromal psychosis is marked by irregularities in choroidal vasculature. The use of in vivo ophthalmological imaging through OCT, a non-intrusive, rapid, and secure technological method, holds promise as a potential biomarker for the quantitative assessment of microvasculature abnormalities in individuals experiencing prodromal psychosis.

S14. LEVELS OF STIMULATION AND SUPPORT PROVIDED AT HOME, STRESSFUL AND TRAUMATIC LIFE EVENTS, AND RISK OF PSYCHOPATHOLOGY AMONG PREADOLESCENT CHILDREN OF PARENTS WITH SCHIZOPHRENIA OR BIPOLAR DISORDER

Background: It is well-established that children of parents with schizophrenia or bipolar disorder are at increased risk of having the same disorder as their parent as well as increased risk of developing other mental disorders. Causes are presumed to include gene-environment interactions through epigenetic mechanisms. Childhood adversity is also a risk factor for mental disorder. Childhood adversity can be subdivided into at least two subdimensions; adversity related to deprivation, meaning the lack of factors expected to be present in the rearing environment and which support healthy development, and adversity related to threat, meaning the presence of factors which the child perceives as a severe stressor, or threat, to its life conditions. Previous studies have indicated that childhood adversity related to the deprivation dimension such as living in a home environment with little stimulation and support increases risk of psychopathology including psychotic disorder among children at risk of severe mental disorder. Concerning the threat dimension, experiencing stressful or traumatic life events has in general population, and high risk, studies been shown to increase risk of later psychopathology, especially psychotic disorder. The prevalence of childhood adversity is higher among children of parents with severe mental disorder compared to controls. Combined with their genetic risk, children of parents with schizophrenia or bipolar disorder thus face an accumulation of risk factors for mental disorder. Knowledge concerning subcategories and combined effects of these types of adversity is needed to identify children at high risk of developing mental disorders including psychotic disorders. We therefore aim to examine how adversity risk factors related to deprivation and threat moderate risk of mental disorder and psychotic experiences among children at familial high risk of schizophrenia or bipolar disorder. We hypothesize that both dimensions of adversity increase risk respectively, and that this risk is further increased when combined.

Methods: In a nationwide population-based cohort study of 522 same-aged children of parents with schizophrenia or bipolar disorder and population-based controls, levels of stimulation and support provided at home was assessed with the semi-structured, age-appropriate at-home interviews MC-HOME at age 7 and EA-HOME at age 11. Stressful life events were assessed through anamnestic interviews with parents at age 7. Child psychopathology and trauma exposure was assessed at age 7 and 11 with the Schedule for Affective Disorders and Schizophrenia for school-age children – present and lifetime version (K-SADS-PL).

Results: Preliminary results will be presented.

Discussion: Knowledge concerning specific risk factors and possible cumulative risks of the social environment of children at familial high risk of schizophrenia or bipolar disorder is needed to inform preventive mental health interventions targeting the rearing environment. Evidence informing future interventions is lacking, although this group of children is

substantial in size, identifiable in health systems, and at increased risk of developing mental disorder which is a major human and economic burden.

S15. CLINICAL AND NEUROCOGNITIVE PROFILES OF A COMBINED CLINICAL HIGH RISK FOR PSYCHOSIS AND CLINICAL CONTROL SAMPLE: A LATENT CLASS ANALYSIS

Miriam Stübke¹, Frauke Schultze-Lutter², Michael Kaess³, Franscini Maurizia⁴, Nina Traber-Walker⁵, Petra Walger⁶, Benno G. Schimmelmann⁷, Kai Vogeley⁸, Joseph Kambeitz⁹, Jochen Kindler¹⁰, Chantal Michel^{*1}

¹University Hospital of Child and Adolescent Psychiatry and Psychotherapy, ²Heinrich-Heine University Düsseldorf, ³Department of Child and Adolescent Psychiatry, Center for Psychosocial Medicine, University Hospital Heidelberg, Germany., ⁴University Hospital of Psychiatry/University of Zurich, ⁵Psychiatric University Hospital Zurich, ⁶University Hospital of Child and Adolescent Psychiatry and Psychotherapy, Cologne, Germany, ⁷University of Bern, University Hospital of Child and Adolescent Psychiatry and Psychotherapy, ⁸Department of Psychiatry and Psychotherapy, University of Cologne, Germany, ⁹Department of Psychiatry, University of Cologne, Germany, ¹⁰University Hospital of Child and Adolescent Psychiatry, University of Bern

Background: The clinical high-risk (CHR) state for psychosis demonstrates considerable clinical heterogeneity, presenting challenges for clinicians and researchers alike. Basic symptoms (BS), to date, have largely been ignored in explorations of clinical profiles. Therefore, we examined clinical profiles using a broader spectrum of CHR symptoms including not only (attenuated) psychotic symptoms but also BS.

Methods: CHR patients (N=875) of early intervention centers in Germany and Switzerland were assessed using the Schizophrenia Proneness Instruments and the Structured Interview for Psychosis-Risk Syndromes. Latent Class Analysis was applied to CHR symptoms to identify clinical profiles. Additionally, demographic, other symptoms, current non-psychotic DSM-IV axis I disorders and neurocognitive variables were assessed to further describe and compare the profiles.

Results: A three-class model was best fitting the data (BIC: 11517.68; AIC: 11236.01; entropy: 0.871), whereby BS (e.g., disturbance of receptive speech: eta square=0.52, p GREATER THAN 0.001; thought perseveration: eta square=0.47, p GREATER THAN 0.001) best differentiated between the profiles. Class 1 (n=523) had a low probability of CHR symptoms, highest functioning and lowest other psychopathology, neurocognitive deficits and transition-to-psychosis rate (1.3%). Class 2 (n=97) had the highest probability of BS and (attenuated) positive symptoms but hallucinations, lowest functioning and the highest symptom load, most neurocognitive deficits and highest transition rate (55.1%). Class 3 (n=255) was mostly characterized by attenuated hallucination and otherwise intermediate between the other two classes (transition rate: 19.6%). Comorbidity rates were comparable across classes with some class differences in diagnostic categories.

Discussion: Our profiles based on BS and (attenuated) psychotic symptoms provide clinically useful entities by parsing out heterogeneity in clinical presentation. In future they also might guide class-specific intervention.

S16. AUDITORY PREDICTIVE CODING DURING A ROVING STANDARD MISMATCH NEGATIVITY PARADIGM IN YOUTH AT CLINICAL HIGH-RISK FOR PSYCHOSIS: RESULTS FROM NAPLS-3

Holly Hamilton*¹, Jessica Hua², Spero Nicholas³, Brian Roach³, Aysenil Belger⁴, Ricardo Carrion⁵, Erica Duncan⁶, Jason Johannesen⁷, Matcheri Keshevan⁸, Sandra Loo⁹, Margaret Niznikiewicz¹⁰, Jean Addington¹¹, Carrie Bearden⁹, Kristin Cadenhead¹², Tyrone Cannon⁷, Barbara Cornblatt⁵, Thomas McGlashan⁷, Diana Perkins⁴, William Stone⁸, Ming Tsuang¹², Elaine Walker⁶, Scott Woods⁷, Daniel Mathalon¹³

¹University of Minnesota/Minneapolis VA Health Care System, ²University of California, San Francisco/San Francisco Veterans Affairs Health Care System, ³San Francisco VA Health Care System, ⁴University of North Carolina, ⁵Zucker Hillside Hospital, ⁶Emory University, ⁷Yale University, ⁸Harvard Medical School / Beth Israel Deaconess Medical Center, ⁹University of California, Los Angeles, ¹⁰Harvard Medical School, ¹¹University of Calgary, ¹²University of California, San Diego, ¹³University of California, San Francisco/San Francisco VA Health Care System

Background: Identifying prognostic biomarkers may improve clinical outcome prediction and clarify mechanisms associated with psychosis onset. Several studies suggest that reduced mismatch negativity (MMN) event-related potential (ERP) component amplitude is associated with greater likelihood of future psychosis onset among individuals at clinical high-risk for psychosis (CHR-P). According to predictive coding models, the MMN is a prediction error signal elicited when a deviant sound violates the prediction that a frequent standard sound will recur, with successive standard repetitions strengthening this prediction. Consistent with this framework, successive standards presented during MMN paradigms produce a progressively increasing repetition positivity (RP) thought to reflect strengthening of the memory trace for the standard. Likewise, deviant tones preceded by a longer series of standard repetitions elicit a larger negativity (i.e., deviant negativity; DN), reflecting a stronger prediction error signal. Parsing these components of MMN is optimally achieved using a “roving standard” paradigm, in which a series of standard tone repetitions are followed by a deviant tone that becomes the new standard stimulus. However, no studies have separately examined these components during a roving standard paradigm in CHR-P individuals to determine if deficits in specific aspects of predictive coding underlying MMN generation are risk factors for psychosis.

Methods: Baseline EEG data were collected during a roving standard MMN paradigm from 710 CHR-P and 96 healthy comparison (HC) participants as part of NAPLS-3. Participants were followed for two years, and those who developed psychosis (CHR-Converters) were compared with those who continued to meet CHR-P criteria (CHR-Persisters) and those who remitted from the CHR-P syndrome (CHR-Remitters). ERP amplitudes to increasing standard stimulus repetitions (RP), immediately subsequent deviants (DN), the corresponding MMN deviant-standard difference wave, and the “traditional” MMN averaged over trials regardless of the number of preceding standards were measured. Analyses were completed in the full sample and in a subset of CHR-P (n=559) who were not taking antipsychotics at baseline.

Results: In an initial analysis of 589 CHR-P and 89 HC, both CHR-P and HC showed significant memory trace effects. For DN and MMN, amplitudes were greater when deviants were preceded by longer trains of standards (33 GREATER THAN 8 GREATER THAN 3; ps LESS THAN .001). For RP, amplitudes increased with standard stimulus repetitions (ps LESS THAN .001). Similar effects were evident for MMN, DN, and RP (ps LESS THAN .001)

across outcome groups. These main effects of task and lack of association with outcomes were evident in the full and unmedicated samples. Differences between outcome groups were present for the DN in the unmedicated subsample only ($p=.03$), with future CHR-Remitters showing greater DN amplitudes across standard stimulus repetitions relative to future CHR-Converters ($p=.01$). The traditional MMN amplitude did not differ between CHR-P and HC in the full or unmedicated sample (p s GREATER THAN .05). In the unmedicated subsample only, however, there was an effect of outcome on the traditional MMN ($p=.03$), such that future CHR-Remitters had greater amplitudes than future CHR-Converters ($p=.04$) and CHR-Persisters ($p=.01$).

Discussion: CHR-P individuals, regardless of future outcomes and medication status, show similar RP, DN, and MMN memory trace effects to HC, suggesting intact predictive code formation and maintenance. However, greater DN and traditional MMN amplitudes among future CHR-Remitters relative to CHR-Converters in the unmedicated subsample suggests the integrity of prediction error signaling may be sensitive to future CHR-P outcomes.

S17. DISRUPTION OF ULTRASONIC VOCALISATION BOUT SEQUENCES IN A RAT MODEL OF SCHIZOPHRENIA RISK

Kieran Scott^{*1}, Lucinda J. Speers², David K. Bilkey¹

¹*University of Otago*, ²*Grenoble Institut de Neurosciences, Inserm*

Background: Timing and sequencing is disrupted in schizophrenia. This could reflect disruption in underlying brain mechanisms and may underlie the disorganisation that is a major symptom dimension in the disorder. Disorganisation symptoms, such as loose associations and illogicality, are strongly related to negative social and vocational outcomes, and to treatment resistance. Thus, understanding how the underlying brain mechanisms are disturbed is an important goal in the search for treatment options. In our lab we have investigated the sequential structure of ~50 kHz ultrasonic vocalizations (USVs) that rats use to communicate. USV structure may be an indicator of the integrity of sequencing mechanisms, and thus, a marker of the effectiveness of potential treatments in preclinical models. We have previously studied USV call structure in rats exposed to Maternal Immune Activation (MIA), a risk factor for schizophrenia in humans. We found changes to transition probabilities between individual USV calls in MIA rats, which may be due to disruptions in sequencing mechanisms. However, vocalizations tend to occur in a series of calls, termed a bout. These bouts have a non-random sequential structure and may be a more meaningful communicative unit than single vocalizations. Thus, we hypothesised that bout structure would be disturbed in MIA rats.

Methods: We recorded USVs in control and MIA rats in two different conditions where animal pairs were able to communicate without physical contact. In the paired animal paradigm, we recorded from 25 control rats, and 27 MIA rats. In our reward paradigm, we recorded from 18 control rats, and 20 MIA rats. The machine learning program VocalMAT was used to detect and categorise. Bouts were then identified as call sequences with less than two seconds between individual calls. Bout structure was analysed using a Levenshtein distance analysis, which generates a measure of the similarity between two sequences, with a higher score indicating greater similarity. To these ends, we calculated set median string candidates for each dataset and group. These candidates were then analysed for similarity with the bout pool using a Levenshtein similarity index (LSI), which normalised for bout length. The candidate with the highest mean LSI was selected, and then compared with the other group set median, and against the other group bout pool. Significance was assessed using Mann-Whitney U tests.

Results: In our paired animal paradigm we recorded 638 bouts from control rats ($\bar{x} = 24.5 \pm 4$), and 570 bouts from MIA rats ($\bar{x} = 25 \pm 3.4$). Bouts from control rats had greater similarity ($\bar{x} = 0.31 \pm .008$) to their set median string when compared to MIA bouts ($\bar{x} = 0.28 \pm .008$; $p < .0001$), indicating greater bout variability in the MIA group. Consistent with this, we also found that the MIA set median was less distant to control bouts ($\bar{x} = 0.32 \pm .008$), than to MIA bouts ($\bar{x} = 0.32 \pm .008$; $p = .005$). In our reward paradigm, we recorded 785 bouts from control rats ($\bar{x} = 42.6 \pm 4.1$), and 942 bouts from MIA rats ($\bar{x} = 46.1 \pm 3.5$). As previously, bouts from control rats had a greater similarity to their set median ($\bar{x} = 0.21 \pm .006$), relative to MIA bouts ($\bar{x} = 0.18 \pm .005$; $p = .0007$). Again, we also found the MIA set median was less distant to control bouts ($\bar{x} = 0.21 \pm .006$), than to MIA bouts ($\bar{x} = 0.18 \pm .005$; $p = .004$).

Discussion: In summary, these findings indicate that there is greater variance in USV bout composition in MIA rats compared to control animals, suggesting a disruption in the mechanisms that control USV sequencing. If this reflects broader sequencing problems in MIA rats then it may provide a useful marker of disorganization that can be used in preclinical studies aimed at finding novel treatments for this characteristic of schizophrenia.

S18. THE ASSOCIATION BETWEEN ATTENTION DEFICIT HYPERACTIVITY DISORDER SYMPTOMS AND ATTENUATED PSYCHOTIC SYMPTOMS IN A GENERAL ADULT POPULATION

Rachel Reeves^{*1}, Ciaran Shannon², Donncha Hanna³, Ryan McIlwaine², Julie-Ann Jordan², Adrian Boyd², Ciaran Mulholland³

¹Impact Research Centre Northern Health and Social Care Trust, ²IMPACT Research Centre, Northern Health and Social Care Trust, ³Queens University Belfast

Background: Attention Deficit Hyperactivity Disorder (ADHD) is a highly prevalent neurodevelopmental disorder. There is a recognised symptomatic overlap between symptoms of ADHD and attenuated psychotic symptoms, yet there is a dearth of research exploring the association between these two conditions. The study aimed to investigate this association and to determine whether ADHD symptoms made a unique contribution in predicting attenuated psychotic symptoms whilst examining and controlling for Adverse Childhood Experiences (ACES), depression and anxiety.

Methods: Amazon's online crowdsourcing service Mechanical Turk (MTurk) was used to conduct an online survey of a US-based general population. 1052 adults (18-38) completed the Adverse Childhood Experiences Questionnaire (ACE-Q), the Prodromal Questionnaire (PQ-16), the Patient Health Questionnaire 9 (PHQ-9), the Generalised Anxiety Disorder 7 (GAD-7) and the Adult ADHD Self-Report Scale (ASRS). Multiple regression analysis explored the predictors of PQ-16 total score.

Results: The average total PQ-16 score was 4.67 out of a possible 16, average ACE-Q score was 2.21 out of a potential 10, average PHQ-9 score was 7.26 out of a possible 27 and average GAD-7 score was 6.75 out of a possible 21. The final regression model, which combined ACES, anxiety, depression and ADHD explained 49.7% of the variance in relation to the total number of items endorsed on the PQ-16. ACES, depression, and ADHD subscales of impulsive motor and impulsive behavioural were significant predictors of PQ-16 total score; anxiety and the ADHD subscale of inattention were not. After controlling for ACES, anxiety and depression, ADHD symptoms made a unique contribution of 7.5% of the variance in PQ-16 total score.

Discussion: The results demonstrate the association between ADHD and attenuated psychotic symptoms in the general population. Impulsive behavioural and motor were important predictive factors, yet exploration of this association has been neglected to date. Future research should consider exploring this association and investigating the possible mechanisms through which impulsivity predicts attenuated psychotic symptoms. A greater understanding of these mechanisms and the symptomatic overlap between ADHD and attenuated psychotic symptoms may aid clinical decision making, diagnostic procedures and early intervention.

S19. DEPERSONALIZATION AND SELF-DISTURBANCE IN INDIVIDUALS AT RISK FOR PSYCHOSIS

Julia Lebovitz^{*1}, Katrina Rbeiz¹, Sohee Park¹

¹*Vanderbilt University*

Background: Self-disturbance is central to schizophrenia (Hur et al., 2013), but less is known about anomalous self-experiences in relation to psychosis-risk. Individuals at risk for psychosis report poor self-concept clarity (Cowan et al., 2023), anomalous embodiment (Torregrossa et al., 2023), porous self-boundary (Benson and Park, 2019), depersonalization (Büetiger et al., 2020) and basic self-disturbances (Nelson et al., 2012). However, the role of depersonalization in psychosis-risk has not been systematically investigated even though it is a common feature of schizophrenia (Černis, 2022). We examined aberrant self-experiences (depersonalization, body disturbance and interoceptive impairment) in relation to psychosis-risk. Furthermore, we assessed loneliness and trauma history, which have been shown to increase psychosis risk (Steenkamp et al., 2022).

Methods: 232 adults (mean age =33.7; 129 women) completed a web-based survey which included measures of psychosis risk (Prodromal Questionnaire-16; PQ-16), depersonalization (Černis Felt Sense of Anomaly Scale; CFSA), interoception (Multidimensional Assessment of Interoceptive Awareness; MAIA), and bodily self-disturbances (Body Disturbances Inventory; B-BODI). In addition, a measure of loneliness (UCLA Loneliness Scale; UCLA) and trauma (Brief Trauma Questionnaire; BTQ) were included to assess social adversity. Psychosis risk was defined using the PQ-16; the low-risk group (LR) scored below 6, and the high-risk group (HR) scored 6 or above (Ising et al., 2012).

Results: There were 64 HR and 168 LR participants. 107 (46%) had received a prior psychiatric diagnosis. There were no group differences in age or sex. Depersonalization and self-disturbances were clearly elevated in HR. Both FSA ($F(1,229) = 9.477$ p LESS THAN .001) and B-BODI ($F(1,229) = 13.173$, p LESS THAN .001) scores were higher in HR than LR. While the MAIA total score was approaching significance ($p=.056$), there were significant differences in the MAIA subscales: not distracting (p LESS THAN .001), not worrying (p LESS THAN .05), and emotional awareness (p LESS THAN .05). The HR group also reported elevated UCLA ($F(1,229) = 5.425$, p LESS THAN .001) and BTQ scores ($F(1,229) = 4.703$, p LESS THAN .001). Separate logistical regression models revealed that CFSA total, (OR=1.06, p LESS THAN .001), B-BODI total (OR=1.76, p LESS THAN .011), MAIA Not Distracting (OR=1.08, p LESS THAN .001), MAIA Not Worrying, (OR=1.12, p LESS THAN 0.01), and MAIA Emotional Awareness (OR=1.11, p LESS THAN 0.01) predicated psychosis HR when controlling for loneliness and trauma history.

Discussion: Depersonalization, bodily self-disturbances, and some aspects of altered interoception were present at higher rates in HR. Although social adversity was also elevated in HR, core symptoms of self-disturbance remained significant after controlling for loneliness

and trauma. Despite the importance of depersonalization, body disturbance, and interoception schizophrenia, they are not routinely assessed in prodromal studies. The results of the present study support the notion of investigating self-disturbances as a risk factor for psychosis and incorporating clinical interventions focused on self-disturbances.

S20. THE ASSOCIATION BETWEEN ADVERSE AND BENEVOLENT CHILDHOOD EXPERIENCES ON ATTENUATED PSYCHOTIC EXPERIENCES USING THE PRODROMAL QUESTIONNAIRE-16 (PQ-16) IN A STRATIFIED YOUTH POPULATION

Ciaran Shannon^{*1}, Joshua Kearns², Clare Howie¹, Mark Shevlin³, Gavin Davidson², Lisa Bunting², Julie Cameron⁴, Anne Grant², Orla McBride³, Claire McCartan¹, Jamie Murphy³, Emma Nolan³, Dirk Schubotz², Ciaran Mulholland²

¹IMPACT Research Centre, Northern Health and Social Care Trust, ²Queen's University Belfast, ³Ulster University, ⁴Mental Health Foundation

Background: There has been a wealth of research published on the negative impact of adverse childhood experiences on the development of mental health disorders, including psychosis and the at-risk mental state. In contrast, less work has been conducted on the protection that may be offered by benevolent childhood experiences. Benevolent childhood experiences are the antithesis to childhood adversity and refers to positive early life experiences, including support, security, predictability and safety. This study aimed to examine the association between adverse and benevolent childhood experiences and attenuated psychotic symptoms in a youth population sample.

Methods: Participants were recruited as part of the Northern Ireland Youth Wellbeing Survey (n=541; mean age = 14.56), a stratified random household survey. Participants completed the Prodromal Questionnaire-16 (PQ-16), Adverse Childhood Experiences Questionnaire (ACES-Q) and the Benevolent Childhood Experiences questionnaire (BCE-Q), as well as demographic information and questions on Troubles-related exposure to paramilitaries. Three separate hierarchical multiple regression analyses were ran, each with four models, to determine predictors for total PQ-16 score, PQ-16 Hallucinations score and PQ-16 General Unusual Experiences score.

Results: The average total PQ-16 score was 2.36 out of a possible 16, average ACE score was 0.73 out of a potential 10 and average BCE score was 7.86 out of a possible 10. For total PQ-16 score, the final regression model indicated that urban/rural living, higher ACE Abuse/Neglect score, higher ACE Household dysfunction score and lower BCE total score were significant predictors of PQ-16 score. For PQ-16 Hallucination score, the final model indicated that higher ACE Abuse/Neglect score and higher ACE Household dysfunction score were significant predictors of rating this subscale. For PQ-16 General Unusual Experiences score, the final model indicated that higher ACE Neglect score, higher ACE household dysfunction score and lower BCE total score were significant predictors of subscale scoring.

Discussion: This study supports previous evidence of the association between childhood adversity and attenuated psychotic symptoms, including hallucinations. It also highlights that an increasing number of benevolent childhood experiences predict a lower number of attenuated psychotic symptoms. These findings can provide potential factors to be aware of when conducting screening of psychotic symptoms in general population settings and also help develop strategies for early intervention.

S21. A LONGITUDINAL MRI STUDY OF RECENT STRESSFUL LIFE EVENTS AND GREY MATTER VOLUME IN INDIVIDUALS AT CLINICAL-HIGH RISK FOR PSYCHOSIS

Cheryl See*¹, Emily P. Hedges¹, Stefania Tognin², Gemma Modinos¹, Mark van der Gaag³, Lieuwe De Haan⁴, Patrick D. McGorry⁵, Barnaby Nelson⁵, Anita Riecher-Rössler⁶, Rodrigo Bressan⁷, Neus Barrantes Vidal⁸, Marie-Odile Krebs⁹, Merete Nordentoft¹⁰, Stephan Ruhrmann¹¹, Gabriele Sachs¹², Bart P. Rutten¹³, Jim Van Os¹³, Gareth J. Barker¹, EU-GEI High Risk Study¹⁴, Steven Williams¹, Philip McGuire¹, Lucia R. Valmaggia¹, Matthew J. Kempton¹

¹King's College London, ²King's College London, ³VU University Amsterdam, ⁴AMC, University of Amsterdam, ⁵University of Melbourne, ⁶University of Basel, ⁷Universidade Federal de Sao Paulo - UNIFESP, ⁸Universitat Autònoma de Barcelona, Spain, ⁹University Paris Cité - INSERM, ¹⁰Mental Health Centre Copenhagen, ¹¹University Hospital - University of Cologne, ¹²Medical University of Vienna, ¹³Maastricht University Medical Centre, ¹⁴EU-GEI High Risk Study

Background: Meta-analytical evidence has confirmed that recent stressful life events (SLEs) are associated with the onset of psychosis, but the related neural mechanisms remain unclear. The present study aims to investigate whether recent SLEs may be associated with smaller grey matter volumes (GMV) observed in the clinical high-risk (CHR) state for psychosis. To our knowledge, there are only two CHR studies that have examined this relationship; both studies focused only on pituitary volumes and neither found a significant association. In healthy adults, six studies found significant reductions in prefrontal cortex and hippocampal volumes associated with recent SLEs, suggesting these areas may represent a vulnerability to stress. By understanding the neural correlates of recent SLEs in CHR individuals, we can better understand how stress is involved in the development of psychosis. In the current study, we have examined if brain volumes in CHR individuals were negatively associated with recent SLEs using a longitudinal dataset.

Methods: 218 CHR individuals between the ages of 15-45 years were recruited through the EU-GEI high risk study from Europe, Australia, and Brazil. 45 participants transitioned to psychosis. T1-weighted images and clinical data were obtained for up to four timepoints over a 24-month period. The List of Threatening Experiences (LTE) questionnaire measured SLEs from 12-months prior and was quantified as the LTE score at each timepoint. A linear mixed model was used to analyse the effects of recent SLEs on changes in GMV over time. LTE score, time, and the interaction term LTE score $\times$ time were included as fixed effects, with site and participant as random effects. Separate models were fitted for six a priori brain regions: 1) total GMV; 2) hippocampus; 3) anterior cingulate cortex (ACC); 4) orbitofrontal cortex (OFC); 5) amygdala; and 6) insula. All models were adjusted for sex and total intracranial volume. We further adjusted for childhood trauma as a potential confounder. We investigated whether sex or transition status (whether an individual transitioned to psychosis) affected the association between recent SLEs and brain volumes. The statistical significance level was set at two-tailed p LESS THAN 0.05, and a 5% false discovery rate correction was applied to adjust for multiple comparisons.

Results: The main effect of LTE score on GMV across all brain regions was not significant, indicating recent SLEs were not associated with changes in GMV. While total GMV, ACC,

and OFC volumes exhibited a significant reduction over time, the interaction term LTE score $\times$ time was not significant, suggesting SLEs did not affect the rate of reduction in GMV. Adjusting for childhood trauma did not affect the significance of the results. There were no significant effects on recent SLEs associated with changes in GMV due to sex or transition status. Sensitivity analyses to test for the effects of scanner model did not change the significance of the results.

Discussion: The results indicated the number of recent SLEs may not have a detectable effect on brain volumes in CHR individuals. The main strength of our study lies in the use of longitudinal data, which enabled us to model the trajectory of changes in GMV relating to recent SLEs. In addition, our sample was larger than those used in previous studies. It is possible the effects of recent SLEs on brain structure are only apparent in individuals who are closer to psychosis onset. As CHR samples are heterogeneous especially in terms of psychosis progression, such effects may be obscured in the current study. The results may also mean the number of events is not relevant to changes in GMV, but instead personal experience of the event could be more important. Future work could consider including subjective stress measures.

S22. EXPLORING COMPONENTS OF ANTICIPATORY PLEASURE AND THEIR IMPACT ON NEGATIVE SCHIZOTYPY AND SUICIDAL IDEATION

Rebecca Salzano*¹, Richard Linscott¹

¹*University of Otago*

Background: Negative schizotypy is a major risk factor for suicidal ideation. Deficiencies in anticipatory pleasure have been identified as a mediator of the relationship between the two constructs. Impairment in anticipatory pleasure encompasses various aspects, including a lack of positive beliefs about future experiences, expectations that future events will not cause pleasure, and reduced ability to mentally represent the value of future experiences. This research investigated these elements of pleasure capacity, exploring their contribution to the relationship between negative schizotypy and suicidal ideation.

Methods: Psychology undergraduates ($n = 335$) completed self-report assessments. These included measures of schizotypy (Brief Revised Updated version of the Schizotypal Personality Questionnaire, SPQ-BRU), dysfunctional beliefs (17-item Dysfunctional Attitudes Scale – Form A, DAS-A-17), expectancy appraisals (Success and Resource Appraisals Questionnaire, SARA-Q) reward valuation (Monetary Choice Questionnaire, MCQ), affective forecasting (Affective Forecasting Questionnaire, AFQ), and suicidal ideation (Columbia-Suicide Severity Rating Scale, C-SSRS). Probit regression was used to investigate whether variables of interest predicted suicidal ideation. A structural equation model with a probit link was tested to assess the mediating roles of expectancy appraisals, dysfunctional beliefs, reward valuation, and affective forecasting. Bias-corrected bootstrapped confidence intervals were used to assess statistical significance.

Results: Probit model results revealed positive effects of expectancy appraisals ($\beta_3 = .01$; 95% confidence interval = $[0.004, 0.026]$, $p = .01$) and perfectionism beliefs ($\beta_4 = .02$ $[0.005, 0.039]$, $p = .01$) on suicidal ideation. The significance of interpersonal schizotypy's association with suicidal ideation was borderline ($\beta_1 = .02$ $[.00, .05]$, $p = .05$). Social anxiety, valuation of future rewards, and affective forecasting were not significant predictors of suicidal ideation.

Interpersonal schizotypy (standardised beta $c1 = .14$; bootstrapped 95% confidence interval = [.08, .29]) and social anxiety ($c2 = .08$ [.03, .29]) had significant total relationships with suicidal ideation. Expectancy appraisals ($a1b1 = .034$ [.01, .07]) and perfectionism beliefs ($a1b2 = .029$ [.01, .07]) fully mediated both associations ($c1' = .07$ [-.004, .12]; $c2' = .02$ [-.04, .07]).

Discussion: Our findings suggested a stronger association of expectancy appraisals and perfectionism beliefs with suicidal ideation than interpersonal schizotypy and social anxiety. Further, these beliefs fully mediated the relationship between negative schizotypy and suicidal ideation. This suggests that beliefs about one's inability to experience pleasure in the future play a key role in the emergence of suicidal ideation among those with negative schizotypy. Addressing these beliefs may offer prevention and intervention strategies for this population.

S23. AN EXPLORATORY STUDY OF PSYCHOSIS RISK FACTORS IN INDIVIDUALS REFERRED BUT NOT MEETING CRITERIA FOR AN EARLY INTERVENTION IN PSYCHOSIS SERVICE

Sean Naughton^{*1}, Aoife Brady², Mary Clarke²

¹*DETECT, Early Intervention in Psychosis Service, Dublin*, ²*DETECT, Early Intervention in Psychosis Service, Dublin, Ireland*

Background: The 'at-risk mental state' (ARMS) for psychosis has been critiqued for its limited prognostic ability and low capacity to prospectively identify those who will develop a first episode of psychosis (FEP). Only a minority of individuals with an incident FEP will have presented to an ARMS service, even in areas where these are well established. Population based studies challenge the assumption that the ARMS model, as currently constructed, represents a universal, or even common entry point to psychosis. This has resulted ARMS services having a negligible effect on FEP incidence and outcomes overall.

Recent work has highlighted the importance of referral pathway and pre-test risk enrichment in ARMS studies. In addition 'clinical pathway risks,' which do not incorporate any specific test for psychotic symptoms, have demonstrated an ability to prospectively identify at-risk populations. Various factors outside of the current attenuated positive symptom model have been reported as important risk markers. Therefore, we hypothesise that those referred to an Early Intervention in Psychosis (EIP) service, but not meeting criteria for an ARMS or FEP remain enriched for psychosis risk factors, and may be an important group for further investigation. Broadening the search for groups at high-risk of psychosis is key to improving population-level ascertainment of psychosis risk.

The aim of the current study is to explore risk-enrichment in diagnostic, demographic and socio-functional domains amongst individuals referred to an EIP service but not meeting ARMS or FEP criteria. The second aim is to compare the demographic and functional markers of this cohort to a FEP cohort as a point of reference.

Methods: A retrospective file review was undertaken in an Irish EIP service of all referrals from its foundation in 2005, to the end of 2021, a sixteen year timespan. All individuals agreeable to review underwent a standardised clinical assessment, including the Structured Clinical Interview for DSM Disorders (SCID). Outcomes of specific DSM disorders met were reported for the 'not meeting criteria' cohort. Totals were compiled and also grouped in diagnostic categories. Demographic (age, gender, family history of psychosis, nationality) and

socio-occupational (relationship status, living status, working status) variables were compiled. The functional markers of the cohort were compared, in an adjusted model, with individuals diagnosed with a FEP during the same period.

Results: From 2005-2021 inclusive, there were 2025 completed index assessments. 27.6% (n=558) did not meet either FEP or ARMS criteria, notably higher than the 5.4% (n=110) meeting ARMS criteria. 60.9% (n=1233) met criteria for a FEP, and 6.1% (n=124) met criteria for a psychotic disorder, but not first episode. The relative proportion of each group varied over the study period. The 'not meeting criteria' group were enriched for non-psychotic psychiatric morbidity, with 65.4% (n=366) meeting criteria for at least one DSM Axis I disorder and 36.4% of those meeting criteria for more than one. The most common diagnostic groups met were substance use disorders, 22.5% (n=164), anxiety disorders, 22.2% (n=162) and depressive disorders, 20.4% (n=149). They were more likely than an FEP cohort to be younger (OR 0.97, CI 0.96-0.98) and male (OR 1.12, CI 1.03-1.71). They were less likely to be of non-Irish nationality (OR 0.85, CI 0.77-0.91). They had an equivalent proportion of family members with a psychotic disorder. They were less likely to be inpatients or undergoing involuntary treatment. Their functional markers were poor and broadly equivalent to a FEP cohort. On one indicator, long term unemployment (GREATER THAN 12 months), they were more impaired than an FEP cohort (adjusted OR 2.83, CI 1.65-4.85).

Discussion: This group is enriched for demographic, diagnostic and functional risk-factors for psychosis. The proportion of their non-psychotic psychiatric morbidity is consistent with what has been reported in ARMS samples, indicating that this characteristic is shared with other EIP service referrals. They are functioning poorly. This is both an important early risk factor, and indicates their high current need. They are a substantially larger group than those meeting ARMS criteria.

The potential significance of these findings is that those 'not meeting criteria' may represent an important, high capacity, risk-enriched population for psychosis. They are easily accessible as they are already in contact with both general adult and EIP services, despite the fact that they currently do not meet criteria for monitoring. In view of these findings, they should be an important focus for further study in the search for at-risk populations beyond the current ARMS model.

S24. ASSOCIATION BETWEEN PSYCHOPATHY TRAITS AND PSYCHOSIS LIKE EXPERIENCES IN A CLINICAL ADOLESCENT SAMPLE

Niklas Granö*¹

¹*Helsinki University Hospital, Department of Adolescent Psychiatry*

Background: Psychopathy and psychosis have been associated with dangerous behavior and hence, must often be assessed together for diagnostic reasons. However, little is known, how psychopathy traits and psychosis like experiences (PLEs) are associated in adolescent years in clinical populations at sub-diagnostic level. While psychopathy describes stable trait dimensions of personality, PLEs are more often dynamic symptoms and reactions to external factors, having multiple biological and psychological vulnerability factors in the background. It is important to understand how stable personality traits are associated with PLEs in the early years of development.

Methods: We assessed 88 adolescents (25 boys and 63 girls) between 13-18 years of age, who were entering psychiatric services at Helsinki University Hospital, Finland, with Youth

Psychopathy Inventory (YPI), Prodromal Questionnaire-Brief (PQ-B) and Beck Depression Inventory (BDI-21). Associations were analyzed between these self-report scales.

Results: Psychopathy sum score (YPI) correlated significantly with PLE (PQ-B) sum score (.366, $p < .001$). Of psychopathy subscales Lying (.346, $p < .001$), Impulsiveness (.410, $p < .001$) and Thrill-seeking (.319, $p = .002$), Remorselessness (.266, $p = .012$), Callousness (.217, $p = .042$) and Irresponsibility (.214, $p = .046$) correlated significantly with PLE sum score. In regression analysis psychopathy sum score explained significantly PLE sum score when age and gender were controlled for ($\beta = .403$, $p < .001$) and association remained significant ($\beta = .341$, $p < .001$) after adjusting regression model with depression sum score (BDI-21).

Discussion: In this study we found an association between psychopathy traits and psychosis like experiences. Association was found especially with some sub scales of psychopathy with PLEs. The association remained significant after adjusting the model with depression. Results suggest that psychopathy traits and PLEs can be discovered already at early stage on subclinical psychopathy dimensions in adolescent years and could be considered in preventive or psychiatric care of adolescents. More studies in the future are needed to explore mechanism between PLEs and psychopathy traits in adolescents.

S25. EYE MOVEMENTS IN THE GAZE PERCEPTION TASK: IMPLICIT SOCIAL COGNITIVE PROCESSING AND A POTENTIAL BIOMARKER FOR DETECTING CLINICAL HIGH RISK FOR PSYCHOSIS

Kam Hung Harry Tsui^{*1}, Janet Hsiao¹, Wing Chung Chang¹, Christy Lai Ming Hui¹, Ho Ming Edwin Lee¹, Eric Yu Hai Chen¹, Sherry Kit Wa Chan¹

¹*Department of Psychiatry, Li Ka Shing Faculty of Medicine, The University of Hong Kong*

Background: The early detection of individuals with at-risk mental states (ARMS) is crucial for initiating preventative interventions and improving long-term outcomes. While eye movement abnormalities have been well-established in schizophrenia, less is known in ARMS subjects, especially in response to social stimuli and gaze perception. This study aims to investigate the atypical eye movements in ARMS subjects and evaluate the potential of eye movement behaviors and the gaze perception task as an early detection method for psychosis risk.

Methods: Thirty-six help-seeking ARMS subjects were identified using the Comprehensive Assessment of At-Risk Mental States (CAARMS) and recruited from the psychiatric outpatient clinics at Queen Mary Hospital, Hong Kong. Fifty healthy controls without previous psychiatric history were recruited from the community.

A computerized gaze perception task was implemented with the eye-tracker method (Chan et al., 2021). The gaze perception task consists of 6 blocks with 30 trials of randomly selected stimuli of faces each. Subjects were asked to judge if the averted gaze with different levels of ambiguity (centre: 0° and 5°; ambiguous gaze: 10° and 15°; unambiguous gaze: 20°, 25° and 30°) were looking at themselves. Self-Referential Gaze Perception (SRGP) rates were calculated for each gaze condition. Fixations and saccades variables during the task were extracted. The group differences of eye movement variables and SRGP rates were assessed using ANCOVA controlling for age and gender. Linear Discriminant Analysis (LDA) was employed to identify the variables best differentiating between ARMS and HC. LDA models were constructed based on SRGP rates, eye movement variables, and a combination of both.

Results: Our results revealed significant differences in eye movement variables between ARMS and control subjects. ARMS had a larger total number of fixation than HC ($F = 18.035$, $p = 0.001$); the duration of fixation in HC was longer than those in ARMS ($F = 8.202$, $p = 0.005$). In terms of saccadic movements, FEP and ARMS had a trend of greater saccade amplitude than HC ($F = 2.888$, $p = 0.093$); and ARMS had a significantly higher velocity of saccade than HC ($F = 4.858$, $p = 0.030$). Also, ARMS exhibited significantly higher ambiguous ($F = 27.409$, $p \text{ LESS THAN } 0.001$) and unambiguous SRGP rates ($F = 14.508$, $p \text{ LESS THAN } 0.001$) than HC. For the ARMS and HC classifications, the LDA model using only SRGP rates exhibited a very good AUC-ROC (0.824, 95% CI: 0.735– 0.913), while the model using only eye movement variables had a good AUC-ROC of 0.781 (95% CI: 0.682– 0.879) (Table X). The model combining both SRGP rates and eye movement variables performed the best with a very good to excellent AUC-ROC of 0.893 (95% CI: 0.825 – 0.962), which was significantly better than the models with only SRGP ($Z = 2.145$, $p = 0.032$) and only eye movement variables ($Z = 2.402$, $p = 0.016$).

Discussion: Our findings indicated that ARMS individuals exhibited erratic and rapid eye movements and distinct SRGP during the gaze perception compared to healthy controls. The combined model, incorporating eye movement and behavioral data, demonstrated superior classification performance, indicating that a multidimensional approach may be more effective for differentiation. This study revealed the eye movement abnormalities in the ARMS population during the gaze perception task, shedding light on their potential utility in the early identification of psychosis risk. Further research is warranted to validate these findings in larger and more diverse samples, and to explore the underlying mechanisms of these observed differences.

S26. AT-RISK MENTAL STATES CONVERSIONS THROUGH NON-VERBAL VARIABLES: LOOKING AT MOVEMENT ABNORMALITIES AS A POSSIBLE INDICATOR

Ana Lopes Rocha^{*1}, Willian Henrique de Paula Ramos², Felipe Argolo¹, Anderson Ara³, João Medrado Gondim⁴, Natalia Mansur Haddad¹, Lucas Hortêncio¹, Leonardo Peroni¹, Julio Cesar Andrade¹, Mauricio Henriques Serpa⁵, Guillermo Cecchi⁶, Cheryl Corcoran⁷, Martinus Theodorus van de Bilt¹, Wagner Gattaz¹, Natalia Mota⁸, Alexandre Andrade Loch¹

¹*Institute of Psychiatry, Laboratory of Neuroscience (LIM 27), University of Sao Paulo, Brazil,*
²*Statistics Department, Federal University of Paraná, Curitiba, PR, Brazil,* ³*Department of Statistics, Federal University of Paraná, Curitiba-PR, Brazil,* ⁴*Federal University of Bahia,*
⁵*Institute of Psychiatry, Laboratory of Psychiatric Neuroimaging (LIM 21), University of Sao Paulo, Brazil,* ⁶*IBM Research,* ⁷*Icahn School of Medicine At Mount Sinai,* ⁸*Federal University of Rio de Janeiro*

Background: Movement abnormalities are commonly seen in schizophrenia spectrum disorders. They affect social interaction interfering in the amount of movement and in the use of expressive gestures, contributing to the blunted affect observed in those individuals. Furthermore, these deficits appear not only to be present in the prodromal stages, called at-risk mental states (ARMS), but also to be indicators of conversion to a psychiatric disorder. In the first stage of the study, we found a reduced movement and increase erraticism in ARMS when compared with healthy control individuals. No differences in gesticulation were observed. Here our aim was to use these variables collected in previous studies to verify, after follow-up, if

there is a difference between ARMS individuals who converted to a psychiatric diagnosis and those who did not.

Methods: In the initial sample formed by fifty-six ARMS and sixty-nine healthy controls, subjects were recorded while performing two speech tasks: the Structured Interview for Prodromal Syndromes (SIPS) subject's overview (SO), and a memory report paradigm (MR) based on the recall of a recent dream, an old dream and memory reports based on positively affective pictures. Data was submitted to an automated motion energy analysis (MEA) software where the variables mean amplitude, frequency, and coefficient of variability of head and torso were obtained. Also, frequency of self-stimulating movements and four gestures categories—iconic, metaphoric, beats and deictic—were manually coded. After a mean of 30 months of follow-up, 27 subjects did not develop a psychiatric disorder (control group), 8 ARMS subjects developed a psychotic syndrome (Psychotic group) and 24 ARMS subjects developed other DSM-5 disorders, what we will refer as General Disorders group.

Results: Kruskal-Wallis test was used to analyze differences between control, psychotic and General Disorders group. No differences were observed for MEA mean amplitude or any category of gesticulation and self-stimulatory movement. However, during the SO video, frequency of torso movement and coefficient of variability for both regions presented significant differences, with Dwass-Steel-Critchlow-Fligner (DSCF) multiple comparisons analysis showing that the General Disorders group presented lower frequency ($W=3.41$, $p=0.042$) compared with the Psychotic group and higher coefficient of variability compared with both the Psychotic group (Head: $W=-4.09$, $p=0.011$; Torso: $W=-4.84$, $p < 0.002$) and controls (Head: $W=-4.09$, $p=0.011$; Torso: $W=-4.31$, $p=0.007$).

Discussion: These results are consistent with our hypothesis that movement behavior differences would be observed after conversion of ARMS individuals. However, contrary to what we expected, the greatest difference was observed between the conversion's groups and not with controls. This finding showed that considering risk states as a single group can lead to the loss of important information. Furthermore, the importance of looking at conversion beyond psychosis and for the possibility of using variables obtained through more naturalistic ways, such as movement during speech.

S27. BIOMARKERS OF NEGATIVE SYMPTOMS IN ULTRA-HIGH-RISK FOR PSYCHOSIS INDIVIDUALS

Amelia Ang^{*1}, Marko Milicevic², Alison Yung², Stephen Wood³, Luba Sominsky²

¹Deakin University, ²Deakin University, ³Orygen, the National Centre of Excellence in Youth Mental Health

Background: Negative symptoms are difficult to treat and cause marked disability in schizophrenia. The underlying causes of negative symptoms are still unclear. There are several lines of evidence linking disturbances in oxidative stress and inflammation to negative symptoms in people with schizophrenia. However, further research is needed especially in the early stages of schizophrenia. The Ultra-high risk (UHR) state identifies individuals at high risk of schizophrenia and could be conceptualised as the earliest detectable stage of schizophrenia. Some studies have shown that alterations in inflammation and oxidative stress are evident in UHR individuals, but what is unknown is whether these processes are associated with negative symptoms in the UHR group. This project will examine:

- 1) if disturbances in oxidative and inflammatory biomarkers can be detected early in UHR individuals.
- 2) whether these processes are associated with negative symptoms in UHR individuals.

Methods: A systematic review was conducted to determine the presence of oxidative stress and inflammation in UHR individuals, and to determine its association to negative symptoms. A comprehensive search strategy was used to search Medline, PsycINFO and Embase. Studies of any design and setting were included if they discuss about topics on altered inflammatory or oxidative stress processes in UHR individuals. Articles were screened by two reviewers independently for inclusion. Relevant data will be extracted according to the pre-determined criteria, and study quality will be assessed using Covidence's quality assessment and data extraction template. Key findings from included studies will be synthesized in narrative form according to the Guidance on the Conduct of Narrative Synthesis in Systematic Reviews.

Results: The database search yielded 878 results. After the removal of 480 duplicates, 398 articles were imported into Covidence for screening. Preliminary results to date suggests that elevated levels of inflammatory and oxidative markers are observed in UHR individuals, but it did not allow the confirmation of our hypothesis that there is a link between negative symptoms and inflammatory/oxidative stress processes.

Discussion: This study will provide important information on oxidative stress and inflammation in UHR which is crucial for the development of therapeutic interventions and for preventative measures to be put in place. It is anticipated that findings from this study will be relevant to clinical and community services and provide the necessary groundwork for future studies to be built on.

S28. CLINICAL HIGH RISK STATE FOR PSYCHOSIS: CLINICAL, NEUROCOGNITIVE AND REDOX PHENOTYPING

Martine Cleusix^{*1}, Elodie Sprungli-Toffel¹, Caroline Conchon¹, Alessandra Solida², Kerstin von Plessen³, Marco Armando³, Kim Q Do⁴, Philippe Conus¹, Paul Klauser⁵, Ines Khadimallah⁴, Luis Alameda¹

¹*Service of General Psychiatry, Department of Psychiatry, Lausanne University Hospital and the University of Lausanne,* ²*Department of Adult Psychiatry, Neuchâtel Psychiatric Center,* ³*Service of Child and Adolescent Psychiatry, Department of Psychiatry, Lausanne University Hospital and the University of Lausanne,* ⁴*Center for Psychiatric Neuroscience, Department of Psychiatry, Lausanne University Hospital and the University of Lausanne,* ⁵*Center for Psychiatric Neuroscience and Service of Child and Adolescent Psychiatry, Department of Psychiatry, Lausanne University Hospital*

Background: The Clinical High Risk state for psychosis (CHR-P) concept was implemented to promote the early detection of help-seeking youth with emerging symptoms of psychosis. Because of a drop in the reported proportion of conversion to psychosis in those with CHR-P in the latest years, other clinical phenotypes that reflect the poor trajectories of the CHR-P patients need to be identified. We aimed to: 1) Identify subgroups of patients with CHR-P with principal components analysis (PCA) using psychopathological and cognitive domains as profiling criteria and examine their clinical, functional and cognitive characteristics, as well as biological profile in terms of markers involved in the oxidative stress pathway; 2) Explore the

validity of the proposed stratification by examining the clinical and functional trajectory over a period of 2 years.

Methods: A total of 55 young help-seeking patients aged 14 to 30 were referred by health care providers for a specialized evaluation in case of suspicion of a prodromal psychotic state. They all met CHR-P criteria according to the Structured Interview for Prodromal Syndromes (SIPS) and/or the Comprehensive Assessment of At-Risk Mental States (CAARMS). Individuals included in the study performed an extensive psychopathological assessment, neuropsychological battery and blood test for redox markers (Glutathione Peroxidase (GPx) and Glutathione Reductase (GR) activities). Based on their clinical and cognitive profile, we made a stratification of the patients using PCA.

Results: Cognitive and psychopathological outcome stratification revealed two subgroups of CHR-P patients with distinct profiles. At baseline, individuals in Group 1 showed a poorer profile with weaker self-esteem, lower autonomy and lower cognitive scores compared to Group 2. Analysis of redox markers revealed a positive correlation between GPx and GR activities (which is a marker of good redox regulation) in Group 2, a correlation disrupted in Group 1 (which has previously been associated with poor clinical outcomes in several studies). The poorer clinical profile in Group 1 remained the same or even worsened at 24 months of follow-up, whilst the clinical trajectory of patients in Group 2 tended to stabilize or improve.

Discussion: Our stratification appears to be a promising option to categorize CHR-P patients with distinctive clinical and biological vulnerability. Validation of these groups in larger cohorts is warranted.

S29. PREDICTING CLOZAPINE INITIATION AMONG PATIENTS WITH SCHIZOPHRENIA USING MACHINE LEARNING ON ELECTRONIC HEALTH RECORD DATA

Erik Perfalk^{*1}, Jakob Grøhn Damgaard¹, Andreas Aalkjaer Danielsen¹, Søren Dinesen Østergaard¹

¹*Department of Affective Disorders, Aarhus University Hospital—Psychiatry, Aarhus, Denmark*

Background: Clozapine is the optimal treatment of treatment-resistant schizophrenia, which affects a quarter of patients with schizophrenia. However, initiation of clozapine treatment is often unduly delayed. If it was possible to predict which patients that ultimately would be prescribed clozapine, the delay in treatment initiation could potentially be reduced, leading to a better prognosis for patients with schizophrenia.

We aimed to develop and subsequently validate a prediction model for clozapine initiation at the level of the individual patient by training machine learning models on routinely collected electronic health record (EHR) data.

Methods: EHR data from patients diagnosed with schizophrenia in the Psychiatric Services of the Central Denmark Region in the period from 2016-2021 will be retrieved. From this dataset, we will derive potential predictors from both structured data (covering e.g., prior diagnoses, medication, and number of hospital contacts) and from EHR descriptions of patients in free text (by means of term frequency – inverse document frequency and sentence transformers). At inpatient- and outpatient hospital contact, we will aim to predict clozapine initiation 12 months ahead using machine learning. Elastic Net regularized logistic regression- and

XGBoost models will be trained on 85% of the dataset after which the best performing model will be tested on the remaining 15% of the data.

Results: The study is in progress. The results will be presented at the conference.

Discussion: If a machine learning model trained on routinely collected EHR data can accurately predict initiation of clozapine, it may be implemented as a clinical decision support tool for earlier identification of patients in need of clozapine treatment.

S30. THE IMPACT OF THE SLEEP-WAKE CYCLE ON COGNITION IN INDIVIDUALS WITH SCHIZOPHRENIA

Bruna Assis¹, Raffael Massuda², Joao Vinicius Salgado¹, Joao Salgado*³

¹*Universidade Federal de Minas Gerais*, ²*Universidade Federal do Parana - Brazil*, ³*Federal University of Minas Gerais*

Background: Schizophrenia is associated with sleep disturbances in up to 80% of cases, indicating numerous circadian rhythm alterations (Chan et al., 2017; Cung et al., 2018). Insomnia is the most frequent sleep disorder in schizophrenia (Kaskie et al., 2017).

Circadian rhythm disturbances may be a pathophysiological risk factor for schizophrenia (Delorme et al., 2020). A manifestation related to circadian rhythm is chronotype, which is divided into morning, evening, or intermediary types (Duarte, 2018). Literature suggests an association between chronotype and mental illness (Taylor and Hasler, 2018). The hypothesis is that individuals with schizophrenia exhibit alterations in circadian rhythm, and these alterations are associated with cognitive impairment.

Methods: In this quasi-experimental study, 67 individuals with schizophrenia were evaluated, recruited from the Schizophrenia Outpatient Clinic of the Federal University of Paraná in Curitiba-PR, the Raul Soares Institute (FHEMIG) and the UFMG Clinics Hospital in Minas Gerais, Belo Horizonte. Inclusion criteria included a confirmed diagnosis of Schizophrenia by SCID-V, age between 18 and 60 years, scoring below 20 points on the PANSS positive subscale, and being without a crisis episode in the last three months.

The tools used were: Socio-demographic Questionnaire, Pittsburgh Sleep Quality Index; Morningness-Eveningness Questionnaire-Self Assessment version (MEQ-SA); Brief Assessment of Cognition in Schizophrenia Short Form (BACS-SF); Lysaker Emotion Recognition Task (BLERT); Hinting Task (Hinting); Insomnia Severity Index (ISI) and Berlin Questionnaire (Berlin). Spearman's correlation tests were applied between cognitive variables and sleep-related variables. Regression models were used for controlling intervening variables. The comparison of cognitive performance among the chronotype categories evaluated by MEQ-SA was done using the Kruskal-Wallis test.

Results: In Spearman's correlation matrix, several significant associations were highlighted, including Education with Hinting (p LESS THAN 0.001) and with Blert (p LESS THAN 0.002), ISI with Hinting (p LESS THAN 0.02). In the linear regression model, which included both education and ISI, this factor did not significantly explain the variation in the Hinting Task (p LESS THAN 0.143; p LESS THAN 0.053).

The Kruskal-Wallis test indicated a significant difference between chronotypes assessed by MEQ in performance on the Hinting Task (p LESS THAN 0.04; sum of squares = 6.34). The post-hoc Tukey analysis indicated a significant difference between morning and intermediary MEQ chronotypes (p LESS THAN 0.023) in performance on the Hinting Task.

Discussion: The results suggested that higher levels of education are associated with enhanced performance in both social cognition and emotional recognition abilities. Chronotype appears to impact social cognition as assessed by the Hinting Task, with morning-type individuals showing better results. Limitations of the study include the small number of participants and the absence of a control group.

S31. THE QUALITY OF LIFE OF PATIENTS WITH SCHIZOPHRENIA IS ASSOCIATED WITH FUNCTIONAL CONNECTIVITY IN THE DEFAULT MODE NETWORK

Miki Ishizuka^{*1}, Syuraku Son², Yukako Nakagami³, Takahiko Kawashima², Yuko Kobayashi², Manabu Kubota², Yujiro Yoshihara², Toshiya MURai², Jun Miyata⁴

¹Kyoto University Graduate School of Medicine, ²Department of Psychiatry, Graduate School of Medicine, Kyoto University, Japan., ³Agency for Student Support and Disability, Kyoto University, Japan., ⁴Department of Psychiatry, Aichi Medical University, Japan.

Background: There has been a growing interest in the quality of life (QoL) of patients with schizophrenia (SCZ) as their independence and social participation have been promoted. There have been many reports on the relationship between QoL of SCZ and neurocognitive impairment (Green et al., 1996), as well as alterations in brain structure (Ubukata et al., 2012). Pathophysiology of schizophrenia, like other psychiatric disorders, is considered a disruption of the brain network recently. However, associations between the QoL of SCZ and brain networks are still unclear. The purpose of this study is to identify the association of QoL with functional connectivity (FC) between brain regions in schizophrenia.

Methods: In this study, 58 schizophrenia patients (SCZ) and 80 healthy controls (HC) were enrolled. We used the WHOQOL, a 26-item self-report questionnaire, as a scale of QoL. It assesses 4 domains: physical, psychological, social, and environmental, as well as overall quality of life. Higher scores in all items indicate better QoL. All subjects underwent magnetic resonance imaging (MRI) on a Siemens 3T scanner to obtain resting-state functional MRI data. After preprocessing and denoising, the FC between each cortical region of interest (ROI) and subcortical region of interest (ROI) in default mode with no ROI set was calculated as a Pearson correlation coefficient using the CONN toolbox. We first identified FCs that differed significantly between groups and then used Spearman's rank correlation to examine correlations between significant FCs and the four domains of WHOQOL and overall QoL. This study was approved by the Ethics Committee of the Graduate School of Medicine and Faculty of Medicine, Kyoto University. After receiving a description of the study, all participants provided written informed consent.

Results: Patients' QoL score was significantly lower in the psychological and social domains than HC's ($p < 0.05$). Among FCs with significant connections detected ($p < 0.05$, false discovery rate (FDR) corrected at seed level), the FCs with different Z-scores among the groups were Occipital - OP r, Occipital - OP l, OP r - OP l, LP(L) - s LOC r ($p < 0.05$). In the SCZ group, a significant correlation was found between their FCs which were different between groups and physical subscale, psychological subscale, social subscale, environmental subscale, and overall QoL ($r > 0.35$, $p < 0.05$).

Discussion: Overall QoL, as well as psychological and social domains, are associated with functional connectivity of the cortical regions in the DMN. DMN is known to play a key role in the reflective/introspective process. Therefore, our findings indicate the importance of

associating an extrospective process overall QoL included such as the psychological and social domains with the introspective process. These findings may contribute to the working on introspective processes and may help improve the QoL of patients.

S32. COMMUNICATIVE-PRAGMATIC IMPAIRMENT IN SCHIZOPHRENIA: ANALYZING ERROR PATTERNS THROUGH SIGNAL DETECTION THEORY

Alberto Parola*¹, Claudio Brasso², Paola Rocca³, Francesca M. Bosco⁴

¹*Centre for Language Technology, University of Copenhagen*, ²*Department of Neuroscience "Rita Levi Montalcini", University of Turin, Turin*, ³*Department of Neuroscience "Rita Levi Montalcini", University of Turin and SC Psichiatria U, Dipartimento di Neuroscienze e Salute Mentale, AOU Città della Salute e della Scienza di Torino, Turin*, ⁴*Department of Psychology, University of Turin, and Institute of Neurosciences of Turin*

Background: Individuals with schizophrenia (SCZ) show a severe impairment in the communicative-pragmatic domain. Previous studies reported a wide range of communicative deficits, such as difficulties in the comprehension of non-literal, figurative, and deceitful communicative acts, as well as narrative and conversational impairment. However, few studies provided an analysis of the errors committed in understanding communicative acts. Error performance may be highly informative of the clinical and cognitive factors underlying patients' failures in communicative-pragmatic tasks, and may thus provide a critical insights into the condition and its clinical and social dimensions. In this study, we evaluated the ability of patients with SCZ to recognize communicative intentions during the comprehension of different communicative acts, and we specifically focused on the analysis of error performance by using signal detection analysis.

Methods: Twenty-six Individuals with schizophrenia and 26 healthy controls (HC), matched for age, gender and education, took part in the study. Participants completed a computerized pragmatic task assessing the comprehension of literal, deceitful and ironic communicative acts, and a battery of tests evaluating cognitive (planning, cognitive flexibility, working memory, verbal intelligence) and theory of mind (ToM) abilities. Signal detection analysis was employed to assess how well participants could identify the communicative intentions of speakers, i.e. sensitivity, and their tendency to mistakenly attribute communicative intentions, i.e. response bias. Additionally, we explored correlations between sensitivity and response bias, clinical aspects and cognitive and ToM functions.

Results: Patients showed a reduced sensitivity ($\beta = -0.75$, $p < .01$), i.e. lower ability in recognizing the speaker's communicative intention, for all pragmatic phenomena, i.e. sincere, deceitful and ironic acts. Further, patients performed worse in recognizing deceit ($\beta = -0.45$, $p < .01$) and irony ($\beta = -0.36$, $p < .01$) compared to sincere acts. Patients also exhibited a stronger response bias for deceitful communicative acts ($\beta = -0.41$, $p < .05$) compared to HC, as they showed a strong tendency compared to HC to respond "deceit" either in deceitful or especially in not deceitful trials. We found significant correlations between planning ability and sensitivity for sincere, deceitful and ironic acts ($p < .05$), between ToM and sensitivity for sincere and deceitful acts ($p < .001$), and between cognitive flexibility and sensitivity for ironic acts ($p < .05$). We found no significant correlation between response bias and cognitive functions.

Discussion: The results showed that the ability to understand communicative intentions is impaired in SCZ. We found that patients showed reduced sensitivity to all pragmatic

phenomena, i.e. sincere, deceitful and ironic acts, compared to HC. Crucially, when committing errors, patients selected the “deceitful” category more frequently than the others. This was reflected in a stronger response bias for deceitful communicative acts and indicated a strong a priori tendency for patients to respond “deceit” for either deceitful or non-deceitful trials. The patients were clinically stable, but most of them had a history of paranoid symptoms such as persecutory delusions. This tendency could persist and result in a bias in the interpretation of other people's communicative intentions and explain their strong tendency to interpret communicative acts as deceptive regardless of context. We also found that the ability to correctly infer communicative intentions was related to various cognitive functions such as planning, cognitive flexibility and ToM. However, we did not find a relationship between response bias and specific cognitive functions. The present study demonstrates the importance of using an error performance analysis to disentangle the relationship between communicative-pragmatic difficulties and socio-cognitive abilities in schizophrenia.

S33. USING MOBILE HEALTH APPLICATION TO ENHANCE MEMORY AND ATTENTION IN YOUTH AT CLINICAL HIGH RISK FOR PSYCHOSIS

Huijun Li^{*1}, Hongmei Chi¹, Shuwen Yang², Jijun Wang³

¹Florida A & M University, ²Shanghai Mental Health Center, ³Shanghai Mental Health Center, Shanghai Jiaotong University School of Medicine

Background: Mental health applications (MHA) have been rapidly designed and are in urgent need of evaluation. Existing evaluation methods are mostly based on application design, such as platform, development, and subjective overall user observations. The purpose of this study was to evaluate the functionality and feasibility of an MHA to train cognitive function in youth at clinical high risk (CHR) for psychosis with a tool that allows a comprehensive user experience evaluation of mobile applications from multiple dimensions.

Methods: Eighty participants with CHR for psychosis were recruited and randomly assigned to the intervention and the group control. Participants in the intervention group used Specific Memory Attention in Real Time (SMART) application for three months. Functionality and feasibility were measured by Mobile Application Rating Scale and qualitative tools.

Results: Participants in the SMART group report that the form and design of this app are simple to operate and the content are trustworthy. They reported improvement of cognitive function and more motivation to seek help to improve their cognitive function. They also pointed out areas of improvement.

Discussion: Clinical implications of MHA in mental health services and research and clinical gaps are discussed.

S34. PROCESSES OF AUDITORY HALLUCINATIONS IN A NON-CLINICAL AND CLINICAL SAMPLE

Camille Jacquet^{*1}, Clément DONDÉ¹, Catherine Bortolon¹

¹Université Grenoble Alpes

Background: Around 80% of people with schizophrenia experience auditory hallucinations (AH). However, from 5% to 15% of non-clinical individuals also report such experiences (Toh et al., 2022). Having both clinical and non-clinical samples allows the discrimination of processes associated with AH from those associated with the need for care.

Disruptions in both top-down and bottom-up processes are suggested to be implicated in AH (Waters et al., 2012). Reduced sensitivity/accuracy for signal-noise discrimination and increased expectation biases for sensory input are among the altered cognitive functions related to AH (Moseley et al., 2021). Perceptual decision-making in AH has often been studied with the auditory Signal Detection Task (aSDT). However, the choice of noises has been poorly justified and has neglected the role of specific frequencies that compose these noises. Few studies have explored the association between basic auditory processing and AH (Dondé, 2019) and most of these studies have important limitations (e.g., related to the definition of AH). Therefore, in this study, we aim to measure bottom-up and top-down processes linked to AH. We hypothesized (1) that patients with schizophrenia will have a poorer ability to discriminate pure tones compared to the general population, even more if they have AH, (2) that individuals with AH will do more false alarms (FA) and have a more liberal response bias, compared to individuals without AH, and even more in the human-noise condition.

Methods: We recruited (and still are) individuals with schizophrenia or schizoaffective disorder, with or without AH, and individuals from the general population, with or without proneness to AH (based on the Launay and Slade Hallucination Scale). Participants completed a series of questionnaires (i.e. Launay and Slade Hallucination Scale – Extended (modified), Hamilton Program for Schizophrenia Voices Questionnaire (patients only) and Creative Experience Questionnaire). They also completed, in a randomized order, the Tone Matching Task (TMT; Dondé, 2019) and the auditory Signal Detection Task (aSDT; Moseley et al., 2021). The TMT assesses early auditory processes. Two different noises were used in the aSDT to assess perceptual decision-making processes: human, with human speech frequencies, or non-human, without these frequencies (Laloyaux et al., 2022).

Results: Our preliminary results (75 non-clinical participants from 100) indicated no significant difference in TMT scores between individuals with and without proneness to AH ($\chi^2=0.23$, $p=.63$, $\varepsilon^2=.003$). Regarding the aSDT, there was no interaction between groups and noises for response bias ($F=0.277$, $p=.6$, $\eta^2=.001$) nor FA ($F=0.29$, $p=.59$, $\eta^2=.001$). In the human noise condition, there was no significant difference between groups for the number of FA ($\chi^2=2.66$, $p=.10$, $\varepsilon^2=.036$) or the response bias ($\chi^2=3.03$, $p=.08$, $\varepsilon^2=.041$). In the non-human noise condition, there was a significant difference between groups for the number of FA ($\chi^2=4.22$, $p=.04$, $\varepsilon^2=.057$) but not for response bias ($\chi^2=3.54$, $p=.06$, $\varepsilon^2=.048$). However, those with a proneness to AH had more FA on both noises but not significantly ($F=2.74$, $p=.10$, $\eta^2=.022$).

Discussion: Our preliminary results indicate that basic auditory processing does not seem to be associated with the presence of AH in the non-clinical sample. As such, these results indicate that these bottom-up processes might not be implicated in the AH, at least, not in non-clinical samples. Depending on noise conditions, differences between groups regarding the number of false alarms and response bias did not always reach significance. Here, it seems that overall, individuals with or without AH tend to have similar response bias.

S35. THE EFFECTS OF EMOTION REGULATION DEFICITS ON NEGATIVE SYMPTOMS AND FUNCTIONING IN PSYCHOSIS: COMPARING SELF-REPORT, BEHAVIORAL, PHYSIOLOGICAL, AND NEURAL MEASURES

Alexander Sahm^{*1}, Lara Wallenwein¹, Daniela Mier¹

¹*University of Konstanz*

Background: Current evidence suggests a close relationship between difficulties in emotion regulation, negative symptoms, and poor functional outcomes in patients with psychosis. However, there is an ongoing debate on how to measure emotion regulation impairments and which measure is most predictive of functional outcome – a necessary first step towards conceiving new therapeutic interventions. To this end, we examine the correlations of self-report, behavioral, physiological, and neural measures of emotion regulation with negative symptoms and global functioning in psychosis.

Methods: We collected data from 17 patients with a psychotic disorder (15 Schizophrenia spectrum disorders, 1 substance induced psychosis, 1 affective psychosis, $M(\text{Age}) = 28.17$, $SD(\text{Age}) = 6.61$, 18 % female) during their inpatient stay at a psychiatric ward and 15 healthy controls from the community ($M(\text{Age}) = 30.67$, $SD(\text{Age}) = 11.70$, 67% female). Data collection is currently ongoing. Negative symptoms and global functioning were assessed via clinical interviews in the patient group (Positive and Negative Syndrome Scale and Personal and Social Performance Scale). All participants completed the Emotion Regulation Questionnaire (ERQ), indicating trait reappraisal and trait suppression tendencies, and heart rate was measured at rest and root mean square of successive differences (RMSSD) was computed as an index of vagal tone. In addition, we conducted a negative emotion regulation experiment with the conditions observe and reappraisal during functional magnetic resonance imaging (fMRI). We defined emotion regulation success as the difference in self-reported valence between the reappraisal and observation condition. fMRI results were analyzed at an exploratory threshold of $p \text{ LESS THAN } .001$ (uncorrected) and $k = 10$. We extracted the eigenvariate of activation from key regions for emotion regulation, i.e. ventromedial prefrontal cortex, dorsolateral prefrontal cortex, anterior insula, anterior cingulate cortex, and amygdala in the patient group. RMSSD, ERQ, emotion regulation success, and extracted eigenvariates were subsequently correlated to negative symptoms and global functioning.

Results: Patients showed significantly higher suppression scores in the ERQ than controls, significantly lower RMSSD, but no differences in their performance in the emotion regulation task. Among controls, our fMRI results showed activation in the left superior temporal sulcus, tempo-parietal junction, orbitofrontal, dorsolateral-prefrontal, and anterior cingulate cortices, as well as bilateral activation of the caudate, polus temporalis and cerebellum. In the psychosis group we found activation in the left supplementary motor and right dorsolateral prefrontal cortices. In direct comparison to controls, patients had higher activation in the right cuneus and precuneus, anterior and posterior cingulate, dorsolateral prefrontal cortex, and temporo-parietal junction, as well as the bilateral insula and rolandic operculum. Only the RMSSD was correlated to global functioning ($r = .70$, $p = .002$) and showed a tendency of association to negative symptoms ($r = -.41$, $p = .100$).

Discussion: We found differences in neural, self-report, and physiological indices of emotion regulation between patients with psychosis and controls. However, only vagally mediated heart rate variability was correlated to global functioning in patients. These results show the usefulness of the multi-modal assessment of emotion regulation difficulties and might inform future interventional research in psychosis. However, collection and analysis of the complete data set is necessary to draw firm conclusions.

S36. REFERENCE CHOICES IN THE NARRATIVE SPEECH OF PEOPLE WITH SCHIZOPHRENIA DURING A WELL-CONTROLLED JOINT TASK: THE STORYTELLING IN SEQUENCE TASK

Maxime Rancourt*¹, Marion Fossard², Dominique Knutsen³, Marc-André Roy⁴, Caroline Cellard⁴, Marie-France Demers⁴, Luc Vigneault⁵, Sara Amrani⁶, Amélie M Achim⁷

¹Université Laval; VITAM - Centre de recherche en santé durable, ²Université de Neuchâtel, ³Université de Lille, ⁴Université Laval; Centre de recherche CERVO, ⁵Patient partner, ⁶Université Laval, ⁷Université Laval; VITAM - Centre de recherche en santé durable; Centre de recherche CERVO

Background: Language production deficits are common in people with schizophrenia spectrum disorders (SSD). While it is clear that people with SSD often produce unclear or ambiguous references, one aspect of reference production that has received little attention so far is their use of reference markers. From the literature in healthy participants, we know that indefinite markers (e.g., “a girl”) are preferred when introducing new referents (e.g., a new story character) in the discourse, pronouns (e.g., “she”) are preferred when maintaining a referent in focus in the discourse and definite references (e.g., “the girl”) are preferred when shifting the focus of the discourse to a different referent. The current study aimed to determine whether people with SSD differ from healthy controls in their use of reference markers when the stages of narrative elaboration (introduction, maintaining and shift) can be separately examined using a well-controlled verbal communication task.

Methods: 51 outpatients (34.8 years, 37 men) with a SSD and 68 healthy controls (28.3 years, 34 men) participated in this study. They all completed the Storytelling in Sequence Task (STST), a collaborative verbal communication task based on the referential communication paradigm. The STST is composed of 9 stories, each illustrated on 6 images. The participant’s task is to tell each story to an interaction partner (a research assistant) who holds the same 6 images in a random order, so that the partner can place her/his images in the correct order. The interaction partner is separated from the participant by an opaque panel and can provide feedback or ask for clarifications if needed. The STST contains several manipulations shown to influence referential choices (i.e., the terms used to refer to the story characters). First, there are 3 different levels of referential complexity, manipulated between stories based on the number of characters in the stories (1 or 2) and, for the stories with 2 characters, their genders (different or same gender). Second, each image of the stories is linked to a specific stage of narrative elaboration (introduction, maintaining or shift of the character in focus). The verbal interactions were tape-recorded and transcribed verbatim. Two independent raters extracted the first reference to the character in focus in each image of each story and coded the type of reference (indefinite, definite, pronoun or other). Logistic mixed models were performed separately for each stage of narrative elaboration and each type of reference marker, to examine whether the probability of using that marker was influenced by group membership and/or levels of referential complexity.

Results: When focusing on the introduction stage, main effects of group emerged such that people with SSD were less likely to use indefinite markers ($F(1,120) = 6.26$, $p < .013$) and more likely to use definite markers ($F(1,147) = 8.34$, $p < .004$) than the healthy controls, without any effects of referential complexity. During the maintaining stage, main effects of levels of complexity emerged such that both groups were more likely to use

pronouns ($F(2, 7.8) = 30.78$, $p < .001$) and less likely to use definite markers ($F(2, 6.9) = 33.84$, $p < .001$) for stories containing only one character relative to the stories with two characters. For the shift stage, none of the effects were statistically significant.

Discussion: Alterations in the use of reference markers in people with SSD were specifically observed when they had to introduce new characters as part of their storytelling. Using well-controlled verbal communication tasks is a good way to examine verbal productions, including choices of reference markers, while the participants speak about predetermined story content.

S37. INDIVIDUAL PERCEPTIONS OF CLUSTERING AND SWITCHING DURING VERBAL FLUENCY TESTS IN A PILOT SAMPLE OF PARTICIPANTS WITH AND WITHOUT A SCHIZOPHRENIA-SPECTRUM DISORDER

Nancy Lundin^{*1}, Bess Bloomer², Emily Gildea³, Peter Todd³, William Hetrick³

¹The Ohio State University Wexner Medical Center, ²National Institutes of Health, ³Indiana University

Background: Verbal fluency tests (VFT) have been used to study thought disorder (i.e., tangential, disorganized speech) among individuals with psychotic disorders. These tasks index retrieval of related concepts in memory and may provide a window into the cognitive architecture of how people connect thoughts and express these thoughts through speech. In VFT, people generate words belonging to a particular category or beginning with a particular letter in a limited time, and people who tend to alternate between "clustering" and "switching" strategies among groupings of related responses produce more words in these tasks. One challenge in this work is determining which responses to classify as clusters or switches, as the relatedness between concepts is multifaceted. Common classification approaches include subcategory-based norms and more recently natural language processing (e.g., using thresholds of semantic similarity between words). A less common but useful approach is to ask individuals performing VFT to share their perceptions of where they think they switched between related concepts. This approach can capture unique features of individuals' semantic memory organization in ways that are particularly relevant for understanding thought disorder among individuals with psychosis.

Methods: In an ongoing study, participants with a schizophrenia-spectrum disorder ($n=10$) and without a psychiatric diagnosis ($n=7$) engaged in four 3-minute category VFT (animals, cities, foods, occupations) and four 3-minute letter VFT (A, F, M, S) trials during functional magnetic resonance imaging (fMRI). After scanning, participants designated consecutive responses that they thought were related (clusters) in the word lists they generated. Participant VFT responses were coded as cluster-related or switch-related based on these participant evaluations for all domains and on subcategory norms for animal and food domains. Animal subcategories were extended from the commonly used Troyer norms and prior research (e.g., canines, farm animals, African animals). Food subcategories were created based on common food groups and regional cuisines (e.g., fruits, grains, East Asian cuisine).

Results: Initial pilot analysis of the behavioral data showed that participants in both the schizophrenia and comparison groups generated a similar number of verbal fluency responses. Participants generated more responses and reported greater percentages of clustered responses for category VFT (particularly in the food and animal domains) than letter VFT. Additionally, groups showed similar match rates between participant-designated and subcategory-based cluster and switch responses (animal VFT ~76% match; food VFT ~67% match). Examination

of discrepancies between these cluster-switch designation methods revealed some participant-designated clusters not captured by the subcategory-based norms which were associative in nature (e.g., pizza toppings, United States Thanksgiving holiday dishes, taco ingredients) or which combined semantic and phonetic cues (e.g., grouping guinea pig and pig within the same cluster).

Discussion: This pilot analysis demonstrates feasibility of collecting VFT responses for 3-minute generation periods during fMRI among individuals with schizophrenia. This work also highlights the value of asking participants to share their individual perceptions of how concepts are related, which may index components of semantic memory organization relevant to thought disorder. Analyses in the larger future sample are needed to determine whether individual perceptions of semantic memory organization differ in individuals with schizophrenia as well as the neural correlates of these processes. Finally, discrepancies between participant-designated and subcategory-based clusters indicate the need for using and refining models of computational linguistic analysis which may better capture associative and combined semantic and phonetic cues used in cognitive search.

S38. CHEMOSENSORY ANHEDONIA IN PATIENTS WITH SCHIZOPHRENIA

Özge Akgül¹, Emine Ilgın Hosgelen^{*2}, Taha Selim Bilgin³, Berna Binnur Akdede⁴, Köksal Alptekin⁴

¹*Izmir Democracy University*, ²*Dokuz Eylül University, Institute of Health Science*, ³*Health Sciences University*, ⁴*İzmir Tepecik Education and Research Hospital*, ⁴*Dokuz Eylül University*,

Background: Anhedonia, defined as the decrease or impairment of the capacity to experience pleasure, is one of the clinical features of schizophrenia (SZ). SZ patients exhibit pronounced levels of physical and social anhedonia. In recent years, there has been a notable focus in schizophrenia research on the analysis of chemosensory hedonic capacities, which pertain to the individual's capacity to perceive pleasure through smell or taste. There exists a convergence of brain regions involved in the regulation of olfactory function and the processing of emotions, including orbitofrontal cortex, amygdala, and hippocampus. Previous research has indicated that olfactory anhedonia is a significant symptom of schizophrenia. Hence, in comparison to other sensory modalities, olfaction may exhibit greater sensitivity in detecting anhedonia. The primary objective of this study was to investigate the relation between chemosensory anhedonia and hedonic features in patients with schizophrenia.

Methods: The data were obtained from individuals who were on treatment at the Schizophrenia Outpatient Unit of Dokuz Eylül University School of Medicine. The study included 92 healthy controls (HC) and 61 patients with schizophrenia based on the diagnostic criteria outlined in the DSM-5. The researchers evaluated the degree of chemosensory anhedonia by employing the Chemosensory Pleasure Scale (CPS), whereas the assessment of hedonic features was conducted using the Chapman Scales for Physical and Social Anhedonia (PAS and SAS). Also, the social functioning of patients was assessed by the Personal and Social Performance Scale (PSP).

Results: There was no significant difference in terms of age between the SZ and HC groups ($p=0.15$). The mean age and total education years are reported as follows: for SZ patients 38.15 ± 9.69 years and 12.13 ± 4.27 years, respectively; and for HC 35.39 ± 12.43 years and 17.06 ± 4.92 years, respectively. The SZ group showed higher physical, social, and chemosensory anhedonia compared to HC ($p < 0.05$), and their PSP score was 57.58 ± 14.07 . In

SZ, CPS was negatively correlated to PAS ($r=-0.322$, $p=0.011$). Especially, the nature subdomain was negatively correlated to PAS ($r=-0.518$, $p < 0.001$) and SAS ($r=-0.291$, $p=0.023$). In HC, both PAS and SAS showed negative correlations to CPS ($r=-0.41$, $p < 0.001$; $r=-0.403$, $p < 0.001$ respectively). Moreover, the PSP was negatively correlated to PAS ($r=-0.364$, $p=0.008$) and SAS ($r=-0.358$, $p=0.009$) in SZ.

Discussion: This study represents the first investigation that employs the self-reported chemosensory pleasure scale regarding to assess and compare the chemosensory hedonic capacity between patients with schizophrenia and healthy controls within the Turkish population. The discovery of reduced pleasure derived from chemosensory stimulation in the SZ group in comparison to HC is consistent with previous studies that reported heightened levels of olfactory anhedonia. Furthermore, patients with SZ demonstrated higher levels of social and physical anhedonia. In line with the literature, CPS showed a correlation with PAS. In addition, as in line with other studies, the schizophrenia group exhibited an association between impaired social functioning and increased levels of physical and social anhedonia. It is known that heightened olfactory anhedonia and elevated negative symptoms are associated. In comparison to other sensory stimuli, olfaction may demonstrate a potentially elevated sensitivity in detecting anhedonia. Moreover, considering the importance of social functioning is mostly dependent on anhedonia, studying chemosensory anhedonia would be important to enhance comprehension of anhedonia as a negative symptom.

S39. THE RELATIONSHIP BETWEEN THE LEVEL OF EXPRESSION OF EMOTIONS OF THE CAREGIVERS IN PATIENTS WITH SCHIZOPHRENIA AND THE LEVEL OF THOUGHT DISORDER IN PATIENTS WITH SCHIZOPHRENIA

Dilşah Gençaslan¹, Köksal Alptekin¹, Emine Ilgin Hosgelen¹, Berna Akdede¹, Tolga Binbay¹, Emine Ilgin Hosgelen*²

¹Dokuz Eylul University, ²Dokuz Eylul University, Institute of Health Science

Background: Schizophrenia significantly impacts individuals and caregivers, influencing their attitudes towards patients. Emotional expression between the patient and caregiver involves concepts like attitude, perspective on the illness, and critical or hostile behavior. The caregiver's emotional expression significantly affects both the patient and clinical symptoms. Emotional expression levels notably impact positive symptoms, depression, and anxiety, despite not being directly linked to negative symptoms. Thought disorder is a crucial symptom, manifesting as difficulties in organizing and expressing thoughts. This study explores the relationship between schizophrenia patients' thought disorder and their caregivers' expressed emotions.

Methods: Sixty-six patients diagnosed with schizophrenia or schizoaffective disorder according to DSM-V criteria and their corresponding 66 caregivers, a total of 132 participants were included into the study. The patient group consists of 27 females (40.9%) and 39 males (59.1%). Of the patients, 49 (74.2%) were diagnosed with Schizophrenia, and 17 (25.8%) were diagnosed with Schizoaffective Disorder. Among the caregivers, 39 (59.1%) are female, and 27 (40.9%) are male. Patients' average age is 45.50, while caregivers' average age is 57.20

Results: In this study we found no significant relationship between the patients' scores on structural thought disorder and caregivers' scores on emotional expression ($r= .23$, $p=.06$). There was a positive correlation between the perceived emotional expression level by patients and the patients' thought disorder scores ($r= .29$, $p= .01$). A negative correlation existed between caregivers' emotional expression levels and neuropsychological test scores. Positive

correlation was observed between patients' perceived emotional expression scores and PANSS scores.

Discussion: The primary objective of this study was to examine the relationship between patients' structural thought disorders and caregivers' levels of emotional expression, representing verbal or non-verbal behaviors. Our core hypothesis, assuming a positive correlation between the caregiver's emotional expression level and the patients' structural thought disorders, was not statistically significant, despite existing a positive relation. However, patients' perceived emotional expression were related to their increased severity of thought disorders. Thought disorder in patients with schizophrenia may be related to their perceived emotional expression of their caregivers.

S40. THE ROLE OF MOTIVATION IN CLINICAL PRESENTATION, TREATMENT ENGAGEMENT AND RESPONSE IN SCHIZOPHRENIA-SPECTRUM DISORDERS: A SYSTEMATIC REVIEW

Helen Thai*¹, Élodie C. Audet¹, Richard Koestner¹, Martin Lepage², Gillian A. O'Driscoll¹

¹*McGill University*, ²*McGill University, Douglas Mental Health University Institute*

Background: Schizophrenia, the most disabling psychiatric disorder, imposes long-term impairments in social and occupational functioning. Negative symptoms, including amotivation, are poor prognostic factors, but patient motivation as a positive force has been less studied. Self-Determination Theory (SDT) is an established theory of human motivation that considers motivation on a continuum from amotivation, to controlled, identified and intrinsic motivation, and emphasizes autonomy, competence, and relatedness as factors that sustain intrinsic motivation. To identify how motivation as framed by SDT has been studied in treatment contexts, we conducted a systematic review.

Methods: PRISMA-P guidelines were used to investigate the question, “How does motivation impact clinical presentation, treatment engagement and response in schizophrenia-spectrum disorders?” Eligible studies were conducted in adult schizophrenia-spectrum disorders (GREATER THAN 50% of the sample), peer-reviewed, quantitative, in English and used a motivation scale. Results were grouped into cross-sectional correlates of motivation at baseline, longitudinal correlates, and the effects of motivational interventions as measured in RCTs.

Results: Fifty-six independent studies, involving 6,829 participants, met inclusion criteria. Twenty motivation scales were used: the Intrinsic Motivation Inventory-Schizophrenia Research (Choi et al., 2010), which measures task-specific motivation across the SDT continuum, and a 3-item Quality-of-Life subscale (Heinrichs, 1984) that assesses intrinsic motivation in one's life generally, were most used. Cross-Sectional Correlates of Baseline Motivation: Social and occupational functioning were positively associated with motivation in 7/8 studies. Neurocognitive global scores were positively correlated with motivation in 7/9 studies. Negative and positive symptoms were both negatively associated with motivation (9/14 and 7/11 studies respectively), with significant results found primarily with the QLS. Longitudinal Correlates: Motivation at treatment initiation predicted treatment response in 6/10 studies. Cognitive remediation studies generally did not observe this effect (1/5 studies) but did find an association with treatment engagement (4/5 studies). Of 15 studies examining whether motivation changed during treatment, 9 found it did. Additionally, 5 found that these changes correlated with treatment response. RCTs of Motivational Interventions: 15 RCTs evaluated the effect of adding a motivation enhancement condition to an established treatment.

The most common motivation enhancement methods were individualized goal-setting and goal-attainment support (12/15 studies), targeting defeatist beliefs to increase perceived competence (7/15), and increasing contact to improve sense of relatedness (7/15). Participants in the motivational intervention groups showed increased motivation (10/13 studies), higher treatment engagement (8/10), and greater treatment response (11/13) than controls.

Discussion: Baseline motivation was found to be associated with clinical presentation and with the magnitude of response to treatments that targeted social and occupational functioning. Relatively few RCTs have been conducted, but they were consistent in finding that motivational interventions increase motivation and enhance treatment engagement and response. More studies are needed that monitor motivation during treatment, as proximal assessments could better identify treatment factors that impact motivation. Such information could allow modification of treatments to enhance the patient experience and improve efficacy.

S41. COGNITIVE MODEL OF PERCEPTUAL ANOMALIES: THE ROLE OF TOP-DOWN INFLUENCE, SOURCE MONITORING AND INHIBITORY CONTROL PROCESSES FOR HALLUCINATIONS IN SCHIZOPHRENIA AND FOR HALLUCINATORY-LIKE EXPERIENCES IN THE GENERAL POPULATION

Adrianna Aleksandrowicz^{*1}, Steffen Moritz², Joachim Kowalski¹, Łukasz Gawęda¹

¹*Institute of Psychology, Polish Academy of Sciences*, ²*University Medical Center Hamburg-Eppendorf*,

Background: Cognitive models emphasize that top-down processes, source monitoring, and inhibitory control contribute to perceptual anomalies such as auditory hallucinations (AHs) and hallucinatory-like experiences (HLEs). The prevalence of perceptual abnormalities such as illusions or even hallucinations is not restricted to the clinical population and represents a continuum. This account assumes that the further one is on the continuum, the more these experiences should be prominent. Still, there is little evidence to confirm such a hypothesis, often presenting mixed findings. The present study aims to investigate whether there are gradual differences in these postulated mechanisms along the continuum of psychosis. We expect that people with a diagnosis of schizophrenia spectrum disorders, people with frequent HLEs and healthy controls will differ in functioning regarding top-down processes, source monitoring and inhibitory control.

Methods: Eighty-six patients with schizophrenia spectrum disorders (SSD) were divided into two groups based on AHs presence - 45 with auditory hallucinations (present in the week prior to the study) and 41 - non-hallucinating (in the month prior to the study), 43 matched healthy controls (HC), and a sample selected from the general population of 26 participants with high HLEs and 33 with low HLEs performed three experimental tasks assessing top-down processes (False Perception Task - FPT), source monitoring (Action Memory Task - AMT), inhibitory control (Go/No-Go Task). Patients were assessed with the Positive and Negative Syndrome Scale, and all groups were screened using the Mini International Neuropsychiatric Interview (MINI) for the presence of mental disorders. Exclusion criteria were as follows: age below 18 years and above 45 years, hearing impairments, neurological disorders, alcohol dependence in the past 12 months, and intellectual impairments. Additionally, for the non-clinical groups, the presence of the current mental disorders was the exclusion criterion. All patients were stable during the assessment and had no major changes in pharmacological treatment in the past two weeks before the study. Group differences between two clinical groups (AH and non-AH), HC,

and two non-clinical groups (high HLEs and low HLEs) were analyzed with Kruskal-Wallis ANOVA and post hoc tests with Dunn's Test.

Results: Both clinical groups committed significantly more false perceptions in the FPT than HC. However, there were no significant differences between clinical groups (SSD with AH vs SSD without current AH) and non-clinical groups (high HLEs vs low HLEs). Moreover, both clinical groups significantly more often misattributed imagined actions as being performed than the HC group. However, there were no significant differences between the clinical groups (SSD with AH vs SSD without current AH) and the non-clinical groups (high HLEs vs low HLEs). Finally, we found no significant differences between groups for false alarms in the Go/No-Go Task.

Discussion: This study sheds further light on the mechanisms of perceptual anomalies in clinical and non-clinical populations.

S42. EXECUTIVE DYSFUNCTIONS IN PATIENTS WITH SCHIZO-OBESSIVE DISORDER

Min-yi Chu^{*1}, Shuai-biao Li¹, Raymond C. K. Chan²

¹Translational Neuropsychology and Applied Cognitive Neuroscience Laboratory, Shanghai Mental Health Centre, Shanghai Jiao Tong University School of Medicine, ²Neuropsychology and Applied Cognitive Neuroscience, CAS Key Laboratory of Mental Health, Institute of Psychology, Chinese Academy of Sciences, Beijing, China; Department of Psychology, University of Chinese Academy of Sciences; Translational Neuropsychology and Applied Cognitive Neuroscience Laboratory, Shanghai Mental Health Centre, Shanghai Jiao Tong University School of Medicine

Background: Schizo-obsessive disorder (SOC) has been proposed to describe patients with schizophrenia (SCZ) exhibiting obsessive-compulsive symptoms or co-morbid the diagnostic criteria for obsessive-compulsive disorder (OCD). These patients are characterized by earlier onset, more severe psychiatric symptoms, and poorer outcomes. However, the underlying pathological mechanisms of SOC are still yet understood. On the other hand, executive dysfunction, the potential endophenotype for both SCZ and OCD, is thought to be a specific alteration in patients with SOC. However, it is still not clear the features of executive dysfunction in patients with SOC. This study adopted a transdiagnostic approach to exploring the features of the specific executive dysfunction in patients with SOC, SCZ, and OCD.

Methods: A total of 38 SOC patients, 82 SCZ patients, 59 OCD patients, and 47 healthy controls (HC) were recruited for this study. We administered the Hayling Complement Sentence Test (HCST), the Sustained Action to Response Task (SART), the n-back task, and the Six-Element Test (SET) to assess the inhibition, updating, shifting, and planning components of executive function to all the participants. All patients also received the assessment of the Positive and Negative Syndrome Scale (PANSS) and the Yale-Brown Obsessive Compulsive Scale (Y-BOCS) for evaluation of symptom severity.

Results: SOC patients exhibited significantly more prominent negative and positive symptoms in subscales of PANSS compared to SCZ patients, but they showed no difference in Y-BOCS scores comparing to OCD patients. Findings from one-way ANOVA analysis showed that SOC, SCZ and OCD groups exhibited significantly higher total error numbers of HCST compared with HCs. Both SOC and SCZ patients also exhibited significantly poorer

performances in SET shifting and planning scores, and n-back task than HC. Moreover, SOC patients also performed significantly poorer than OCD patients in SET planning scores.

Discussion: These findings suggested that the poor inhibition ability is a shared impairment among the SOC, SCZ, and OCD patients, and SOC and SCZ patients exhibited more pronounced impairments in other components of executive function, including updating, shifting, and planning abilities. These results supported the notion that SOC may represent a subtype of SCZ with distinct cognitive characteristics.

S43. EVALUATING SOCIAL INTERACTIONS IN SCHIZOTYPY USING ECOLOGICAL MOMENTARY ASSESSMENT

Madisen Russell^{*1}, Tess Filip², Sarah Akhras², Heather Busanet³, Katharine Thakkar³, Amanda Mccleery², Kyle Minor¹

¹Indiana University; ²Purdue University, ³The University of Iowa, ³Michigan State University,

Background: Social functioning deficits are prevalent in individuals with high levels of schizotypal traits (Debbané et al., 2015; Kwapil et al., 2013). Much of the research in this area has been limited to laboratory-based assessments such as interview-rated, self-report, or performance-based measures, where the accuracy of participants' recalled information is compromised by reconstructive processes (Moskowitz and Young, 2006). Ecological momentary assessment (EMA), which collects self-reported information closer in time to its occurrence, can offer a more advantageous approach to assessing individuals' functioning and day-to-day experiences (e.g., Minor et al., 2020). To date, no prior research has evaluated how specific types of schizotypal traits predict key real-world social interaction variables, including: 1) likelihood of interacting; 2) depth of interactions; and 3) enjoyment of interactions. This study seeks to fill this gap by examining if positive, negative, and disorganized schizotypal traits predict these aspects of social functioning in individuals' daily lives. In turn, this will contribute to a deeper understanding of social functioning deficits within schizotypy. I hypothesized that negative schizotypal traits would exhibit the strongest inverse association with social interaction likelihood, depth, and enjoyment.

Methods: Across three midwestern U.S. universities, 185 college student participants completed an online measure of schizotypy (SPQ-BR; Cohen et al., 2010), as well as one or two weeks of EMA to assess daily social interactions. Participants were prompted six times per day to provide information on their social interactions: 1) whether they were interacting with anyone; 2) the depth of that interaction (e.g., small talk, sharing opinions, expressing feelings); and 3) their enjoyment of the interaction. Multilevel modeling was used to examine if schizotypal traits (i.e., positive, negative, and disorganized) can predict the likelihood, depth, and enjoyment of individuals' everyday social interactions.

Results: The average EMA adherence rate was 70.32% (SD=15.76%) and did not significantly differ between sites ($p=.330$). Negative schizotypal traits significantly predicted individuals' likelihood of interacting ($b=-.005$, $SE=.002$, $p=.016$) and ratings of social interaction enjoyment ($b=-.066$, $SE=.019$, $p < .001$), but did not predict individuals' social interaction depth, $b=-.014$, $SE=.008$, $p=.079$. Positive and disorganized traits did not significantly predict individuals' likelihood of interacting (p -values GREATER THAN .552), enjoyment (p -values GREATER THAN .116), or depth (p -values GREATER THAN .090) of social interactions.

Discussion: Negative schizotypal traits inversely predicted the likelihood of whether an individual was interacting with others in their daily lives and how much they enjoyed their interactions. Positive and disorganized traits did not significantly predict any of the social interaction outcome variables. These findings are complementary to the growing body of evidence that suggests negative schizotypal traits play a more significant role in social functioning deficits than positive or disorganized traits (e.g., Abu-Akel et al., 2018; Kwapil et al., 2012). Given the complex relationship between schizotypal traits, affect, and social outcomes (e.g., Kwapil et al., 2020; Minor et al., 2020), future research should examine these interactions and their implications for social functioning in individuals with increased schizotypal traits.

S44. EXAMINING THE CONTRIBUTION OF SOCIAL COGNITIVE BIAS TO SYMPTOMS AND MOMENTARY EXPERIENCES OF PARANOID IDEATION AND NEGATIVE AFFECT IN PSYCHOSIS

Ryan Orth^{*1}, Imani Todd², Laura Hemphill², Melanie Bennett³, Jack Blanchard²

¹*University of Maryland - College Park*, ²*University of Maryland- College Park*, ³*University of Maryland- School of Medicine*

Background: Hostile social cognitive bias, the tendency to interpret the actions of others as intentional and hostile (Combs et al., 2007), is a major component of the social cognitive deficits common in psychosis (Mancuso et al., 2011). Social cognitive bias relates to negative affect and positive symptoms (Mancuso et al., 2011) and predicts paranoid ideation in both clinical psychosis (Buck et al., 2016; Combs et al., 2009) and in non-clinical community samples (Combs et al., 2013). Additional work suggests that social cognitive bias contributes to social impairment in psychosis (Buck et al., 2018; Pinkham et al., 2016), and that this contribution is unrelated to negative symptoms (Mancuso et al., 2011). While social cognitive bias appears to be an important factor in both symptoms and functioning in psychosis, research to date has largely relied upon symptom self-reports and clinician ratings with very little work utilizing methods such as ecological momentary assessment (EMA). Thus, it remains unclear how laboratory and self-report measures of social cognitive bias may predict daily experiences of symptoms.

Methods: The current study seeks to expand current literature by examining how social cognitive bias relates to daily experiences of negative affect and paranoid ideation. We hypothesize that 1) social cognitive bias will relate to greater paranoid ideation and negative affect; 2) social cognitive bias will relate to greater momentary paranoid ideation and negative affect; 3) social cognitive bias will remain related to momentary paranoid ideation and negative affect when controlling for baseline levels of these constructs.

Data were collected from a transdiagnostic sample of adults with clinical psychosis and non-clinical participants living in the Baltimore-Washington metropolitan area of the United States. Social cognitive bias was measured using the overall “blame score” (based on the subscores of perceived intentionality, anger, and blame) of the Ambiguous Intentions Hostility Questionnaire (AIHQ; Combs et al., 2007). Paranoid ideation was measured using the Revised Green Paranoid Thoughts Scale (R-GPTS; Freeman et al., 2021) and negative affect was measured using previously established factors of Brief Psychiatric Rating Scale (BPRS; Kopelowicz et al., 2008; Ventura et al., 1993). Momentary paranoid ideation and negative affect were calculated using average responses from a week of EMA (Orth et al., 2022).

Results: Analyses (N = 86) indicated that the total blame score of the AIHQ was related to R-GPTS ($r = .49$, p LESS THAN .001) and BPRS negative affect ($r = .36$, p LESS THAN .001). The AIHQ was not related to EMA paranoid ideation ($r = .22$, $p = .07$) or negative affect ($r = .13$, $p = .25$). Post-hoc analyses revealed a component of the AIHQ, perceived intentionality, was related to greater EMA paranoid ideation ($r = .24$, $p = .04$). However, when controlling for R-GPTS scores, perceived intentionality was no longer related to EMA paranoid ideation ($t = -1.12$, $p = .26$).

Discussion: As hypothesized, social cognitive bias was related to symptom ratings of paranoid ideation and negative affect. A component of social cognitive bias, perceived intentionality, was also related to momentary paranoid ideation, indicating that individuals more likely to assign hostile intent to ambiguous social situations experienced greater momentary paranoid ideation. However, this relation was no longer significant when controlling for paranoid ideation. These results replicate previous findings regarding the relation between social cognitive bias and paranoid ideation and extend findings to indicate that these biases manifest in momentary experiences of paranoid ideation. Implications of current results will be discussed further at the time of presentation.

S45. EXAMINING THE RELATIONSHIP BETWEEN SCHIZOPHRENIA, CREATIVITY, AND COGNITIVE FUNCTIONING: INSIGHTS FROM THE REMOTE ASSOCIATES TEST

Hanna Kucwaj^{*1}, Bartłomiej Krocze², Zdzisław Gajewski³

¹SWPS University, ²Jagiellonian University in Cracow, ³Barbara Borzym Psychiatric Hospital

Background: The relationship between psychopathology and creativity has been the subject of debate for decades, with some researchers suggesting that mental disorders might be related to enhanced creativity. The findings on the relationship between creativity and schizophrenia remain ambiguous. We aimed to investigate this issue by applying the Remote Associates Test (RAT), which has been rarely used in clinical groups. The RAT allows us to not only compare general accuracy but also examine the pattern of errors, providing a deeper insight into potential differences in the process of generating creative ideas. In the RAT, participants are asked to find one word that is somehow related to each of three given words (e.g., 'hotel,' 'captain,' 'sky'; response: 'stars'). We sought to verify whether schizophrenia patients differ from healthy controls in their performance on this task in two respects: (1) general accuracy and (2) effectiveness in evaluating and rejecting incorrect associations. Importantly, we applied a fluid intelligence test to control for an important source of variation, as previous research has shown that creativity benefits from intelligence.

Methods: We administered the RAT to 68 schizophrenia patients and 75 healthy controls. To assess the ability to reject incorrect associations, we computed an incorrect response rate (the number of incorrect responses to all errors after accounting for general accuracy in the task). Additionally, in the patients' group, we evaluated symptom severity using PANSS-6 and ACE-III.

Results: After controlling for fluid intelligence, the patients and the healthy controls did not differ significantly in either general accuracy or incorrect response rate (p 's GREATER THAN .05). Within the patients' group, performance in the RAT did not correlate with symptom severity measured with PANSS-6 assessing positive and negative symptoms (p GREATER THAN .05). However, it exhibited a positive correlation with cognitive functioning measured using ACE-III ($p = .367$, $p = .002$).

Discussion: After adjusting for fluid intelligence, patients performed comparably to controls on a creative thinking task that assessed both divergent thinking (at the stage of idea generation) and convergent thinking (at the stage of rejecting invalid associations). The absence of correlations between the RAT performance and positive/negative symptoms, coupled with its significant relationship with the ACE-III score, suggests that cognitive functioning is vital for successful creative thinking.

S46. DAILY VARIATIONS IN INTENTION TO BE PHYSICALLY ACTIVE AND AFFECT IN PEOPLE WITH PSYCHOTIC DISORDERS

Valérie Chauvin*¹, Paquito BERNARD², Yannick FRANCILLETTE³, Sébastien GABOURY³, Kevin Bouchard³, Daniel Fulford⁴, Ahmed Jerome ROMAIN¹

¹University of Montreal, ²Université du Québec à Montreal, ³Université du Québec à Chicoutimi, ⁴Boston University

Background: Although physical activity is recommended for people with psychotic disorders, the majority are inactive, and their main barrier is low motivation. Intentions to be physically active is known to influence the level of motivation and physical activity, yet there is a gap between having the intention to be active and the actual practice of physical activity. Also, affect is known to influence motivation and physical activity. However, no studies have examined the relationship and interaction between intention and affect over time. One solution to expose this relationship is to use momentary ecological assessment (real-time data) probed on the participants' cell phones daily.

Methods: Preliminary analysis of a 4-week multicenter intervention study in which participants (aged 18-50) with a diagnosis of psychotic disorder played with an exergame ("Ocean Empire", mobile physical activity application) created to increase physical activity levels in this population. Using momentary Ecological Assessments, participants rated their intentions to be active and their affect twice a day on a 7-point visual analog scale. In the morning survey, participants ranked their intentions to be active during the day and their affect at the time of the survey, while they ranked their intentions to be active the following day and their affect in the evening survey.

Results: 4 adults (3 females, 1 male) with a mean age of 32.5 ± 6.0 years old with a diagnosis of psychotic disorder, with a mean body mass index of $28.23 \pm 6.5 \text{ kg/m}^2$ and they were all full-time workers. The response rate for the daily momentary ecological assessment was 73.43% ($\pm 11.51\%$) corresponding to a total of 181 completed ecological momentary assessment logs. Intention to be physically active on the same day ranked low with a mean range between 1,68 and 3,64 (± 1.61) in the morning, and the intention to be active the next day had a mean range between 2,60 and 3,75 (± 1.85). Three of the participants had slightly higher intention to be active the following day than during the same day (variation mean = 1.88 ± 0.44). Three of the participants ranked their affect as being mainly happy, awake, full of energy and calm both in the morning and evening without specific patterns in daily variation, while the other participant ranked low on all affect both in the morning and evening. No initial associations were found between affect and intentions to be active.

Discussion: Variation in affect and intention to be active varied on an individual level both between days and within the same day emphasizing the need for individualized physical activity approaches which would be time depending. Preliminarily, the relationship between affect and intentions to be active is still unclear in people with psychotic disorder. Time varying

network model and analysis using accelerometry will be performed to further verify the dynamic between affect, intentions to be active and physical activity.

S47. EXAMINING THE JOINT CONTRIBUTION OF TRAUMA AND ADVERSE NEIGHBORHOOD CHARACTERISTICS ON PARANOID IDEATION: A MULTI-METHOD APPROACH IN A TRANSDIAGNOSTIC SAMPLE

Imani Todd*¹, Ryan Orth¹, Laura Hemphill¹, Melanie Bennett², Jack Blanchard¹

¹*University of Maryland - College Park*, ²*University of Maryland School of Medicine*

Background: Paranoid ideation is common in psychosis and is associated with impairment (Fett et al., 2022; Pinkham et al., 2016). Multiple cognitive factors influence paranoid ideation including lack of belief flexibility and hostile attributions (Freeman et al., 2016; Pinkham et al., 2016). Separately, negative affect precedes and maintains later paranoid ideation (Ben-zeev et al., 2011). Research on what provokes these cognitive and affective biases highlights the influence of trauma and environmental stress (Freeman and Garety, 2014).

Traumatic experiences are a reliable risk factor for psychotic disorders and suspiciousness (Moffa et al., 2017). Prior literature examining trauma and paranoid ideation only uses broad indicators of positive symptoms or single-item assessments (Alameda et al., 2021). Additionally, this literature often examines trauma in isolation without regard for environmental-level factors.

Environmental research identifies two major facets that contribute to the development and maintenance of psychotic symptoms: neighborhood deprivation and crime (Wickham et al., 2014; Wilson et al., 2016). Population studies show that individuals who reside in deprived neighborhoods are more likely to experience increased paranoid ideation (Kirkbride et al., 2017; McElroy et al., 2019). Crime may also influence perceptions of threat and hostility and has been related to paranoid ideation (Vargas et al., 2020).

Aside from objective assessments of neighborhood deprivation and crime, neighborhood perceptions also impact paranoid ideation, above and beyond area-level assessments of neighborhood features (Newbury et al., 2017). Although trauma, neighborhood deprivation, and crime have been shown to impact paranoid ideation, few have examined these constructs in tandem. The current study seeks to examine the association between individual-level (i.e., trauma, neighborhood perceptions) and system-level (i.e., neighborhood deprivation and crime) factors and paranoid ideation. We hypothesize that the experience of more traumas, neighborhood perceptions of violence, deprivation, and area-level crime will be related to greater paranoid ideation. Additionally, we hypothesize that trauma history and neighborhood characteristics will jointly contribute to more severe paranoid ideation.

Methods: Data was collected from a transdiagnostic sample of adults with psychotic disorders and non-clinical participants. Paranoid ideation was assessed using the Revised Green Paranoid Thought Scale (Freeman et al., 2021). Trauma was measured using the Trauma History Questionnaire (Hooper et al., 2011). Neighborhood perceptions were measured using the Neighborhood Environmental Scale (Mujahid et al., 2007). The Area Deprivation Index (Kind et al., 2015) was used to assess neighborhood deprivation objectively. To measure area-level crime, CrimeRisk was used (Applied Geographic Solutions, 2020).

Results: Analyses supported our hypothesis that greater paranoid ideation was related to greater traumas ($r = .33$, $p < .01$) and neighborhood perceptions of violence ($r = .33$, $p < .01$), but not to objective indices of neighborhood deprivation or area-level crime. Regression analyses also revealed that both greater trauma ($\beta = .31$, $p < .01$) and neighborhood perceptions of violence ($\beta = -.30$, $p < .01$) predicted greater paranoid ideation above and beyond other demographic factors.

Discussion: Results indicated that trauma and perceived neighborhood violence jointly contributed to paranoid ideation. These results indicate the importance of considering both trauma history and neighborhood factors in understanding paranoid ideation. Additional results and implications will be discussed at the time of presentation.

S48. THE INFLUENCE OF EMOTION-BEHAVIOUR DECOUPLING ON CLINICAL AND FUNCTIONAL OUTCOMES IN PATIENTS WITH SCHIZOPHRENIA: FURTHER EVIDENCE FROM A CLUSTER ANALYSIS FOLLOWING THE RDOC APPROACH

Simon S. Y. LUI^{*1}, Kimberly K Y Yip², Ezmond S. L. Cheung¹, Raisie W K Wong¹, Cherry H. Y. Lam¹, Christy H. Y. Wong¹, Eunice Shing¹, Wing-Chung Chang¹, Eric Y. H. Chen¹, Pak C. Sham¹, Raymond C. K. Chan³

¹The University of Hong Kong, ²Castle Peak Hospital, ³CAS Key Laboratory of Mental Health, Institute of Psychology

Background: Emotion-behaviour decoupling refers to the failure to translate emotion into motivated behaviour. A recent longitudinal cluster analysis showed that emotion-behaviour decoupling and experiential pleasure deficits predicted clinical and functional outcome of schizophrenia. Research Domain Criteria (RDoC) framework advocated multiple measures to characterize schizophrenia patients, but our earlier analysis did not include working memory and clinical symptoms as clustering variables. To extend our earlier findings according to the RDoC perspective, we conducted this study using an independent sample, and adding working memory and clinical symptoms to emotion-behaviour decoupling as clustering variables. We aimed to characterize schizophrenia patients using emotion-behaviour decoupling and other measures, and to compare the difference in clinical and functional outcome between resultant clusters.

Methods: Our cross-sectional sample comprised 132 schizophrenia patients. Participants completed the Temporal Experience of Pleasure Scale (TEPS), Emotional Expressivity Scale (EES), and Clinical Assessment Interview for Negative Symptoms (CAINS). We also administered the Anticipatory and Consummatory Pleasure (ACP) Task and the Letter-Number Span Test (LNT). A two-stage hierarchical cluster analysis was used, with the TEPS, EES, CAINS-MAP, CAINS-EXP, LNT, and emotion-behaviour decoupling as the clustering variables. We validated the resultant clusters by comparing the between-cluster social functioning.

Results: We found a four-cluster solution. Cluster 1 and Cluster 3 both had low CAINS-MAP and EXP factors, but differed in TEPS and EES. Cluster 2 and Cluster 4 both had high CAINS-MAP and EXP factors, but Cluster 4 had the highest CAINS-MAP factor, and lowest TEPS-consummatory pleasure, and Cluster 2 had the weakness emotion-behaviour decoupling during wanting. Working memory was comparable among the four clusters. Upon validations, Cluster 2 and Cluster 3 had significantly lower functioning than the other clusters.

Discussion: Our findings suggested a modest role of emotion-behaviour decoupling in influencing schizophrenia patients' functional outcome. However, our findings supported the feasibility of characterizing schizophrenia patients using multimodal measures of negative symptoms and related constructs.

S49. COGNITIVE DIFFERENCES BETWEEN SCHIZOPHRENIA OFFSPRING WITH ADHD AND ADHD BORN TO HEALTHY PARENTS

Aitana Bigorra^{*1}, Elena De la Serna², Gisela Sugranyes³, Patricia Camprodon-Boadas³, Dolores Moreno⁴, Inmaculada Baeza³, Yamila Tosetti³, Sara Parrilla⁴, Covadonga Diaz-Caneja⁴, Josefina Castro-Fornieles³

¹*Institut Clinic de Neurociències, Hospital Clinic Universitari*, ²*Centro de Investigación Biomédica en Red de Salud Mental (CIBERSAM)*, ³*Hospital Clínic de Barcelona*, ⁴*Hospital General Universitario Gregorio Marañón*

Background: While there has been wide agreement that schizophrenia is a neurodevelopmental disorder (Weinberger, 1987) the status of cognitive deficits as specific risk markers for schizophrenia remains uncertain (Mohn-Haugen et al., 2022). Given the high heritability of this condition (Rasic et al., 2014), one approach to exploring early markers of vulnerability to psychosis is to assess the first-degree relatives of individuals with schizophrenia.

Children and adolescents who are first-degree relatives of individuals diagnosed with schizophrenia may exhibit neurodevelopmental characteristics similar to those observed in young people diagnosed with attention deficit hyperactivity disorder (ADHD) (Keshavan et al., 2003). In fact, ADHD is the most prevalent form of psychopathology in schizophrenia offspring (SZoff), with rates ranging between 20-46% (De la Serna et al., 2021). Although some studies have described overlap in cognitive difficulties between youth-onset psychosis and ADHD (Karatekin et al., 2008, 2009; Karatekin and Asarnow, 1998), there are very few studies that have investigated the relationship between SZoff and ADHD.

The objective of this study is to compare the cognitive characteristics of a SZoff group with ADHD (SZoff-ADHD) to a group of children and adolescents diagnosed with ADHD (ADHD) but without a history of psychotic disorders in their first-degree relatives.

Methods: The participants comprised 22 SZoff-ADHD and 69 ADHD children and adolescents. The results of the Wechsler Intelligence Scale for Children-IV (WISC-IV) (Wechsler, 2005) and Conners' Performance Test (CPT-II) (Conners, 2000) were compared with mean comparison T-tests, following verification of the conditions for their application.

Results: Compared to the ADHD group, SZoff-ADHD obtained worse results in several subscales of the WISC-IV: Vocabulary ($t=3.25$, $p=0.002$), Block Design ($t=2.38$, $p=0.019$), Similarities ($t=2.30$, $p=0.002$), Digit Span ($t=3.32$, $p=0.001$), Letter-Number Sequencing ($t=2.76$, $p=0.007$), Matrix Reasoning ($t=2.37$, $p=0.02$), as well as in Verbal Comprehension ($t=2.67$, $p=0.009$), Perceptual Reasoning ($t=2.07$, $p=0.041$), Working Memory ($t=3.28$, $p=0.001$), and General Ability indices ($t=3.49$, $p=0.001$). In contrast, the ADHD group obtained worse results in Commissions ($t=3.51$, $p=0.003$) and d' ($t=3.12$, $p=0.005$) of the CPT-II.

Discussion: There are cognitive differences between ADHD and SZoff-ADHD: the SZoff-ADHD group scored lower on general cognitive measures related to abstract reasoning and

working memory, while ADHD individuals showed greater inhibition difficulties. These results suggest that although both groups have similar clinical characteristics (ADHD diagnosis), they likely exhibit specific neurodevelopmental alterations.

S50. OPPOSITE DIRECTION SPATIAL WORKING MEMORY BIASES IN PEOPLE WITH SCHIZOPHRENIA AND HEALTHY CONTROLS

James Gold^{*1}, Sonia Bansal¹, Benjamin Robinson¹, Alan Anticevic², Steven Luck³

¹MPRC, ²Yale University, ³U.C. Davis

Background: Recent research has shown that spatial working memory representations are unconsciously biased by prior trials such that current-trial responses are attracted to previous-trial responses (serial dependence). It is thought that these types of cross-trial biases result from different neural processes than those that mediate performance within a single WM trial. Data from single cell recordings suggest that WM representations are mediated by sustained firing of neurons that represent the to-be-remembered feature, which stops after the response is completed on that trial (1). Across-trial biases are thought to be mediated by short-term synaptic plasticity that can represent information after the cessation of sustained neural activity. The persistence of these synaptic changes from trial N-1 interact with the representation on trial N, causing the latter representation to drift towards the former. This opens a new window to examine how schizophrenia impacts both the sustained neural firing representing the current-trial target and longer-term synaptic plasticity that stores previous-trial information. Serial dependence effects are of special interest because the normal attractive bias is abolished in patients with NMDA receptor encephalitis, suggesting that this system may be implicated in mediating these longer-term cross trial effects.

Methods: 41 clinically stable people with schizophrenia (PSZ) and 32 demographically similar healthy controls (HCS) participated. We examined response accuracy in a single-item spatial working memory test with delay intervals of 0, 2, 4, or 8 seconds. The main question was whether the reported location on a given trial was influenced by the target location on the previous trial. Our main dependent variable was the bias index, which quantifies the extent to which the current-trial responses were biased toward or away from the previous-trial target.

Results: PSZ and HCs showed opposite-direction serial dependence bias effects: the bias became progressively more positive over increasing delays in HCS (attraction) and progressively more negative over increasing delays in PSZ (repulsion). HCS (attraction) and progressively more negative over increasing delays in PSZ (repulsion). A 2-way ANOVA with factors of Group and maintenance period delay yielded a significant Group X maintenance period interaction ($F [2.58, 186.21] = 3.95, p=0.013, \eta^2p=0.05$). The main effect of Group was also significant ($F [1, 72] = 33.22, p \text{ LESS THAN } 0.001, \eta^2p=0.32$). but the main effect of maintenance period was not ($F [2.58, 186.21] = 2.02, p=0.12, \eta^2p=0.27$). Post-hoc between-group comparisons were significant for the 2, 4, and 8 s delays. In PSZ, the magnitude of the repulsion bias correlated negatively with broad measures of cognitive ability and working memory capacity, suggesting that the bias measure is indexing a core process implicated in the broad cognitive impairment seen in schizophrenia.

Discussion: PSZ show a qualitative, opposite-direction alteration in the effects of previous trials on working memory. This stands in contrast to typical evidence of cognitive impairment where PSZ perform more poorly than HCs-- showing a quantitative performance difference. Qualitatively distinct differences in performance are extremely rare in psychopathology and may index a fundamental alteration in neural processing that could serve as a valuable

biomarker for pathophysiology and treatment development research. Such qualitative differences are uniquely important because they cannot be explained by poor attention, reduced motivation, or general intellectual impairments-- factors that complicated the interpretation of most cognitive findings. Importantly, NMDA encephalitis patients fail to show the repulsion bias seen in schizophrenia. Thus it is likely that the findings in PSZ suggest the impact of an additional process beyond reduced short-term synaptic plasticity. The results could be accounted for by a combination of reduced synaptic plasticity accompanied by unopposed long term neuronal adaptation effects that can result in repulsive biases as seen here.

S51. SEX DIFFERENCES IN SOCIAL COGNITION AMONG INDIVIDUALS WITH SCHIZOPHRENIA AND HEALTHY CONTROL PARTICIPANTS

Anja Vaskinn^{*1}, Torill Ueland², Ingrid Melle², Kjetil Sundet³

¹*Centre for Research and Education in Forensic Psychiatry, Oslo University Hospital,*

²*University of Oslo and Oslo Univeristy Hospital,* ³*Univ of Oslo*

Background: There is limited evidence for sex differences in social cognition in schizophrenia, with conducted studies yielding mixed findings. Studies from the general population, however, indicate the possibility for a small female-advantage in social cognition. Since sex differences are present for other characteristics of schizophrenia, it is important to establish whether this is the case also for social cognition as it may serve as a basis for sex-specific treatment.

Methods: The presence of sex differences in social cognition among individuals with schizophrenia (n = 30-91) and in healthy controls (n = 71-185) was examined with five social cognitive tests. Emotion perception was assessed with Pictures of Facial Affect (PFA) and Emotion in Biological Motion (EmoBio). Social perception was measured with the Relationships Across Domains Test (RAD); ToM with the Movie for the Assessment of Social Cognition (MASC) and Hinting Task.

Results: Using two-way analyses of variance, we found a significant effect of group for all tests, in that healthy controls performed better than individuals with schizophrenia. Significant sex effects were present for PFA and Hinting Task, but we did not identify any significant interaction effects. In within-group independent samples follow-up t-tests, the only significant sex difference appeared among healthy controls for PFA.

Discussion: We found very few social cognitive sex differences. Although females had better facial emotion perception than males, this difference was statistically significant only among healthy controls. There were no significant sex differences for other social cognitive domains. The study did not find evidence for a general female advantage in social cognition. The results suggest that there is no need for sex-specific treatment of schizophrenia in terms of social cognition.

S52. FACIAL EXPRESSION AND EMOTION EXPERIENCE IN PATIENTS WITH SCHIZOPHRENIA

Shuaibiao Li^{*1}, Minyi Chu¹, Lingling Wang², Qinyu Lv¹, Simon S. Y. Lui³, Zhenghui Yi¹, Raymond C. K. Chan⁴

¹Shanghai Mental Health Center, ²Shanghai Normal University, ³The University of Hong Kong, ⁴Chinese Academy of Sciences

Background: Patients with schizophrenia (SCZ) usually exhibit blunted affect or disturbance of affect. However, it is still unclear whether these symptoms are caused by the deficits of the emotion experience process or the deficits of the emotion expression process. This study aimed to examine the relationship between emotional experience and emotional expression in patients with SCZ.

Methods: We recruited 28 SCZ patients and 27 healthy controls (HC). All participants watched three types of video clips: positive, neutral, and negative. Self-report measures of valence (unpleasant-pleasant) and arousal (deactivation-activation) were measured before and after viewing each movie clip. Moreover, we also used FaceReader to conduct real-time analysis of participants' facial expression while they were watching the video clips.

Results: Our results showed that there was no significant difference between SCZ and HC in the self-reported emotion valence of different types of video clips. However, SCZ patients' arousal after watching negative video clips was significantly lower than HC. HC also exhibited significantly higher facial expression of sadness while watching negative as compared to positive and neutral video clips. However, SCZ patients exhibited no significant difference among three different types of video clips.

Discussion: Patients with SCZ exhibited reduced emotional arousal and expressed reduced facial expression of sadness after watching negative video clips. These preliminary findings suggest that patients with SCZ may be impaired in the process of emotional expression and emotional experience of negative emotions.

S53. EMOTIONAL CONTAGION AND EMOTIONAL MIMICRY IN INDIVIDUALS WITH SCHIZOPHRENIA: A SYSTEMATIC REVIEW

Mathilde Parisi*¹, Ludovic Marin², Tifenn Fauviaux², Aigoïn Emilie², Stéphane Raffard³

¹EuroMov Digital Health in Motion, ²EuroMov Digital Health in Motion, Univ Montpellier, IMT Mines Ales, ³Epsilon Laboratory Dynamic of Human Abilities and Health Behaviors, University of Montpellier

Background: Individuals with a diagnosis of schizophrenia were shown to have social interaction deficits. Two emotional processes: emotional contagion (i.e., the transfer of emotion between individuals) and emotional mimicry (i.e., the imitation of emotional expressions) are associated with several social benefits including increased social interaction quality. Therefore, this review aimed to report measures of emotional contagion and emotional mimicry in individuals with a diagnosis of schizophrenia.

Methods: We conducted a Pubmed, Web of Science, and PsycInfo database search. Inclusion and exclusion criteria were determined based on the definition of emotional contagion and emotional mimicry rather than on using specific terminology to consider every field of research. More specially, to be considered in the review, studies must propose an experimental procedure with a human or an avatar stimulus expressing emotions through facial expression, vocalization, posture, or movement. Then, searchers must have measured the emotional state (i.e., through self-reported emotion or psychophysiological reactions) for emotional contagion or the emotional expression (e.g., facial expressions) for emotional mimicry of the participant in response to that stimulus. In addition, participants should be separated into at least two

groups, one group of individuals with a diagnosis of schizophrenia according to the DSM-V and one control group.

Results: Forty-two studies were included in the review, among which six were emotional mimicry studies and thirty-six were emotional contagion studies. The current findings suggested decreased or inappropriate emotional mimicry in individuals with a diagnosis of schizophrenia. Relating to emotional contagion, results showed altered brain and psychophysiological activity in individuals with a diagnosis of schizophrenia whereas self-reported measures indicated no difference between groups. The relationships between emotional contagion, emotional mimicry, and psychotic symptom severity showed variability across studies whereas no association between antipsychotic dosage and both emotional mimicry and emotional contagion were found.

Discussion: This review highlights three major points. First, there are limitations to the existing literature, indeed, there are huge discrepancies in methodologies and results within and across fields of research in the measure of emotional contagion. In addition, there are yet very few emotional mimicry studies in schizophrenia making it difficult to generalize a conclusion. However, the studies included in this review still point out potential emotional contagion and emotional mimicry alterations in schizophrenia. As emphasized previously, emotional contagion and emotional mimicry are associated with many social benefits. However, when these phenomena are decreased or incongruent, which seems to be the case in individuals with a diagnosis of schizophrenia, it not only prevents them from taking advantage of the social benefits but also worsens the quality of the interaction. Consequently, while this review encourages future studies to continue assessing emotional contagion and emotional mimicry in schizophrenia to reinforce the literature, it is also clear that emotional contagion and emotional mimicry training should from now on be incorporated into the social rehabilitation of individuals with a diagnosis of schizophrenia. Guidelines for future studies and clinical implications are discussed.

S54. PROBING VISUAL DISTORTIONS IN THE PSYCHOSIS PRODROME USING VIRTUAL REALITY

William Palmer^{*1}, Fabian Mueller², Nan Wang², Leon Franzen³, Steven Silverstein⁴, Philipp Sterzer², Dominique de Quervain², Tyrone Cannon¹, Albert Powers¹

¹*Yale University*, ²*University of Basel*, ³*University of Lübeck*, ⁴*University of Rochester Medical Center*

Background: There has been a growing recognition for the role of distorted perceptual experiences that do not rise to the level of complex hallucinations during early stages of psychosis. Recent studies have reported that over 60% of patients with schizophrenia endorsed experiencing visual distortions. These distortions have been associated with conversion to full-blown psychosis as well as core clinical features such as delusions and hallucinations. According to the Predictive Coding hypothesis of psychosis, symptoms are the result of aberrant perceptual inference due to imprecise integration of prior expectation and incoming sensory evidence. However, it remains inconclusive whether visual distortions originate from abnormal perceptual sensitivity or heightened sensory expectations. Furthermore, conventional experimental tasks typically fall short of capturing the phenomenology of natural perceptual disturbances, potentially limiting the generalizability of the findings. To address these issues, we have developed two psychometric tasks to disentangle perceptual sensitivity from bias

using immersive virtual reality (VR) videos of commonly endorsed visual distortions in ecologically valid environments. We have also created a Visual Distortion Screener that unlike conventional self-report measures provides video examples of the phenomena of interest to facilitate accurate symptom reporting. The psychometric tasks and clinical measure are currently being tested in an in-person study of clinical high risk (CHR) for psychosis patients and healthy controls as well as an online general population study.

Methods: In an ongoing pilot study, 30 CHR and 30 healthy controls are being recruited from New Haven, Connecticut. All participants first complete a VR task measuring sensitivity and bias to perceiving an unknown visual distortion. Participants are placed in a 360° video scenario and instructed to report when they detect any change in their environment. During the initial 30 seconds of the task, no distortion is presented, allowing for false percepts as a measure of bias. Then, one of the six distortions is gradually faded in over 90 seconds and the first accurate identification is used as a measure of sensitivity. Next, participants are administered our novel Visual Distortion Screener, which presents video examples of the distortions and assesses experiences by examining frequency, duration, perceived control, and distress. Finally, participants complete a two-interval forced choice task that measures participant-specific sensitivity to perceiving a target distortion. Over the course of 60 trials, the distortion intensity will be adapted using the Quest+ algorithm to attain a 75% detection threshold estimate. Following the lab visit, participants complete self-report measures of personality traits, perceptual experiences, and delusional thinking. CHR patients are also followed for one year with the Scale of Psychosis-Risk Symptoms scores recorded at baseline, 6 months, and one year.

In the online study, 100 adult participants are being recruited via Prolific. These participants complete an online version of our screener and additional measures of psychosis symptoms. Data collected from this sample will be used to determine base rates of these distortions in a general sample as well as establish how visual distortions relate to subclinical psychotic-like symptoms.

Results: Data collection and analysis is currently ongoing for the pilot and online study. We plan to present initial findings of the occurrence of visual distortions in a general sample and the relationship between visual distortion intensity and subclinical psychotic-like symptoms. We hypothesize that elevated visual distortion intensity will be associated with higher subclinical psychotic-like symptoms.

Discussion: Our Visual Distortion Screener may improve symptom characterization by circumventing the need for a patient to translate verbal descriptions into mental images by directly providing visual examples. Once validated, our video scenarios and screener will be openly released online. Furthermore, identifying whether visual distortions are rooted in poor bottom-up perceptual sensitivity or strong cognitive bias, could advance our understanding of the underlying mechanisms of visual distortions. Our novel psychometric tasks also lay the groundwork for uncovering brain markers of visual distortions as neural responses to complex, naturalistic stimuli are known to differ from conventional experimental stimuli. Given previous findings that these symptoms emerge early and are hypothesized to contribute to delusion formation, improved symptom identification and mechanistic understanding may provide novel opportunities and targets for prevention.

S55. PSYCHOTIC AND NEURODEVELOPMENTAL DISORDERS: A DIAGNOSTIC ISSUE. VALIDATION OF SPAIDD-P "SYSTEMATIC PSYCHOPATHOLOGICAL ASSESSMENT FOR PERSONS WITH INTELLECTUAL AND DEVELOPMENTAL DISABILITIES- PSYCHOTIC DISORDERS"

Luciana Forte*¹, Marco Bertelli¹, Felice Iasevoli², Annamaria Bianco¹

¹CREA (Research and Clinical Centre), Fondazione San Sebastiano, Misericordia di Firenze,

²Dipartimento di Neuroscienze e Scienze Riproduttive ed Odontostomatologiche, Università degli Studi di Napoli Federico II

Background: The global prevalence of Intellectual Disabilities (ID) ranges from 1% to 6%. The prevalence of autism spectrum disorder (ASD) reaches 2.8%. Around 35% of people with ID exhibit autistic traits, while up to 60% of those with ASD exhibit some degree of ID. The coexistence of ASD and ID configures the low-functioning ASD (LF-ASD), which increases the likelihood of developing psychiatric disorders in affected individuals by 4-5 times. The prevalence of psychotic disorders (PD) ranges from 3% to 8% and appears to rise with age, peaking between the ages of 33 and 44, although persons with ID can show an earlier onset than the general population. Non-affective psychosis is 10 times more common in individuals with ASD compared to the general population²⁰, with onset occurring in 30-50% of cases during childhood. 30% of persons with ID have an undiagnosed psychiatric disorder²². Distinguishing between ID, ASD, and other psychiatric disorders is challenging, especially for those in the schizophrenia spectrum, due to high co-occurrence rates and potential overlapping symptoms in people with LF-ASD. These disorders share alterations in cognitive functions, brain regions, neurotransmitter systems, and genes. In around half of cases, Problem Behaviours (PBs) represent Behavioral Equivalent (BEs) of psychopathological symptoms or clusters of symptoms. Specialized diagnostic tools can help identify BEs, enhancing knowledge of psychopathological features in people with ID/LF-ASD. The SPAIDD project (Systematic Psychopathological Assessment for people with Intellectual and Developmental Disabilities), is aimed to develop a complex array of psychopathological assessment tools for the diagnosis of major psychiatric disorders in persons with ID, based on behavioural observation, irrespective of the severity of cognitive impairment. The present paper reports the first results of a PhD research aimed at validating the SPAIDD-P, PD version of the SPAIDD battery, as well as evaluating its psychometric characteristics.

Methods: The first two versions of the SPAIDD-P were administered to a consecutive sample of 110 adults with ID and/or LF-ASD, who also underwent a comprehensive clinical and psychopathological assessment. Contemporarily, a systematic literature mapping on the presentation of PD in persons with ID/LF-ASD was carried out to identify possible new BEs to be included in the tool.

Results: Previous versions of SPAIDD-P demonstrated good internal consistency (Cronbach $\alpha \geq .6$) and a significant correlation between clinical diagnoses and the tool diagnostic scores (Pearson's $r = .280$; $p \leq .01$). Three factors, hallucinatory, delusional, and paranoid, explained 50% of the tool score variance, unaffected by gender, age, ID severity, co-occurrence of ASD. These processes allowed to produce a new checklist.

Discussion: SPAIDD-P seems to be a valid tool for assessing psychotic disorders in people with ID / LF-ASD due to its good psychometric features. The revised SPAIDD-P includes 24 items, each corresponding to a symptom or cluster of symptoms for diagnosis according to DSM-5 and ICD-11 criteria. It identifies Delusional Disorder, Brief Psychotic Disorder, Schizophreniform Disorder, Schizophrenia, and Personality Disorders.

S56. SELF-RATED EMPATHY AND COMPASSION IN SCHIZOPHRENIA

Federica Klaus*¹, Rebecca Daly¹, Ellen Lee¹, Lisa Eyster¹

¹*University of California - San Diego*

Background: People with schizophrenia (SZ) experience lower levels of social functioning than people without (HC). Impairments in social functioning cause significant disability, hindering recovery. Most mental health research is focused on deficits, while a strength-based, recovery-oriented approach focusing on positive psychological traits could improve well-being.

Positive psychological traits include compassion, self-compassion and empathy (EC), which can be considered to enhance social functioning. Higher levels of EC are associated with better well-being, more positive affect, less depressive symptoms, and better mental health. In SZ, most studies point to reduced participant-reported aspects of empathy compared to HC; few studies have compared compassion or self-compassion between SZ and HC, with one study observing lower levels of compassion and self-compassion in SZ vs HC. Within SZ, a relationship of more self-compassion with fewer symptoms of SZ and better physical well-being was observed. To our knowledge, the level and correlates of participant-reported compassion, self-compassion and empathy in SZ and how this differs from matched HC have not been elucidated in the same sample. We hypothesized lower levels of self-rated EC in SZ vs HC and that higher EC would be related to higher resilience and happiness and lower depression particularly in the SZ group

Methods: In a cross-diagnostic, observational approach, group differences in participant-reported levels of compassion (Santa Clara Brief Compassion Scale score), self-compassion (Neff Self-Compassion Scale) and empathy (composite of empathy related items from SD-WISE) in a dataset of 201 people (115/86 (HC/SZ, age range 29-73 years, age- and gender-matched)) were compared. Levels of resilience (Connor Davidson Resilience Scale) and depression and happiness (CESD) were correlated with EC measures. Linear mixed models controlled for age and gender. All tests are two-sided with $\alpha=0.05$.

Results: The mean (SD) age of participants was 52.3 (11.6) years, 53% female, and education was 16.6 (2.0)/13.8 (2.4) years. The racial/ethnic distribution was 60% White, 11% Black/African American, 27% Hispanic, 4% Asian, and 3% More than One Race. Partially in line with our hypotheses, levels of self-rated self-compassion ($F(1,164)=10.3$, $p=0.002$) and empathy ($F(1,172)=38.1$, $p < 0.001$) were lower in SZ vs HC, with no differences in compassion towards others ($F(1,174)=1$, $p=0.31$). While significant in both groups, correlates were generally stronger in HC vs SZ, including a stronger positive relationship of resilience and happiness with self-compassion and of resilience with empathy, and a stronger negative relationship of depression with self-compassion.

Discussion: Our hypothesis on differential experiences of EC between groups is supported, while on the direction of significant moderator's influence is not. Potentially the SZ group could benefit from interventions to increase resilience, happiness and reduce depression to boost the experience of positive psychological mechanisms. Understanding subjective perceptions of EC and specifically self-compassion could help to improve social functioning in SZ. Interventions to increase self-compassion might reduce perceptions of low self-efficacy, counter defeatist beliefs about social processes and increase positive affect. Specifically in SZ, reduction in defeatist beliefs have been shown to be linked to improved functioning. Ideally, these findings would advance the existing research on EC as positive psychological traits that foster wellbeing and allow development of novel EC-focused interventions to increase well-being in SZ.

S57. UNDERSTANDING THE DIMENSIONS OF SOCIAL COGNITION IN AUTISM SPECTRUM AND SCHIZOPHRENIA SPECTRUM DISORDERS

Ayesha Rashidi*¹, Lindsay Oliver², Colin Hawco¹, George Foussias¹, Robert Buchanan³, Anil Malhotra⁴, Meng-Chuan Lai², Aristotle Voineskos¹, Stephanie Ameis¹

¹*Centre for Addiction and Mental Health, University of Toronto*, ²*Centre for Addiction and Mental Health*, ³*Maryland Psychiatric Research Center, University of Maryland School of Medicine*, ⁴*Zucker Hillside Hospital, Feinstein Institute for Medical Research*

Background: Individuals with autism spectrum disorder (autism) or schizophrenia spectrum disorders (SSDs) exhibit greater deficits in social cognition compared to those without these conditions (i.e., typically developing controls, TDCs). Studies have shown that these social cognitive deficits severely impair psychosocial functioning and quality of life, however, the underlying mechanism behind this impairment is poorly understood. To better determine the effects of social cognition on mental health symptoms and functioning, we aim to examine the underlying factor structure related to social cognitive performance across a transdiagnostic dataset, including participants with autism and SSDs.

Methods: This study utilizes data from two harmonized NIMH-funded RDoC studies, including n= 100 autism (aged 16-35 years), 276 SSDs, and 209 typically developing controls (TDCs) (SSDs/TDC: aged 18-55 years). All participants completed a variety of validated assessments including social cognitive (e.g., ER-40, TASIT-R, RMET, Empathic Accuracy), neurocognitive (e.g., MCCB), clinical, and functional measures (e.g., Birchwood Social Functioning Scale, BSFS). Initial group-wise comparisons were carried out to examine performance characteristics across groups. Structural equation modeling was then used to test whether social cognitive measures acquired across a transdiagnostic dataset are consistent with a two-factor model including a lower-level and higher-level factor, as found in SSDs/TDCs.

Results: Group-wise comparisons revealed significant between-group differences in social cognitive performance on all tasks (p LESS THAN 0.001). Lower scores were consistently found in SSDs compared to controls (p LESS THAN 0.001), whereas autistic-control differences were limited to those found on TASIT-2 (simple and paradoxical sarcasm) and TASIT-3 Lies subscales (p LESS THAN 0.001), and ER-40 (p LESS THAN 0.01). Notably, autistic individuals outperformed those with SSDs in most tasks (all p LESS THAN 0.001), except ER-40, TASIT-1, TASIT-3-Lies. The hypothesized two-factor social cognition model, comprising a lower-level "simulation" factor (e.g., emotion detection) and higher-level "mentalizing" (e.g., theory of mind) factor exhibited an adequate fit in our transdiagnostic sample ($\chi^2 = 40.53$, $df = 13$, $P \text{ LESS THAN } 0.001$, $CFI = 0.979$, $TLI = 0.966$, $RMSEA = 0.06$, $SRMR = 0.03$).

Discussion: Preliminary findings in this sample reveal a pattern indicating broader impairments across social cognitive tasks in SSDs than autism. Autistic individuals displayed selective impairments, indicating a more circumscribed impairment on low and high-level social cognitive tasks at the group level. Despite disorder-specific patterns, a transdiagnostic two-factor social cognitive model suggests a common structure of social cognition, including separate simulation and mentalizing factors. However, further investigation of the group-specific models and related fit measures is required to fully characterize the complexity and variability of social cognitive processes across groups. The anticipated results of this study will enhance our understanding of the overlapping nature of social cognitive impairments in autism

and SSDs. The study's findings, especially efforts to establish a transdiagnostic social cognition model, serve as an important foundational step to facilitate future research to develop targeted interventions and enhance the quality of life for individuals affected by these disorders.

S58. LONG-TERM COGNITIVE FUNCTION IN PATIENTS WITH SCHIZOPHRENIA SPECTRUM DISORDERS: LONGITUDINAL CHANGES 10 TO 20 YEARS AFTER FIRST DIAGNOSIS

Marie Starzer*¹, Helene Gjervig Hansen², Nikolai Albert³, Carsten Hjorthøj⁴, Merete Nordentoft⁵, Louise Birkedal Glenthøj⁶

¹Gentofte University Hospital, University of Copenhagen, ²Copenhagen Research Centre for Mental Health, University of Copenhagen, ³Copenhagen Research Center for Mental Health – CORE, ⁴Copenhagen University Hospital, Mental Health Center Copenhagen, ⁵Mental Health Center Copenhagen, University of Copenhagen, ⁶Copenhagen Research Center for Mental Health (CORE), Mental Health Center Copenhagen, AND University of Copenhagen, Faculty of Social Sciences, Department of Psychology,

Background: Cognitive deficits are a core feature of schizophrenia and are closely associated with poor functional outcomes. While a lot of research has focused on cognitive development, long-term results are scarce, and it remains unclear if cognitive deficits progress over time or remain stable. Determining patients at increased risk of progressive worsening might help targeted neurocognitive remediation approaches.

Methods: This 20-year follow-up study examined the neurocognitive outcomes of 156 participants from the OPUS I trial. Neurocognition was assessed using the brief assessment of cognition in schizophrenia at the 10- and 20-year follow-up, allowing us to examine changes in neurocognition over a 10-year period during the later course of illness.

Results: We found that 30.5% of patients have a declining course of neurocognition, 49.2% have a stable course of neurocognition, and 20.3% experience improvements in neurocognition. Good cognitive functioning at the 20-year follow-up was significantly associated with higher levels of social functioning while increasing experiential negative symptoms were significantly correlated to cognitive worsening. Older age at inclusion and low level of education (below 10 years) predicted declining neurocognition, while cannabis cessation after the 10-year assessment and early remission predicted improved executive functioning.

Discussion: Our findings support the notion of different schizophrenia subtypes with varying trajectories and emphasize the need to examine cognition individually and not as a group mean, because the course differs between patients. Neurocognitive impairment at the 20-year follow-up was associated with other poor outcomes, highlighting the importance of treatments to improve neurocognition in patients with schizophrenia spectrum disorders. Since cognitive remediation therapy has been proven very successful, this treatment should be prioritized for patients at risk of cognitive decline.

S59. IDENTIFYING PROTEIN MARKERS ASSOCIATED WITH ECT IN SCHIZOPHRENIA PATIENTS: A PRELIMINARY STUDY

Sunghyun Park*¹, Minah Kim², Jun Soo Kwon²

¹Seoul National University Hospital, ²Department of Psychiatry, Seoul National University College of Medicine

Background: Electroconvulsive therapy (ECT) is an effective treatment for treatment-resistant schizophrenia, though underused due to social stigma, resource demands, and potential side effects like memory loss. Biomarkers that mediate ECT response could lead to less invasive alternatives and enable more targeted treatments. While biomarker research in depression is well-established, it is limited in schizophrenia.

Serum proteomic analysis is a promising approach due to its accessibility and ability to reflect rapid biological changes from ECT. Prior studies have shown serum BDNF and proBDNF/BDNF ratio changes in schizophrenia patients post-ECT, correlating these with treatment response and brain structural changes.

This study investigates serum proteomic profiles in schizophrenia patients undergoing ECT and pharmacotherapy, versus pharmacotherapy alone, aiming to identify ECT-specific changes. This could enhance our understanding of ECT's mechanisms and support predictive models for treatment response.

Methods: This study, conducted at Seoul National University Hospital between June 2018 and December 2022, involved a total of 65 patients diagnosed with schizophrenia or schizoaffective disorder. The participants were divided into two groups: 34 patients underwent electroconvulsive therapy (ECT) and medication treatment while 31 received medication-only treatment during the same period. The ECT group received bitemporal brief-pulse ECT 2-3 times per week, totaling 8-20 sessions. Psychiatric medications were continued as before, with necessary adjustments made based on clinician's decision. Clinical assessments, including the Positive and Negative Syndrome Scale (PANSS), and blood sampling were conducted before the start and within one week after the end of ECT treatment for the ECT group, and at recruitment and 4 weeks later for the medication-only control group. After removing abundant proteins, label-free quantification was performed using liquid chromatography-tandem mass spectrometry.

Results: A total of 1130 proteins were quantified. Among these, 112 proteins exhibited significant changes in expression levels after ECT in the ECT group. Notably, 106 of these proteins showed changes exclusive to the ECT group, with no corresponding changes observed in the medication control group. Pathway analysis revealed that these proteins were associated with pathways related to the innate immune system, complement cascade, and hemostasis, indicating an overrepresentation of these pathways in the response to ECT. Further analysis showed that among the 106 differentially expressed proteins, changes in three specific proteins – Podocalyxin (PODXL; $r=0.0856$), Insulin-like Growth Factor 2 (IGF-2; $r=0.2032$), and Biglycan (BGN; $r=0.3509$) – were significantly positively correlated with reductions in PANSS (Positive and Negative Syndrome Scale) scores.

Discussion: These results provide insights into the specific protein changes associated with ECT in schizophrenia spectrum disorders, highlighting potential biomarkers and molecular pathways implicated in the therapeutic response to ECT.

S60. CLASSIFYING SCHIZOPHRENIA WITH MACHINE LEARNING ALGORITHMS: A META-ANALYTIC INVESTIGATION OF TASK-BASED NEUROIMAGING DATA

Chao Yan^{*1}, Xuan Wang², Peng-yuan Yang³, Zheng Xia⁴, Xin-lu Cai⁵, Yi Wang², Sze Kwok⁶, Raymond Chan²

¹Key Laboratory of Brain Functional Genomics (MOE and STCSM), Shanghai Changning-ECNU Mental Health Center, School of Psychology and Cognitive Science, East China Normal University, ²Neuropsychology and Applied Cognitive Neuroscience Laboratory; CAS Key Laboratory of Mental Health, Institute of Psychology, Chinese Academy of Sciences, ³Department of Psychology, University of Chinese Academy of Sciences, Beijing, China e Social and Health psychology, Maastricht University, ⁴Key Laboratory of Brain Functional Genomics (MOE and STCSM), Affiliated Mental Health Center (ECNU), School of Psychology and Cognitive Science, East China Normal University, ⁵Institute of Brain Science and Department of Physiology, School of Basic Medical Sciences, Hangzhou Normal University, ⁶Phylo-Cognition Laboratory, Division of Natural and Applied Sciences, Data Science Research Center, Duke Kunshan University, Kunshan

Background: Schizophrenia (SCZ) poses a complex and heterogeneous challenge for researchers seeking reliable biomarkers to enhance diagnostic accuracy. The advent of machine learning (ML) techniques has provided opportunities for discovering biomarkers linked to SCZ through task-related fMRI (t-fMRI) designs. In the present study, we aimed to assess the efficacy of this approach by conducting a meta-analysis of task-related fMRI (t-fMRI) studies utilizing a bivariate model.

Methods: There were 30 papers, encompassing 31 studies, identified. We used the bivariate model proposed by Reitsma to conduct a meta-analysis, assuming that sensitivity and specificity followed a binomial normal distribution. To evaluate the possibility of publication bias, we conducted the Deek's test that examines the significance of funnel plot asymmetry. To investigate the impact of various factors on the chosen classification performance indicators, we conducted moderator analyses on those factors such as neuropsychological domains, demographic factors, ML approach-related factors, classification algorithm used, as well as clinical factors.

Results: We observed a notable overall sensitivity of .83 and specificity of .82 in t-fMRI studies. Notably, the classification performance was influenced by neuropsychological domains, where selective attention exhibited significantly higher specificity compared to working memory ($\beta = 0.98$, $z = 2.11$, $p = .04$). T-fMRI studies on selective attention had higher sensitivity and specificity than sMRI studies (Sensitivity: $\beta = .87$, $z = 3.77$, $p < .001$; Specificity: $\beta = .76$, $z = 3.24$, $p = .001$) and higher specificity than r-fMRI studies ($\beta = .79$, $z = 3.38$, $p = .001$). Moreover, studies involving older, chronic SCZ patients reported higher sensitivity ($p < .015$) and specificity ($p < .001$) than those involving younger, first-episode patients or high-risk individuals for psychosis. Furthermore, we identified a positive association between the severity of negative symptoms and the specificity of the classification model ($\beta = 7.19$, $z = 2.20$, $p = .03$).

Discussion: In summary, these findings underscore the promise of utilizing task-based fMRI data in conjunction with machine learning techniques to pinpoint biomarkers associated with symptom outcomes in SCZ. This presents a hopeful path toward enhancing diagnostic accuracy and treatment efficacy. Future endeavors in ML classification should carefully address considerations such as algorithm selection, data quality and quantity, and issues related to generalization.

S61. THalamo-CORTICAL WHITE MATTER CONNECTIVITY AS AN INDICATOR OF ELECTROCONVULSIVE THERAPY RESPONSE IN PATIENTS WITH SCHIZOPHRENIA SPECTRUM DISORDER

Minah Kim^{*1}, Hyungyou Park², Jun Soo Kwon³

¹Seoul National University Hospital, ²Department of Brain and Cognitive Sciences, Seoul National University College of Natural Sciences, ³Department of Psychiatry, Seoul National University College of Medicine, Department of Brain and Cognitive Sciences, Seoul National University,

Background: Electroconvulsive therapy (ECT) is an effective treatment for patients with treatment resistant schizophrenia spectrum disorders (SSD). However, understanding of underlying mechanisms for ECT response has not yet been sufficient in addition to lack of knowledge regarding the target for region specific neuromodulation. Therefore, we investigated thalamo-cortical white matter (WM) connectivity as an indicator of ECT response in patients with SSD.

Methods: A total of 26 SSD patients and age-, sex-matched 28 healthy controls (HCs) underwent diffusion tensor imaging (DTI) to examine the probabilistic tractography of thalamo-cortical WM connectivity. DTI recordings were performed twice before (T1) and after (T2) the course of ECT (i.e., 1-2 months interval) in SSD group, and data were compared across time and groups (i.e., SSD vs. HCs). Relationship of change in thalamo-cortical WM connectivity and symptomatic improvement by ECT was explored in SSD patients.

Results: At T1, SSD patients showed lower thalamo-lateral prefrontal cortex WM connectivity and higher thalamo-parietal cortex (PC) WM connectivity than in HCs. At T2, difference of thalamo-PC WM connectivity shown at T1 was disappeared between SSD patients and HCs. In SSD patients, there was significant decrease of thalamo-PC WM connectivity between T1 and T2. In addition, change in thalamo-PC WM connectivity was significantly associated with improvement in Positive and Negative Syndrome Scale total and Clinical Global Impression-Severity scores in SSD patients.

Discussion: The current study results suggest that decrease in thalamo-PC WM connectivity can be an indicator of ECT response in SSD patients. Furthermore, PC may be a future target for region specific neuromodulation in patients with treatment resistant SSD.

S62. INSULIN RESISTANCE IN SCHIZOPHRENIA: IS IT RELATED TO GUT-BRAIN AXIS?

Manuel Couce-Sánchez^{*1}, Gonzalo Paniagua¹, Leticia González-Blanco¹, Ainoa García-Fernández², Clara Matínez-Cao², Francesco Dal Santo¹, Paula Zurrón¹, Julio Bobes², María Paz García-Portilla¹, Pilar Alejandra Sáiz¹

¹Central University Hospital of Asturias, ²University of Oviedo

Background: Glucose metabolism is impaired in patients with schizophrenia (SZ), even in naïve patients with psychosis (Xiu et al. 2023; Greenhalgh et al. 2017), but the causes remain unclear. As gut dysbiosis (imbalance of intestinal microbiota composition) seems to play a role in the etiopathology of SZ (Shi et al. 2023) and has also been shown in general population with

insulin resistance (Kant et al. 2022), we aim to find out if alterations in gut-brain axis play a role in glucose metabolism in SZ.

Gut dysbiosis can be evaluated indirectly through lipopolisaccharide binding protein (LBP), a plasmatic marker of increased gut permeability and bacterial translocation from gut to blood (Severance et al. 2013).

Methods: Cross-sectional study of 101 patients [mean age = 41.0 ± 12.08 , range = 18-67; males = 62 (61.4%)] with diagnosis (DSM-5) of SZ (without antidiabetics or a diagnosis of diabetes) recruited from their mental health outpatient clinics in Oviedo (Spain).

Assessment:

- Plasmatic glucose (mg/dL), insulin ($\mu\text{U/mL}$), HOMA-IR (Homeostasis model assessment: insulin resistance); insulin resistance = $\text{HOMA-IR} \geq 3.0$.
- Plasmatic LBP ($\mu\text{g/mL}$), C-reactive protein (CRP; mg/dL).
- International Physical Activity Questionnaires (IPAQ: low activity vs moderate/vigorous), Mediterranean Diet Adherence Score (MEDAS), toxic habits (alcohol use/smoking/cannabis).
- CGI, Chlorpromazine equivalent doses (CPZ-ED), body mass index (BMI) (kg/cm^2).

Statistics: Spearman correlation, t Student, χ^2 , stepwise logistic regression.

Results: 54 patients (53.5%) showed insulin resistance, with a mean HOMA-IR = 4.14 ± 3.3 , while 36 people (35.6%) had increased gut permeability (LBP GREATER THAN $15 \mu\text{g/mL}$).

We found relation between HOMA-IR values and BMI ($r = 0.545$, $p \text{ LESS THAN } 0.001$), but not with age, sex, length of illness, CRP, CGI, CPZ-ED and MEDAS. A partial correlation for HOMA-IR and LBP controlled by BMI was near to statistical signification ($r=0.197$, $p=0.060$).

Patients with insulin resistance had higher levels of LBP ($t = 3.754$, $p \text{ LESS THAN } 0.001$) and BMI ($t = 4.570$, $p \text{ LESS THAN } 0.001$). Insulin resistance was more prevalent in people with low physical activity based on IPAQ ($\chi^2 = 7.944$, $p = 0.005$) but no differences were found by other studied variables.

A logistic regression analysis was performed for insulin resistance considering LBP, BMI and IPAQ as independent variables. The overall regression was statistically significant (Cox-Snell $R^2 = 0.352$, $p = 0.01$), including all variables in the model: LBP (OR = 1.25, $p \text{ LESS THAN } 0.001$), BMI (OR = 1.18, $p \text{ LESS THAN } 0.001$) and high/moderate physical activity (OR = 0.24, $p = 0.013$).

Discussion: In our sample of SZ patients there is a high prevalence of increased gut permeability and insulin resistance, as previously described (Xiu et al., 2023; Greenhalgh et al., 2017; Shi et al., 2023), so gut permeability seems to be a risk factor for developing insulin resistance in patients with SZ, as well as BMI and low physical activity.

S63. SPARING OF NATURAL LANGUAGE PROCESSING DEFICITS IN SCHIZOTYPAL PERSONALITY DISORDER COMPARED WITH SCHIZOPHRENIA: NEGATIVE SYMPTOM AND SUPERIOR TEMPORAL GYRUS VOLUME CORRELATES

Erin A. Hazlett^{*1}, Mary Kowalchuk², Alessia McGowan², Sean Hollander², Elen-Sarrah Dolgopolskaia², Katelyn N. Challman¹, Agrima Srivastava², Chi C. Chan², M. Mercedes Perez-Rodriguez², M. Mehmet Haznedar¹, Margaret M. McClure², Stephen Heisig², Kim E. Goldstein², Philip Szeszko¹, Cheryl Corcoran¹

¹*Icahn School of Medicine at Mount Sinai and James J. Peters VA*, ²*Icahn School of Medicine at Mount Sinai*

Background: Thought disorder and disorganized speech occur across the schizophrenia (SZ) spectrum, including deficits in syntactic complexity (e.g., poverty of speech) and semantic coherence (e.g., perseveration, tangentiality, looseness of associations). Traditionally, this has been assessed using clinical assessments. More recently, these metrics are being studied using automated methods of natural language processing (NLP). While previously examined in SZ, clinical high risk (CHR) for psychosis, and psychometric schizotypy, this is the first study to examine: (a) NLP across the SZ spectrum, including healthy controls (HCs), individuals with schizotypal personality disorder (SPD), and recent-onset SZ patients and (b) how NLP is correlated with clinical symptom severity and volume of key language brain regions across the spectrum. The four brain regions were: Pars Opercularis/Brodmann area (BA)44 (language production); Pars Triangularis/BA45 (semantic processing); Pars Orbitalis/BA47 (language processing); and Superior Temporal Gyrus (STG)/BA22 (auditory).

Methods: Participants in this ongoing study were 41 HCs, 26 individuals with SPD, and 26 SZ patients. The participants were rigorously screened and assessments included SCID-5 and SIDP structured diagnostic interviews and the Positive and Negative Syndrome Scale (PANSS).

NLP: Naturalistic speech samples were obtained using an open-ended 45-min narrative research interview identical to our prior SZ and CHR studies. Interviews were then transcribed using a HIPAA-compliant transcription service. Next, the text from the interview was processed following our standard NLP pipeline. Part-of-Speech tags, phrase length, and Bidirectional Encoder Representations from Transformers (BERT) embeddings were generated for analysis of complexity and coherence. Groups were compared using ANCOVA (covarying age/sex) and follow-up Tukey HSD post-hoc tests.

MRI: All participants received a 3T MRI scan (Siemens MAGNETOM). Cortical reconstruction and volumetric segmentation were performed on MP-RAGE using Freesurfer image-analysis software. Bivariate-correlations were calculated to examine associations between NLP, clinical symptom severity, and volume of the four key language brain regions in the left and right hemisphere.

Results: SZ patients showed: a) reduced complexity compared with HC (p LESS THAN 0.08) and SPD (p LESS THAN 0.03) groups, 1-way ANCOVA, p=0.05. Interestingly, across the SPD+SZ groups, reduced complexity was associated with smaller left but not right STG volume (p LESS THAN 0.05). 2) greater coherence, consistent with perseveration, compared with both HC (p LESS THAN 0.001) and SPD (p LESS THAN 0.02) groups (SPD group was intermediate and did not differ from HCs). Importantly, across the SPD+SZ groups, greater coherence was associated with greater negative but not positive symptom severity (p LESS THAN 0.03).

Discussion: This is the first study to show that SZ patients have reduced syntactic complexity compared to individuals with SPD. Prior work has shown SZ patients have reduced complexity compared with HCs. Our finding of reduced complexity being associated with smaller left STG volume across the SZ spectrum is novel and consistent with prior work showing left

hemisphere dominance for language, and SZ-related STG volume deficits which are less marked in SPD. SZ patients also had greater coherence, consistent with perseveration, compared with both HC and SPD groups and this was associated with greater negative (deficit) symptom severity. These findings suggest that in SPD, sparing of language and STG volume deficits may serve as protective factors in mitigating psychosis. Next steps include continuing to grow our sample size, examining prosody (e.g., intonation), and examining whether NLP at baseline predicts functional outcome and changes in brain function/connectivity/volume, and cognition at 18-month follow-up.

S64. ALTERATIONS OF ASTROCYTES IN THE MEDIAL ORBITOFRONTAL CORTEX AND COGNITIVE FUNCTIONS IN PATIENTS WITH SCHIZOPHRENIA

Sunah Choi^{*1}, Minah Kim², Sang Soo Cho¹, Woori Choi¹, Harin Oh¹, Jongrak Kim¹, Jungha Lee¹, Su-Jin An¹, Jun Seo Hwang¹, Yun-Sang Lee², In Chan Song², Sun-Young Moon³, Silvia Kyungjin Lho⁴, Jun Soo Kwon¹

¹Seoul National University College of Natural Sciences, ²Seoul National University College of Medicine, ³Seoul National University Bundang Hospital, ⁴Seoul Metropolitan Government-Seoul National University Boramae Medical Center

Background: The underlying mechanism of cognitive and negative symptoms in schizophrenia remains poorly understood. Studies suggested that changes in the medial orbitofrontal cortex (mOFC) and abnormal astrocytes may contribute to the development of the symptoms. However, there is inconsistency in in vivo findings using previous imaging targets. Reactive astrocytes upregulate monoamine oxidase B (MAO-B) expression, and MAO-B binding positron emission tomography (PET) enables the in vivo imaging of astrocyte reactivity. In this study, we aimed to investigate the relationship between cognitive and negative symptoms and reactive astrocytes in the mOFC in patients with schizophrenia using MAO-B binding PET.

Methods: This study analyzed MAO-B binding [18F]THK5351 PET data from 33 patients with schizophrenia and 35 age- and sex-matched healthy controls (HCs). We tested group differences in standardized uptake value ratio (SUVr) in the mOFC and their association with Wisconsin Card Sorting Test (WCST) performance scores and Positive and Negative Syndrome Scale (PANSS) negative symptom scores.

Results: Schizophrenia patients showed higher SUVr in the bilateral mOFC compared to HCs (left, $t = -2.01$, $p = 0.048$; right, $t = -2.04$, $p = 0.045$). Negative correlations were observed between SUVr and WCST performance scores (left, $r = -0.33$, $p = 0.006$; right, $r = -0.26$, $p = 0.032$). The correlation between SUVr and PANSS negative symptom scores was not statistically significant.

Discussion: These findings provide evidence supporting an association between reactive astrocytes in the mOFC and cognitive functioning including executive function in schizophrenia. Our study suggests a potential biomarker for the neurobiological mechanism underlying cognitive symptoms in schizophrenia.

S65. VALIDATION OF DIAGNOSTIC AND PREDICTIVE FMRI BIOMARKERS IN SCHIZOPHRENIA

Jose Rubio*¹, Todd Lencz², Hengyi Cao³, Elvisha Dhamala⁴, Nina Kraguljac⁵, Juan Gallego², Guillermo Horga⁶, John Kane⁷, Anil Malhotra⁸

¹Northwell Health, ²The Zucker Hillside Hospital, ³Feinstein Institute for Medical Research and Zucker Hillside Hospital, ⁴Feinstein Institutes for Medical Research, ⁵The Ohio State University, ⁶Columbia University and New York State Psychiatric Institute, ⁷The Donald and Barbara Zucker School of Medicine at Hofstra/Northwell, ⁸The Feinstein Institutes for Medical Research

Background: fMRI readouts of function in the striatum have emerged as promising diagnostic and predictive biomarkers in schizophrenia. For instance, the Functional Striatal Abnormalities (FSA) score was developed to classify individuals with schizophrenia vs healthy controls using inputs from striatal functional connectivity and striatal fALFF, two measures derived from resting state fMRI. In a rigorous internal validation, the FSA demonstrated high diagnostic accuracy (GREATER THAN 80%) and there were data to suggest that it could predict treatment response. Separately, our team developed another biomarker, the Striatal Connectivity Index (SCI), a measure that summarizes functional striatocortical connections relevant to treatment response. In the initial publication, the SCI was externally validated in a separate cohort of 40 individuals, which yielded classification accuracy of ultimate treatment response of 78%. To bring these biomarkers closer to clinical application, it is critical to demonstrate that they do replicate in unseen data. Here we are presenting replications of the diagnostic and predictive ability of the FSA, and of the predictive performance of the SCI in novel datasets.

Methods: Using the original scripts, we calculated FSA scores in the Human Connectome Project for Early Psychosis dataset, which includes individuals within 5 years of a diagnosis of a psychotic disorder (n=101) and healthy controls (n=51). This dataset has different demographic and MRI acquisition characteristics to the FSA development dataset. Similarly, and also using the original scripts, we calculated SCI values from scans of individuals participating in the Human Connectome Project for Early Psychosis, as well as in a separate cohort of 97 individuals with first episode psychosis who were subsequently treated with risperidone or aripiprazole for 12 weeks, and for whom treatment response could be determined prospectively. We tested classification accuracy for cases vs controls in the Human Connectome Project dataset for the FSA (diagnostic biomarker performance) by the area under the curve (AUC) in receiver operator characteristic (ROC) curves. Similarly, we attempted to replicate the prediction of treatment response by the FSA and SCI in the treatment cohort by calculating AUCs for ROCs that used a categorical definitions of treatment response in agreement with our previous work.

Results: The FSA had good/excellent diagnostic discrimination (AUC=75.4%, 95%CI=67.0%-83.3%; in non-affective psychosis AUC=80.5%, 95%CI=72.1-88.0%, and in affective psychosis AUC=58.7%, 95%CI=44.2-72.0%). However, when tested in the treatment cohort, baseline FSA scores did not classify those who would be responders from non-responders better than chance. Tested in an independent treatment cohort, baseline SCI scores classified responders from non-responders better than chance (AUC=72.1%, 95%CI=65.1%-80.2%).

Discussion: Using independent data, we replicated the individual prediction performance for the indication for which each fMRI biomarkers was originally developed: The FSA for diagnostic classification and the SCI for prediction of treatment response. These data show that fMRI biomarkers are generalizable, a prerequisite for their clinical application. The FSA replication yielded better performance than that of the SCI, which likely reflects the large dataset in which it was originally developed (n=1,100 for the FSA vs n=41 for the SCI). Despite

replication performance was good for the SCI, it falls short of the minimum accuracy of 80% generally recommended for clinical use. Optimization of the SCI using pooled datasets may further improve predictive performance, enough to be used in clinical applications.

S66. CEREBELLAR MORPHOMETRY IN SCHIZOPHRENIA: AN INVESTIGATION ACROSS DIFFERENT ILLNESS STAGES

Neelabja Roy*¹, Rakshathi Basavaraju¹, Urvakhsh Meherwan Mehta¹

¹*National Institute of Mental Health and Neurosciences*

Background: Brain connectivity within the cerebellar-thalamo-cortical circuits has been found to be impaired in schizophrenia (Andrease, Paradiso, and O'Leary., 1998). It is not well established if there are morphometric abnormalities in the individual structures that comprise this critical circuitry. We aim to compare volumetric measures in these brain regions between individuals with schizophrenia (two MRIs acquired 2 years apart) and healthy comparison subjects.

Methods: We recruited three groups of subjects at the National Institute of Mental Health and Neurosciences, Bangalore, India: a clinical group of 54 drug naïve first-episode schizophrenia (FESdn), 22 FES remitted group after 2 years of treatment with risperidone (FESrm) and 43 healthy comparison participants (HC) recruited locally. MRI scans were obtained on a 3-Tesla MRI scanner using a 32-channel head coil to acquire high-resolution structural MRI (T1 MPRAGE sequence; 5m) of 1-mm section with no inter-slice gap. The scans were then subjected to Freesurfer recon-all processes for volumetric morphometry. Post validation of satisfactory segmentation with successful visual inspection, the aseg and aparc volumes of the regions of our interests were derived for all subjects across all groups. Then independent t tests were performed for volumetric differences between HC-FESdn and HC-FESrm.

Results: We found significantly reduced volumes in the right ($p=.001$, Cohen's $d=.667$) and left ($p=.006$, $d=.573$) cerebellar cortices in FESdn compared to HC group. and no difference in either thalamus between HC and FESdn. We also observed significantly reduced volumes in the right ($p \text{ LESS THAN } .001$, $d=.996$) and left ($p=.002$, $d=.818$) cerebellar cortices and the left thalamus ($p=.019$, $d=.625$) in FESrm compared to HC. We also observed significant differences in Left Posterior Cingulate ($p=.007$, $d=.558$), Right Posterior Cingulate ($p=.000$, $d=.743$), Right Rostral Anterior Cingulate ($p=.047$, $d=.410$) between HC and FESdn, and significance in difference in Left Posterior Cingulate ($p=.007$, $d=.558$), Right Posterior Cingulate ($p=.000$, $d=.743$), Right Rostral Anterior Cingulate ($p=.047$, $d=.410$) between HC and FESrm. The cerebellar volume differences in both the patient groups remained significant on FDR corrections.

Discussion: Cerebellar structural deficiencies in terms of volume reductions may play a central role in schizophrenia across stages of illness. Future studies may examine if these structural deficiencies are associated with functional aberrations in the cerebellar-thalamo-cortical circuits in schizophrenia. Lack of follow-up data in the HC group and the lack of randomized treatment allocation limits our inferences on the progressive nature of these aberrations and the potential role medications might play.

S67. INCREASED PLASMA LEVELS OF MATRIX METALLOPROTEINASES IN EARLY PSYCHOSIS, ANXIETY AND DEPRESSION: EVIDENCE FROM THE ALSPAC COHORT.

Lorenzo Ghelfi^{*1}, David Mongan¹, David Cotter¹

¹*Royal College of Surgeons in Ireland*

Background: Converging evidence supports the role of Matrix Metalloproteinases (MMPs) in psychiatric disorders. Originally identified as regulators of the extracellular matrix (ECM), MMPs functions span multiple processes, including inflammation, synaptic plasticity, neuronal migration, and blood-brain barrier maintenance. Tissue Inhibitors of Metalloproteinases (TIMPs) on the other hand are major regulators of MMPs. In the present study we examined the associations of plasma MMPs and TIMPs with mental disorders in young adults aged 24 years in the Avon Longitudinal Study of Parents and Children (ALSPAC).

Methods: The present study comprised 775 participants (of 4019 who attended at age 24 years) who completed psychiatric assessments and provided plasma samples. Of these, 35 met the criteria for psychotic disorder, 201 for mild/moderate depressive disorder, and 266 for generalised anxiety disorder. The remaining 401 participants constituted controls without these disorders. Plasma concentrations of MMP2, MMP3, MMP9, and TIMP-4 were quantified using proximity extension assays. Logistic regression compared standardised MMPs and TIMPs levels in cases and controls. Additionally, negative binomial regression was utilized to measure associations between MMPs and TIMPs levels and psychiatric comorbidities (number of disorders). Models were adjusted for sex, body mass index, and cigarette smoking.

Results: Compared to controls, cases exhibited slightly higher mean BMI and higher proportions of female participants, daily tobacco smokers, regular cannabis users, individuals under medication, and not in employment, education or training (NEET) status.

Limited evidence of an association between TIMP4 and psychotic disorders was observed in unadjusted analysis (Odds Ratio [OR]: 1.79, 95% CI 1.22-2.63). However, this association lost significance after adjustment for multiple comparisons. Evidence supporting an association between TIMP4 and depressive disorders was found in unadjusted analysis (OR: 1.83, 95% CI 1.50-22.39). After adjusting for sex, BMI, and smoking habits, evidence was also found for an association between both MMP3 (OR: 1.35, 95% CI 1.06-1.73) and TIMP4 with depressive disorders (OR: 1.51, 95% CI 1.22-1.87).

Unadjusted logistic regression revealed evidence for an association between MMP3 and anxiety disorders (OR: 0.78, 95% CI 0.66-0.91). Additionally, associations were observed between anxiety disorders and MMP9 (OR: 1.22, 95% CI 1.04-1.43) and TIMP4 (OR: 1.65, 95% CI 1.38-1.97). However, after adjusting for covariates, only evidence for an association between TIMP4 and anxiety persisted (OR: 1.44, 95% CI 1.19-1.73).

Unadjusted negative binomial regression analyses demonstrated an inverse association between MMP3 levels and psychiatric comorbidities (β -0.72, 95% CI -1.28 -0.17, p-value: 0.02). Additionally, positive associations were observed between psychiatric comorbidities and MMP9 levels (β 0.63, 95% CI 0.10 1.16, p-value: 0.025) as well as TIMP4 levels (β 1.89, 95% CI 1.27 2.50, p-value: LESS THAN 0.005). However, upon adjusting for covariates, including BMI, sex, and smoking habits, only the association between TIMP4 levels and psychiatric comorbidities remained significant (β 1.26, 95% CI 0.61 1.92, p-value: LESS THAN 0.005).

Discussion: This study revealed that young adults from the ALSPAC cohort with depressive disorders exhibited elevated plasma concentrations of MMP-3 and TIMP-4 compared to

controls. Additionally, we identified an association between TIMP-4 plasma levels and generalised anxiety disorder. Furthermore, the study suggests the potential role of TIMP-4 as a transdiagnostic marker for mental illness. However, no compelling evidence for an association between plasma metalloproteinases and psychotic disorders was observed. These findings contribute to the growing evidence supporting the involvement of metalloproteinases in mental disorders during early adulthood.

S68. ASSOCIATIONS BETWEEN NEUROMELANIN ACCUMULATION IN PATIENTS WITH SCHIZOPHRENIA AND TREATMENT RESPONSIVENESS: A CROSS-SECTIONAL NM-MRI STUDY

Fumihiko Ueno^{*1}, Yusuke Iwata², Shiori Honda³, Guillermo Horga⁴, Clifford Cassidy⁵, Edgardo Torres-Carmona¹, Jianmeng Song¹, Vincenzo De Luca¹, Sakiko Tsugawa³, Yoshihiro Noda³, Sri Mahavir Agarwal¹, Gary Remington¹, Philip Gerretsen¹, Shinichiro Nakajima³, Ariel Graff-Guerrero¹

¹Centre for Addiction and Mental Health, University of Toronto, ²Department of Neuropsychiatry, University of Yamanashi Faculty of Medicine, ³Department of Neuropsychiatry, Keio University School of Medicine, ⁴Columbia University and New York State Psychiatric Institute, ⁵The Royal's Institute of Mental Health Research Affiliated with the University of Ottawa

Background: Neuromelanin (NM) is a product of monoamine metabolism, including dopamine. NM-sensitive magnetic resonance imaging (NM-MRI) sequences allow in vivo quantification of NM levels in the substantia nigra (SN). NM-MRI signal is believed to serve as a surrogate marker for SN dopamine neuron integrity and, consequently, striatal dopaminergic functioning. Higher striatal dopamine synthesis is associated with first-line antipsychotic responsive (FLR) patients with schizophrenia, while normal striatal dopamine synthesis is linked to the pathophysiology of treatment-resistant schizophrenia (TRS). Clozapine is currently the only antipsychotic approved for TRS. However, no studies have yet investigated the relationship between SN accumulations, as measured by NM-MRI, and clozapine response in patients with TRS.

Methods: This study enrolled patients with TRS who either did not respond to clozapine (ultra-resistant schizophrenia [URS]) or responded to clozapine (non-URS), FLR, and healthy controls (HCs). TRS was defined as resistance to at least two first-line antipsychotics and ongoing clozapine treatment at the time of the study. SN-NM were measured using 3T-MRI. The contrast ratio (CR) was calculated as the relative signal intensity difference between SN and crus-cerebri. SN-CR were compared between the groups, controlling for age and sex. The associations between SN-CR and symptom severity scores were also explored within the patient groups.

Results: A total of 78 participants (URS: n=16; non-URS: n=16; FLR: n=20; HCs: n=26) completed the study. We found the overall group differences in SN-CR values ($F(3,72)=3.80$, $\eta^2=0.21$, $p=0.001$). Specifically, patients with URS (Cohen's $d=0.86$, $p=0.049$) and FLR (Cohen's $d=1.27$, $p < .0001$) exhibited higher SN-CR values compared to HCs. SN-CR values showed no associations with any of the symptom severity scores within each group or the entire patient group.

Discussion: Our study is the first to assess a proxy measure of mesostriatal dopamine function in patients with schizophrenia, stratified according to their treatment responsiveness, using

NM-MRI. We found high SN-NM contrast in patients with URS and FLR compared to HCs, and similar to HCs in non-URS. Longitudinal studies are warranted to establish whether SN-NM levels are suitable as a biomarker to predict treatment response in schizophrenia.

S69. ALTERED CORTICAL GYRIFICATION AS A MARKER OF TREATMENT RESISTANCE IN PATIENTS WITH FIRST-EPISODE PSYCHOSIS

Moonyoung Jang^{*1}, Jun Soo Kwon², Minah Kim³, Inkyung Park⁴, Sunghyun Park⁵

¹*Seoul National University College of Medicine, ²Seoul National University College of Medicine; Seoul National University Hospital; Seoul National University College of Natural Sciences; Institute of Human Behavioral Medicine, SNU-MRC, ³Seoul National University Hospital; Seoul National University College of Medicine, ⁴Seoul National University College of Natural Sciences, ⁵Seoul National University Hospital*

Background: Predicting resistance to drug treatment in the early stages of schizophrenia can improve patient outcomes and ultimately enable more personalized therapies, potentially leading to healthcare cost savings. Currently, there is no biomarker that accurately predicts the prognosis of first-episode psychosis patients. Alterations in gyrification represent abnormal neurodevelopmental processes and have the potential to identify treatment resistance at the onset of the illness. However, only a few studies have explored the gyrification patterns of first-episode psychosis, and none of them suggested alterations in gyrification as a predictive marker of treatment resistance. This study aims to investigate cortical gyrification as a viable biomarker candidate for predicting resistance to drug treatment in the first-episode of schizophrenia.

Methods: A cohort of 101 individuals diagnosed with first-episode psychosis and an equivalent number of age- and sex-matched healthy controls underwent T1-weighted magnetic resonance imaging scans immediately after their initial contact. Patients received treatment in a naturalistic clinical setting, and treatment resistance was assessed at the last follow-up. Treatment resistance was defined as either taking clozapine or exhibiting moderate to severe symptoms despite of taking more than two types of antipsychotics in sufficient amounts and duration at their last follow-up point, based on Treatment Response and Resistance in Psychosis Working Group Consensus criteria. Cortical gyrification was calculated using the local gyrification index in a vertex-wise manner across the entire cortical surface, employing Freesurfer pipeline. Local gyrification indices were compared across treatment-resistant patients, non-treatment-resistant patients, and healthy controls.

Results: Patients with first-episode psychosis exhibited hypogyria compared to healthy controls in three clusters: (1) precuneus, cuneus, and lingual gyrus, (2) precentral and postcentral gyrus, and (3) insula. Patients classified as treatment-resistant showed significant reduction in cortical gyrification compared to healthy controls in a cluster including precuneus, cuneus, and lingual gyri. Meanwhile, patients not categorized as treatment-resistant exhibited significantly reduced cortical gyrification compared to healthy controls in a cluster including precentral and postcentral areas (all clusters significant at $P < 0.05$).

Discussion: The present study revealed that the treatment-resistant group exhibited hypogyria in the parieto-occipital region, consistent with previous findings in patients with first-episode psychosis who showed poor response to initial antipsychotic treatments and in asymptomatic individuals at a genetic high risk for schizophrenia. Conversely, patients not classified as treatment-resistant exhibited hypogyria in the fronto-parietal region, aligning with previous

findings in first-episode psychosis patients. The observed disparities in gyrification patterns between the two groups suggest the presence of discrete neurodevelopmental anomalies underlying these distinct groups. These findings indicate that cortical gyrification may serve as a promising biomarker for early prediction of treatment resistance in conventional antipsychotic interventions within the context of psychotic disorders.

S70. SMOOTH PURSUIT DYSFUNCTION AS A SENSORIMOTOR BIOMARKER FOR PSYCHOSIS – EVIDENCE FROM COMPREHENSIVE EXTERNAL VALIDATION STUDIES

Rebekka Lencer^{*1}, Inga Meyhöfer², Andreas Sprenger³, David Derad³, Dominik Grotegerd², Ramona Leenings², Elisabeth J. Leehr², Fabian Breuer², Marian Surmann², Volker Arolt², Georg Romer², Markus Lappe², Johanna Rehder², Nikolaos Koutsouleris⁴, Stefan Borgwardt³, Frauke Schultze-Lutter⁵, Eva Meisenzahl⁵, Tilo T. Kircher⁶, Sarah S. Keedy⁷, Jeffrey Bishop⁸, Elena Ivleva⁹, Jennifer E. McDowell¹⁰, James L. Reilly¹¹, Kristian S. Hill¹², Godfrey D. Pearlson¹³, Carol A. Tamminga⁹, Matcheri Keshavan¹⁴, Elliot S. Gershon⁷, John A. Sweeney¹⁵, Tim Hahn², Udo Dannlowski², Brett A. Clementz¹⁰

¹University of Lübeck, ²University of Münster, ³University of Lübeck, ⁴Ludwig-Maximilians-University, ⁵University of Düsseldorf, ⁶University of Marburg, ⁷University of Chicago, ⁸University of Minnesota, ⁹UT Southwestern Medical Center, ¹⁰University of Georgia, ¹¹Northwestern University, ¹²Rosalind Franklin University of Medicine and Science, ¹³Yale University, ¹⁴Harvard Medical School, ¹⁵University of Cincinnati College of Medicine

Background: Using neurobiological markers for classifying psychiatric syndromes on an individual level is limited by heterogeneity. Implementing machine learning algorithms for classifications purposes requires comprehensive external validation studies to avoid overestimation of prediction models. Considering this, balanced accuracies (BAC) of 60-70% for the correct identification can be expected. Here, we studied quantifiable measures of different aspects of sensorimotor function derived from smooth pursuit eye movements which are regarded as neurobiological markers for psychosis.

Methods: A multivariate pattern algorithm was trained in a large sample of chronically ill psychosis probands (N=674, mean illness duration 15.4 y) and healthy controls (HC, N=305) from the Bipolar-Schizophrenia Network on Intermediate Phenotypes (B-SNIP1) cohort to generate predictions (psychosis proband vs. HC). The derived model was externally validated in three independent large samples with external validation-1 including chronically ill psychosis probands (N=727, mean illness duration 17.9 y) vs. HC (N=292), external validation-2 comprising a sample of bipolar probands with (N=49, mean illness duration 11.9 y) and without (N=36, mean illness duration 9.4 y) psychotic symptoms vs. HC (N=71), and external validation-3, a sample comprising probands with affective disorders without psychotic symptoms (N=119, mean illness duration 7.5 y) and psychosis probands (N=51, mean illness duration 9.6 y) vs. HC (N=72). Following an exploratory approach, the model was further tested using data from a sample of recent-onset psychosis or depression (N=28, mean illness duration 0.7 y) as well as Clinical High Risk (CHR) state for the development of psychosis (N=19) vs. HC (N=16). Statistical inference was examined using permutation distributions created from 1000 random rearrangement of the two group labels (healthy controls vs. psychosis group) to the predictors.

Results: Our model trained in the B-SNIP1 sample was able to discriminate psychosis probands from HC based on sensorimotor function with a BAC of 64%. External validation in independent large samples resulted in a BAC of 65% by external validation-1, a BAC of 66% for the identification of psychotic bipolar disorder by external validation-2, and a BAC of 58% for identifying psychosis patients by external validation-3. Notably, 80% of probands with major depression without psychosis were correctly classified as non-psychotic, i.e. being similar to HC with respect to sensorimotor function. Regarding early disease states, 42% of CHR-participants were classified as psychosis patients but only 18% of recent-onset psychosis probands. Of the probands with recent-onset, non-psychotic depression, 76% were correctly classified as non-psychotic. Associations between eye movement performance and possible confounds, i.e., cognition scores or chlorpromazine equivalents, were negligible.

Discussion: Balanced accuracies of about 65% for the individual prediction of psychosis status based on psychosis-related visual sensorimotor dysfunction are in line with recent results from other large heterogeneous psychiatric samples. Our findings underline the impact of sensorimotor dysfunction in a considerable subgroup of chronically ill psychosis patients, which point to specific, illness-related deficits in the transformation of visual sensory motion signals into motor action being associated with alterations in occipito-parieto-frontal networks. Our exploratory observations from the small recent-onset psychosis group suggest that smooth pursuit eye movement dysfunctions may serve as illness progression markers. Future studies should broaden this biomarker approach by combining multiple significant neurobiological measures, e. g. brain structure indices, that might improve prediction accuracies and help to pave the way to improve the clinical diagnostic process for psychotic disorders.

S71. A PRAGMATIC ANALYSIS OF SCHIZOPHRENIA THROUGH THE COOPERATIVE PRINCIPLE AND GRICE'S MAXIMS

Dalia Elleuch*¹

¹*University of Sfax*

Background: Schizophrenia, a complex neuropsychiatric disorder, has captivated the attention of medical and language experts, yet its multifaceted nature has hindered the quest for definitive answers.

Methods: This study takes a pragmatic approach, employing the Cooperative Principle and Grice's maxims to explore linguistic aspects of the illness. Five interviews with clinically diagnosed Schizophrenia patients form the corpus, transcribed and annotated using the UAM Corpus tool 3.3v. Employing both quantitative and qualitative methods, the research examines the hypothesis that Schizophrenia influences speech with distinct patterns of Gricean maxim non-observance.

Results: Results reveal a consistent pattern of non-observance, particularly in flouting the maxim of quality (hallucinations) and the maxim of relation (derailment and incoherence). Schizophrenia patients exhibit a lack of awareness regarding maxim violations in their speech, exacerbating language deficits and thought disorders.

Discussion: The discussion of the observed inadequacies relating to the cooperative principle, and Grice's maxims suggests the need to observe these principles when interviewing a schizophrenic patient, and to reconsider applying these principles when teaching students with Schizophrenia.

S72. PLASMA COMPLEMENT AND COAGULATION PROTEINS AS PROGNOSTIC FACTORS OF NEGATIVE SYMPTOMS: AN ANALYSIS OF THE NAPLS 2 AND 3 STUDIES

Jonah Byrne^{*1}, Colm Healy², Melanie Föcking², Meike Heurich³, Subash Raj Susai², David Mongan⁴, Kieran Wynne⁵, Eleftheria Kodosaki³, Scott Woods⁶, Barbara Cornblatt⁷, William Stone⁸, Daniel Mathalon⁹, Carrie Bearden¹⁰, Kristin Cadenhead¹¹, Jean Addington¹², Elaine Walker¹³, Tyrone Cannon¹⁴, Mary Cannon², Clark Jeffries¹⁵, Diana Perkins¹⁶, David Cotter²

¹Royal College of Surgeons in Ireland, ²RCSI University of Medicine and Health Sciences, ³Cardiff University, ⁴Centre for Public Health, Queen's University Belfast, United Kingdom and Royal College of Surgeons in Ireland, ⁵Proteome Research Centre, University College Dublin, ⁶Department of Psychiatry, Yale University, ⁷The Zucker Hillside Hospital, Department of Psychiatry Research, ⁸Harvard Medical School / Beth Israel Deaconess Medical Center, ⁹Department of Psychiatry, University of California San Francisco, California, ¹⁰University of California, Los Angeles, ¹¹Department of Psychiatry, University of California, San Diego, ¹²University of Calgary, Department of Psychiatry, ¹³Departments of Psychology and Psychiatry, Emory University, ¹⁴Departments of Psychology and Psychiatry, Yale University, ¹⁵University of North Carolina at Chapel Hill, ¹⁶Department of Psychiatry, University of North Carolina, Chapel Hill

Background: Negative symptoms impact the quality of life of individuals with psychosis and current treatment options for negative symptoms have limited effectiveness. Previous studies have demonstrated that complement and coagulation pathway protein levels are related to later psychotic experiences, psychotic disorder, and functioning. However, the relationship between complement and coagulation proteins and negative symptoms is poorly characterised.

Methods: In the North American Prodrome Longitudinal Studies 2 and 3, negative symptoms in 438 individuals at clinical high-risk for psychosis were measured at multiple visits over 2 years using the Scale of Psychosis-Risk Symptoms. Plasma proteins were quantified at baseline using mass spectrometry. Four factors were derived to represent levels of proteins involved in the activation or regulation of the complement or coagulation systems. Their relationships with serial measurements of negative symptoms over time were modelled using generalised least squares. Analyses were adjusted for baseline candidate prognostic factors: negative symptoms, positive symptoms, functioning, depressive symptoms, suicidal ideation, cannabis use, tobacco use, antipsychotic use, antidepressant use, age, and sex.

Results: Clinical and demographic prognostic factors of follow-up negative symptoms included negative, positive, and depressive symptoms, functioning, and age. Adjusting for all candidate prognostic factors, the complement regulators group and the coagulation regulators group were identified as prognostic factors of follow-up negative symptoms (β : 0.379, 95% CI: 0.121, 0.637; β : 0.345, 95% CI: 0.064, 0.626 respectively). The relationship between complement regulator levels and negative symptoms was also observed in NAPLS2 alone (β : 0.379, 95% CI: -0.028, 0.785) and NAPLS3 alone, additionally adjusting for BMI (β : 0.334, 95% CI: 0.096, 0.573).

Discussion: The results indicate that complement and coagulation regulators are prognostic factors of negative symptoms, beyond clinical and demographic prognostic factors. These results suggest complement and coagulation regulator levels could have utility in informing treatment decisions for negative symptoms in individuals at risk.

S73. MACHINE LEARNING FOR PREDICTION OF SCHIZOPHRENIA USING THE BIOMARKERS IN NIACIN FLUSH PATHWAY

Yu-En Kang*¹

¹*National Cheng Kung University, Tainan*

Background: Abnormal niacin flush response may serve as a stable biomarker of schizophrenia. The abnormality has the potential to affect downstream molecular signaling and lead to anti-inflammatory responses. Previous studies have suggested that the downstream metabolites (e.g., prostaglandins and their receptors) are catabolized by the GPR109A-COX-prostaglandin pathway. The main function of prostaglandins is to mediate inflammation in the surrounding tissues and may cause vasodilation. The underlying pathogenesis and molecular mechanisms of niacin-induced flushing pathway in schizophrenia remain incompletely understood. Therefore, our study aimed to use potential biomarkers in niacin flush pathway to predict schizophrenia by machine learning algorithm.

Methods: The study recruited 150 schizophrenia patients and 100 healthy controls. Initially, niacin responses on subjects' arms were measured using the niacin skin patch test. Next, blood cells isolated within 24 hours were analyzed via flow cytometry for niacin receptor GPR109A and prostaglandin receptor DP1 expressions. Enzyme-linked immunosorbent assays are used to measure the levels of prostaglandins, thromboxanes, and their receptors in plasma. In statistical analysis, we compared the expressions of biomarkers in niacin flush pathway between schizophrenia patients and healthy controls. We employed the ROC curve analysis based on logistic regression and machine learning algorithm to evaluate the discriminative capability of these biomarkers. Finally, the selected biomarkers in niacin flush pathway were combined to construct a discriminant model for predicting schizophrenia.

Results: The results showed that nine biomarkers in niacin flush pathway could differentiate between schizophrenia patients and healthy controls. The AUC values of the nine biomarkers were from 0.62 to 0.80 using ROC curve analysis by logistic regression. We selected the top three biomarkers (flush response and two receptors) that showed good discrimination to establish a risk model for schizophrenia. When we combined the selected biomarkers to assess the discriminant performance by logistic regression, the results showed the AUC was 0.87 and 95% CI was 0.82-0.92 for the prediction of schizophrenia. Further, we performed a supervised machine learning algorithm-Support Vector Machine (SVM) to estimate the discrimination ability of the selected biomarkers for differentiating schizophrenia patients from healthy controls. The results showed AUC was 0.93 and 95% CI was 0.87-0.98 using the combined top three biomarkers in SVM model.

Discussion: In summary, this study focused on exploring the role of niacin and prostaglandin receptors signaling in schizophrenia. Our findings supported the hypothesis that the biomarkers in niacin flush pathway would be abnormally expressed in schizophrenia patients. The findings indicated that the top three biomarkers involved in niacin-related signaling pathway may be considered as useful indicators to discriminate schizophrenia patients from healthy controls. We furthermore used the selected biomarkers to construct a risk prediction model of schizophrenia for clinical practice or research purposes. Through our study, we expect to assist researchers and clinicians in better assessing the risk of schizophrenia.

S74. SCHIZOPHRENIA GENETIC RESILIENCE SCORE MODERATES ENVIRONMENTAL RISK ON WORKING MEMORY CONNECTIVITY

Didenur Sahin Cevik*¹, Hao Yang Tan², Shizong Han², Daniel R. Weinberger³, Timothea Touloupoulou⁴

Background: Schizophrenia is characterized by abnormalities in the functional integration of working memory (WM) brain networks. Exposure to environmental risks during critical periods of brain development can disrupt the typical trajectory of brain maturation and increase the risk of schizophrenia. Investigating how genetic resilience, defined as a heritable measure of variation that increases resistance to disease by reducing the impact of risk loci, influences this link is critical to understanding the disorder's causal mechanisms.

Methods: 350 individual healthy twins oversampled for familial schizophrenia risk (175 pairs) aged 14-23 provided blood samples and underwent an fMRI scan while performing a WM task. Functional connectivity (FC) indexes were calculated by the Conn toolbox, including seed regions of the paracingulate gyrus (PCG) and precentral area. We examined whether connectivity patterns in these regions were predicted by environmental risks, including discrimination and childhood trauma, and whether the polygenic resilience score influenced this link.

Results: Genetic resilience moderated the relationship between environmental risk and brain connectivity. At lower levels of resilience, childhood trauma significantly reduced connectivity at the precentral right region ($p = 0.012$). Likewise, exposure to higher levels of discrimination significantly reduced PCG connectivity at lower levels of resilience ($p < 0.001$). We did not find significant interaction effects at higher levels of resilience. We did not find significant interaction effects at higher levels of genetic resilience.

Discussion: These findings underscore the interplay between genetics, environmental risk, and the neural mechanism in building resilience to schizophrenia. As PCG and precentral are relevant in schizophrenia, optimal connectivity in these regions may enhance a person's ability to cope with adversity. The moderating role of genetic resilience highlights the importance of gene-environment interactions in investigating neural mechanisms responsible for genetic resilience to adversity.

S75. MACHINE LEARNING METHODS TO CONSTRUCT A RISK PREDICTION MODEL AND IDENTIFY THE PRIMARY AND INTERACTION EFFECTS OF MINOR PHYSICAL ANOMALIES FOR TREATMENT-RESISTANT SCHIZOPHRENIA

Chih-Wei Lin*¹, Jin-Jia Lin², Huai-Hsuan Tseng³, Fong-Lin Jang², Ming-Kun Lu⁴, Po-See Chen⁵, Chih-Chun Huang⁶, Wei-Hung Chang⁷, Hung-Pin Tan⁸, Sheng-Hsiang Lin⁹

¹College of Medicine, National Cheng Kung University, Tainan, ²Chi Mei Medical Center, ³National Cheng Kung University Hospital, ⁴Jianan Mental Hospital, Chia Nan University of Pharmacy and Science, ⁵National Cheng Kung University Hospital, National Cheng Kung University Hospital, Dou-Liou Branch, ⁶National Cheng Kung University Hospital, Dou-Liou Branch, ⁷National Cheng Kung University Hospital, Dou-Liou Branch, ⁸Jianan Mental Hospital, ⁹National Cheng Kung University

Background: Treatment-resistant schizophrenia (TRS) is defined as patients with schizophrenia who despite treatment still have symptoms and poor outcomes. Previous studies showed that neurodevelopmental causes in etiology have a relationship between treatment resistance. In the neurodevelopmental model of schizophrenia, minor physical anomalies (MPAs) were demonstrated as a neurodevelopment marker for schizophrenia. However, the association between MPAs and TRS still needs to be studied. The aim of the study was to use machine learning methods to identify the primary and the interaction effect of MPAs items that can distinguish TRS and non-TRS.

Methods: The study included 87 TRS patients and 97 non-TRS patients. We used two machine learning methods, random forest (RF) and support vector machine (SVM) to build the prediction models and select the important items and the interaction effects of MPAs.

Results: The results showed that the six selected MPAs items of mouth and facial regions using RF and SVM models had the area under the curve (AUC) values of 0.70 and 0.72, respectively. Further ROC analyses of RF and SVM indicated that the AUC values of combining the six selected MPAs and three demographic variables (age, sex, BMI) were both 0.76. Then, we identified the interaction effects in these six MPAs items to find that skull height and outer canthal distance had the strongest interaction.

Discussion: In conclusion, the MPAs can be used as a neurodevelopment marker of treatment resistance in schizophrenia and the machine learning model can have great performance to assess the risk of TRS.

S76. MATERNAL CHILDHOOD TRAUMA PREDICTS ADOLESCENT INFLAMMATORY MARKERS: IS FAMILY SOCIO-ECONOMIC STATUS A MODERATOR OF THIS RELATIONSHIP?

Nare Amasi-Hartoonian*¹, Xuemei Ma¹, Andrew J. Lawrence¹, Rebecca Pollard¹, Pei-Jung Chen¹, Maryam Matter¹, Svenja Kretzer¹, Corentin Vallee¹, Olivia Johnson-Trewick¹, Giulia Giordano¹, Eleni Vargiamidou¹, Sofia Panzeri¹, Craig Morgan¹, Seeromanie Harding², Gunter Schumann¹, Carmine Pariante¹, Mitul Mehta², Giovanni Montana³, Ana Rodriguez-Mateos², Chiara Nosarti¹, Paola Dazzan¹

¹King's College London, Institute of Psychiatry, ²King's College London, ³University of Warwick

Background: Maternal early life adversity can lead to poor psychiatric outcomes in the offspring. However, it remains unclear how maternal early life stress affects the biological systems in the offspring, particularly during a critical developmental period like adolescence. The role of the immune system is particularly interesting, given evidence that immune

activation is associated with mental health problems. Still, studies have mainly investigated the relationship between maternal depressive symptoms and a limited number of immunological markers in adolescents, with conflicting results. Furthermore, postnatal environment and exposure to stressors linked to socio-economic status (SES) can also affect offspring inflammation, and thus may be involved in the pathway leading to poor health in the offspring. In this study, we investigated the relationship between maternal childhood trauma and inflammation in adolescents, also exploring the possible interaction with SES.

Methods: A total of $n=230$ school adolescents aged 11-14 (mean age = 12.9 years (SD 0.94); 44.3% male) participated were included in this study. Maternal childhood trauma was assessed using the Childhood Trauma Questionnaire (CTQ) from mothers, and a total CTQ score was obtained by summing the scores of the five subscales. We evaluated CRP and cytokines (TNF- α , IFN- γ , IL-2, IL-4, IL-6, IL-8, IL-10, IL-12, IL-13) from plasma and values were log-transformed. Eligibility for free school meals (FSM) was used as a proxy measure of familial SES. Partial correlation analysis was conducted to identify which immune markers were predicted by maternal CTQ when adjusting for covariates (age, sex, ethnicity, and BMI). We then investigated whether family SES moderated the relationship between maternal CTQ and levels of immune markers in the offspring while controlling for covariates.

Results: Maternal CTQ was only positively correlated with IL-2 ($r=0.304$, $N=80$, $p=0.008$) and IL-10 ($r=0.279$, $N=80$, $p=0.015$). A multiple linear regression analysis was conducted to test for the interaction between maternal CTQ and familial SES. However, the relationship between maternal CTQ and IL-2, as well as with IL-10, was not moderated by family SES. The interaction between maternal CTQ and family SES was not statistically significant for either IL-2 ($R^2=0.25$, $B=-0.013$, $SE=0.008$, $t=-1.671$, $p=0.099$) or for IL-10 ($R^2=0.21$, $B=0.013$, $SE=0.008$, $t=1.582$, $p=0.119$).

Discussion: We found that the experience of childhood trauma in mothers was associated with mild immune activation in adolescents. It is possible that maternal childhood trauma influences the inflammatory fetal biology, thus impacting the offspring's physiological stress systems which are linked to the immune system. Contrary to what was expected, familial SES however, did not moderate this relationship. This suggests that maternal childhood trauma may have an independent rather than a synergistic effect on offspring immune activation. Future research will explore whether the presence of maternal childhood trauma has a persistent and more extensive impact on adolescent inflammation at later time points in development.

S77. THE IMPACT OF DEPRIVATION ON CORTICAL DEVELOPMENT AND PSYCHOTIC SYMPTOMS IN YOUTH

Megan Thomas^{*1}, Sarah Whittle², Vanessa Cropley³

¹Melbourne Neuropsychiatry Centre, ²Melbourne Neuropsychiatry Centre, Department of Psychiatry, The University of Melbourne and Melbourne Health, Victoria, Australia, ³The University of Melbourne, Melbourne Neuropsychiatry Centre

Background: People with early experiences of deprivation (e.g., neglect, poverty) are more likely to develop psychotic symptoms, both of clinical and non-clinical severity. Research suggests that disruption to the structural development of the cerebral cortex in childhood and adolescence may play a role in these associations. However, the specific cortical regions involved, the temporal relationship between these factors, and the extent to which potential mechanisms overlap for different forms of deprivation, are not well understood. Investigating

these relationships longitudinally in youth, whilst also considering sex-specific effects, may help to elucidate cortical pathways from deprivation to psychosis.

Methods: For the current study, we utilised data for 6323 youth participating in the Adolescent Brain Cognitive Development study, from two study timepoints, two years apart. The data included several measures of exposure to deprivation, regional cortical volumes derived from T1-weighted imaging, and a measure of sub-clinical psychotic-like experiences (PLEs). Linear mixed models were performed to examine the effects of deprivation at age 9/10 years (measured as one overarching construct, and split into material, interpersonal, cognitive and neighbourhood deprivation), on PLEs at age 11/12 years. Associations between deprivation measures and both cortical volume at baseline and the rate of cortical volume change from baseline to follow-up, were also examined for 34 regions spanning the cortex. Finally, mediation analyses were conducted to investigate whether implicated cortical metrics mediated associations between deprivation measures and later PLEs. Sex-specific effects were explored throughout. To evaluate whether findings were specific to individual deprivation subtypes, analyses were repeated with all subtypes included in models simultaneously.

Results: All deprivation measures were significantly associated with a greater number of PLEs (all $p < 0.001$, standardised- β ranging from 0.15-0.25), and, with the exception of interpersonal deprivation (i.e., caregiver neglect), all had widespread associations with lower baseline cortical volume, and steeper cortical volume decline from baseline to follow-up, with the strongest effects in temporal regions. Mediation analyses revealed small but significant indirect effects of total, material, cognitive and neighbourhood deprivation on greater PLEs via lower baseline cortical volumes; most widespread in parietal areas but with certain temporal and occipital regions yielding some of the strongest effects. While fewer significant mediation effects were found for the rate of cortical volume change from baseline to follow-up, moderated mediation analyses revealed that steeper cortical volume decline in several (most commonly occipital) regions partially mediated associations between total, material, cognitive and neighbourhood deprivation, and greater PLEs, in females but not males. When analyses were repeated with all deprivation subtypes included in models simultaneously, the majority of associations between deprivation subtypes and cortical measures, and indirect effects of deprivation subtypes on PLEs via cortical measures, lost significance. This indicates a substantial level of overlap in the cortical mechanisms linking different forms of deprivation with PLEs.

Discussion: The findings of this study are consistent with a pathway from early experiences of deprivation to psychotic symptoms via disruption to cortical development, that is largely common to several forms of deprivation, and persists into adolescence for certain regions, particularly in females.

S78. GENDER DISPARITIES IN PSYCHOPATHOLOGICAL OUTCOMES ASSOCIATED WITH DIFFERENT DIMENSIONS OF ADVERSITY EXPERIENCE

Rebecca Pollard^{*1}, Pei-Jung Chen¹, Corentin Vallee¹, Andrew J. Lawrence¹, Xuemei Ma², Nare Amasi-Hartoonian¹, Svenja Kretzer³, Craig Morgan⁴, Seeromanie Harding¹, Gunter Schumann¹, Carmine Pariante⁵, Mitul Mehta⁶, Giovanni Montana⁷, Chiara Nosarti⁸, Sylvane Desrivieres¹, Ana Rodriguez-Mateos¹, Paola Dazzan⁹

¹King's College London, Institute of Psychiatry, ²Institute of Psychiatry, King's College,

³King's College London; Agency for Science, Technology and Research (A*STAR), Singapore,

⁴Centre for Society and Mental Health, King's College London, ⁵Department of Psychological Medicine, Institute of Psychiatry, Psychology and Neuroscience, King's College London,

⁶Center for Neuroimaging Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, ⁷Department of Data Science, University of Warwick, ⁸Department of Psychosis Studies, King's College London, Institute of Psychiatry, Psychology and Neuroscience King's College London, ⁹Institute of Psychiatry, Psychology and Neuroscience, King's College London

Background: Exposure to early life adversity (ELA) has been shown to be a risk factor for the development of psychopathology during adolescence and adulthood. According to the Dimensional Model of Adversity and Psychopathology (DMAP), there is evidence to suggest that different dimensions of adversity would confer risk for different psychopathological outcomes, and that they are associated with distinct neurobiological mechanisms. There is also evidence for differential effects of adverse experiences in males and females, as well as a between-sex differences in outcomes, with females reporting a significantly higher level of internalising symptoms. It is essential to understand more about the impact and mechanisms of different adversity dimensions on the emergence of psychopathological domains during adolescence to provide rationale for specific evidence-based interventions.

Methods: We included in this study a total of $n=230$ school adolescents, aged 11-14 (mean age = 12.4 years $SD=0.98$, 44.8% males) and $n=185$ returned 1 year later for a follow up (mean age = 14 years, $SD = 0.93$, 47% males). Experiences of adversity were assessed using a semi-structured interview derived from the Brief Adolescent Life Events Checklist. Experiences were categorised into 3 dimensions according to DMAP: Threat, Deprivation and Unpredictability. Experiences of each adverse experience were binarized and the total number of adversities in each subgroup was summed to create a total score for each dimension. Internalizing and externalizing symptoms were assessed using the Strengths and Difficulties Questionnaire (SDQ), and psychotic experiences using a questionnaire devised from adolescent psychotic-like symptom screen (APSS).

Univariate analyses were conducted to test for associations between each ELA dimension and psychopathology outcome at both time points. We then used linear regression to investigate whether sex was a significant predictor in the relationship between ELA dimensions and outcomes.

Results: Only Threatening experiences were associated with outcomes at 1-year follow-up (Internalizing symptoms, externalizing symptoms, and psychotic experiences (r ranging 0.23-0.42, p LESS THAN 0.005). There was no significant association between Deprivation and Unpredictable experiences and psychopathology (p GREATER THAN 0.05).

Female participants reported a significantly higher level of internalizing symptoms ($t = -2.6$, $df = 228$, p LESS THAN 0.05) and psychotic experiences ($t = -.27$, $df = 228$, p LESS THAN 0.05), while there was no significant sex difference in externalising symptoms.

In the linear regression, sex, alongside Threat exposure, was a significant predictor of both internalising symptoms ($R^2 = 0.14$, p LESS THAN 0.001) and psychotic experiences ($R^2 = 0.1$, p LESS THAN 0.001), but was not a significant predictor of externalising symptoms.

Discussion: Only threatening experiences were associated with psychopathology outcomes at 1-year follow-up. This could suggest that the effect of threat exposure becomes apparent earlier in life compared to the effects of other adversities. This finding underscores the necessity of using a dimensional approach to adversity research, as different adversity subtypes may increase the risk of distinct outcomes.

Our data suggest that the higher risk for females to develop mental health symptoms during adolescence might be associated with a higher vulnerability to threatening experience exposure.

Future longitudinal work will evaluate the potential mechanisms by which sex differences in vulnerability to threatening experiences occur and elucidate the trajectories of psychopathology emergence following exposure to adversity during adolescence.

S79. THE SOCIAL MISTRUST SCALE – ITALIAN (SMS-I): FACTOR STRUCTURE AND CONVERGENT VALIDITY WITH ANXIETY, DEPRESSION, AND SCHIZOTYPY IN 286 ITALIAN COMMUNITY AND CLINICAL 8- TO 14-YEAR-OLDS

Valerio Zaccaria*¹, Ignazio Ardizzone¹, Susanna Maggi¹, Emiliano Luchetti², Federica Forte², Elvira Piazza², Chiara Rogora², Francesco Pisani¹, Keri Ka-Yee Wong³

¹*Sapienza University of Rome*, ²*ASL Roma 2 TSMREE 6th district, Rome*, ³*University College London*

Background: Paranoia and suspiciousness exist in the adult general population as well as in children and are a key feature of schizotypy and schizophrenia-spectrum disorders. Attempts to develop age-appropriate tools to assess suspiciousness and its associations with common psychopathological disorders is ongoing. The present study explored childhood mistrust and suspiciousness by validating the Italian Social Mistrust Scale (SMS) and its correlations with internalizing and externalizing in community and clinical samples.

Methods: A community (N = 242) and clinical sample with a diagnosis of anxiety and/or mood disorder (N = 44) of 8-to 14-year-olds were recruited from two public schools and from the Child Neuropsychiatry Institute of Policlinico Umberto I and Italian Local Health Unit in Rome respectively. Both samples completed the SMS and other tests of schizotypal traits, anxiety, depression, and internalizing and externalizing problems.

Results: The Total Score of the SMS was positively skewed, with 50% of the children scoring 3 points or less; the top 15% score was 7 points or more. Exploratory and Confirmatory Factor Analysis (EFA/CFA) revealed a three-factor model (i.e., General Mistrust, Home Mistrust, and School Mistrust) as per the English SMS. As expected, in the community sample childhood mistrust was positively correlated with schizotypal traits, anxiety, and depression ($\rho = 0.49, 0.42, \text{ and } 0.54$ respectively). Similar results were observed in the clinical sample, where these correlations were even stronger ($\rho = 0.75, 0.51, \text{ and } 0.85$ respectively). Overall, the SMS has good internal reliability (Total = 0.74, School Mistrust = 0.66, Home Mistrust = 0.49, General Mistrust = 0.62).

Discussion: Replicating previous studies, childhood mistrust exists on a continuum and is measurable in Italian children and is associated with higher levels of childhood psychopathology.

S80. ADDITION OF EVENAMIDE FOR 1-YEAR TO ANTIPSYCHOTICS IN TRS PATIENTS RESULTS IN INCREASING CLINICALLY IMPORTANT BENEFIT TO AN EXTENT THAT A SUBSTANTIAL PROPORTION NO LONGER MEET INTERNATIONAL CRITERIA FOR TREATMENT RESISTANCE

Ravi Anand*¹, Alessio Turolla², Giovanni Chinellato³, Francesca Sansi², Rodolfo Giuliani², Richard Hartman⁴

¹Anand Pharma Consulting, ²Newron Pharmaceuticals SpA, ³Newron pharmaceuticals, ⁴NeurWrite LLC

Background: The combination of first-and-second-generation antipsychotics (APs) in patients with TRS are not being shown to be beneficial, most likely as all result in modulation of dopaminergic and serotonergic transmission (Galling et al., 2017). As treatment resistant schizophrenia is noted in ~30% of patients within 5 years of treatment and results in increased morbidity, suicidality, and mortality, there is a high unfulfilled medical need to find innovative treatments for this population. Findings from neurochemistry, neurometabolism, and functional imaging studies in TRS patients indicate abnormalities in glutamatergic rather than dopaminergic neurotransmission (Moghaddam et al., 2012; Demjaha et al., 2014; Mouchlianitis et al., 2016). Evenamide, a selective inhibitor of voltage-gated sodium channels, is devoid of biological activity at GREATER THAN 130 CNS targets, normalizes glutamate release without affecting basal levels, and demonstrated benefits in animal models of psychosis as monotherapy and as an add on to APs (Anand et al., 2018)

Methods: Study 014/015 was a 1-year, randomized, open-label, rater-blinded, international study in patients with diagnosis of TRS not responding to a therapeutic dose of an AP with an initial assessment at week-6 followed by regular efficacy and safety assessments every 10-12 weeks up to 1-year of treatment. TRS patients were selected based on the following selection severity criteria: PANSS total score of 70-90, moderately to severely ill (CGI-S of 4 to 6), positive symptoms GREATER THAN 20 and at least 2 of the core symptoms of psychosis rated as at least moderate (4 or more). Eligible patients were randomized to three fixed oral doses of evenamide (7.5, 15 and 30 mg bid) to 52 weeks of treatment. Efficacy ratings were performed by a trained psychiatrist blinded to the evenamide dose. Data from all 3 doses pooled were analyzed to assess the responder rate, maintenance of the response up to 1 year and conversion of patients already on an AP from TRS into a responsive state, according to the operational severity selection criteria for TRS. Assessment of efficacy was based on changes on PANSS, CGI-S/C and functioning (Strauss-Carpenter LOF), while tolerability was assessed based on all safety measures.

Results: The 161 TRS patients randomized to treatment tolerated the study medication very well with a high completion rate at 1 year (~75% at 1-year) and low ADO rate (1.9%). During the 1-year treatment period, ~50% of the patients achieved a clinically meaningful benefit (GREATER THAN =20% improvement on PANSS total score): of the patients who achieved this clinically important reduction, ~40% preserved this benefit for at least 12 weeks according to TRRIP criteria. Remarkably, ~50% of the patients no longer met the operational severity criteria used to diagnose TRS at baseline, therefore converting patients into a responsive state. Detailed results from further analyses will be presented at the Congress.

Discussion: The multi-domain benefits of the addition of evenamide to antipsychotics in TRS patients were associated with clinically meaningful improvement in symptoms of psychosis to an extent that over 50% of these patients no longer met the criteria for TRS. These results suggest that the modulation of glutamate with evenamide in TRS patients on an antipsychotic may be a promising advance for their management (Anand et al., 2023)

S81. TOWARDS A PERSONALIZED MEDICINE APPROACH TO PSYCHOLOGICAL TREATMENT FOR PSYCHOSIS

Maria Lamarca*¹, Steffen Moritz², Fabrice Berna³, Lukasz Gaweda⁴, Vanessa Acuña⁵, Caroline König⁶, Susana Ochoa¹

¹*Parc Sanitari Sant Joan de Déu*, ²*University Medical Center Hamburg, Department of Psychiatry*, ³*Inserm*, ⁴*Institute of Psychology, Polish Academy of Science*, ⁵*Universidad de Valparaíso*, ⁶*Universitat Politècnica de Catalunya*

Background: Despite extensive evidence on the efficacy of psychological interventions at improving symptoms in people diagnosed with Schizophrenia, there is a lack of widely available treatments for this population. There is a need for cost- and time-efficient interventions for mental health disorders worldwide. Moreover, there is growing interest on the benefits of personalised medicine, tailoring interventions to individual needs. Metacognitive Training (MCT) is an ideal candidate for personalised treatment due to its proven efficacy in treating Schizophrenia and its content delivery. The aim of PERMEPSY (Personalised Medicine approach to psychological treatment for Psychosis) is to offer personalised delivery of MCT for people with Schizophrenia.

Methods: PERMEPSY is a three-year project composed of 5 clinical partners from 5 different countries (Spain, Germany, France, Poland and Chile) and one technological team (Spain). PERMEPSY members collaborate by reviewing the literature on the variables associated with better treatment response in Schizophrenia and identifying key factors predicting MCT effectiveness. PERMEPSY aims to analyse multimodal retrospective data from previous clinical trials using machine learning (ML) techniques and the variables identified via systematic reviews. The ML algorithm will inform the development of a prototype platform which will be made freely available to clinicians worldwide to aid their clinical decision-making when treating patients with Schizophrenia. The platform will be validated with a pilot clinical trial with two arms, comparing classical MCT to a personalised delivery recommended by the platform, testing its predictive power. Therefore, PERMEPSY has three main aims: (1) identify key sociodemographic, clinical, cognitive and metacognitive variables and biomarkers associated to treatment response in Schizophrenia; (2) demonstrate which variables best improve treatment outcomes using a stratification strategy based on ML applied to multimodal retrospective databases; and (3) develop and validate a platform via a proof-of-concept pilot clinical trial that includes the user's perspective at each stage.

Results: Data from 22 clinical trials has been collected and harmonised yielding a database with over 20 sociodemographic, clinical, cognitive and meta-cognitive variables from over 700 patients. ML experts will analyse the database and extract the variables that best predict MCT efficacy. A predictive platform will be developed from this analysis and a proof-of-concept clinical trial will validate the prototype platform's predictive power. The ML algorithm will dictate which variables will be input to the platform at baseline. The expected outputs for the platform will include predicted changes in positive symptoms, delusions, insight, self-esteem and the probability of treatment adherence for a given patient profile.

Discussion: Reducing the personal, social, and economic burden of Schizophrenia is a vexing need at both the mental and global health levels. Despite decades of research focusing on improving outcomes of psychosis, these remain a clinical challenge. Predictive models of personalised medicine are still in their infancy. This project aims to fill in the gap by providing clinicians with a tool to predict which patients will benefit from receiving MCT, and how to tailor the treatment to maximize its effects. The predictive platform will not only aid in decision-making but will also result in reduced economic and labour costs for clinicians. The novelty of this approach resides in integrating sociodemographic, lifestyle, environmental, clinical, cognitive, and biological data.

S82. TV-44749, A LONG-ACTING SUBCUTANEOUS (SC) INJECTABLE FORMULATION OF OLANZAPINE IS DESIGNED TO PROVIDE SUSTAINED CONTROLLED CONCENTRATIONS AND TO ELIMINATE THE CAUSES OF POST-INJECTION DELIRIUM/SEDATION SYNDROME (PDSS)

Iva Krtalić¹, Marina Juretić¹, Andrea Komlosi², Ivana Šoljić Jerbić¹, Mateja Prpić¹, Tunde Szabo², Biserka Cetina-Čižmek¹, Irina Cherniakov³, Avia Merenlender Wagner³, Kristina Ferderber*¹

¹Teva PLIVA Croatia Ltd, ²Teva Pharmaceutical Industries, Hungary, ³Teva Pharmaceutical Industries, Ltd.

Background: Use of the intramuscular (im) formulation of olanzapine (Zyprexa Relprevv, Inke S.A.) has been limited because of a black-box warning of post-injection delirium sedation syndrome (PDSS) and associated REMS. PDSS has occurred in 0.07% im injections and is thought to be due to the inadvertent intravascular access of olanzapine pamoate during the IM injection process. This results in a fast dissolution of olanzapine pamoate and unexpectedly high olanzapine plasma concentrations related to PDSS.

TV-44749 (Teva) is a long-acting subcutaneous (sc) injectable formulation of olanzapine and is based on a novel copolymer drug delivery technology that forms a depot under the skin that ensures controlled release of olanzapine. TV-44749's sc route of administration and formulation were also designed to eliminate causes of PDSS. Subcutaneous tissue is much less vascularized compared to muscular tissue, therefore inadvertent intravascular access is assumed to be less likely. To explore the risk of PDSS following TV-44749 sc injection, a study of in vitro release (IVR) in human plasma of TV-44749 in comparison to the IM formulation was undertaken. The pharmacokinetic and safety results concerning PDSS are also reported from the first in human phase 1 study of TV-44749.

Methods: The stability and solubility of base crystalline form II (the active pharmaceutical ingredient (API) in TV-44749) and olanzapine pamoate monohydrate (the API in the IM formulation) in commercially available human plasma were tested to implement optimal parameters in the IVR analysis. The depots of TV-44749 at the beginning and end of the IVR analysis in human plasma were characterized; including surface and cross section morphological properties, changes in copolymer molecular weight distribution and drug substance particle size.

In the phase 1 study, participants (n=91) received oral olanzapine doses for 7 days followed by a washout, and then received TV-44749 single sc injection of either 70mg or 105mg for healthy volunteers; single 318mg, 425mg or 531mg, or three q1m sc injections of 283mg or 566mg for patients with schizophrenia. All who were administered TV-44749 remained under clinical observation for at least 3 hours postdose to monitor for any possible symptom suggestive of PDSS occurrence.

Results: The results show that both APIs were stable in human plasma, however, olanzapine base in crystalline form II in TV-44749 showed 1.8 times lower solubility than olanzapine pamoate monohydrate of the IM formulation. For the IM formulation, 39% of olanzapine is released within first 0.5 h with complete release achieved within 24 hours. For TV-44749, only 3% of olanzapine is released within 4 hours and at the end of IVR experiment at 72 hours, only 14% of olanzapine is released. At the end of the IVR analysis after 72 hours, the depots appear slightly swollen and olanzapine particles are smoothly covered by copolymers, which is in

accordance with the IVR results showing that more than 85% of olanzapine still entrapped within. These results are in line with the phase 1 study which found that following TV-44749 administration, the pharmacokinetic profile demonstrated sustained-release attributes and there were no confirmed or suspected PDSS events.

Discussion: The in vitro study demonstrates that upon contact with human plasma, copolymers of TV-44749 instantly form a depot which entraps olanzapine particles preventing their rapid dissolution in plasma. Overall the sc route of administration and formulation characteristics of TV-44749 appear to eliminate the causes of PDSS. These results are further supported by the lack of PDSS events in the phase 1 study.

S83. EFFECTS OF LUMATEPERONE ON PSYCHOSOCIAL FUNCTIONING: POST HOC ANALYSIS OF A RANDOMIZED CONTROLLED TRIAL

Suresh Durgam¹, Susan Kozauer¹, Robert E Davis¹, Kimberly E Vanover¹, Jason Huo¹, Tobie Escher*¹, Philip D Harvey²

¹*Intra-Cellular Therapies, Inc.*, ²*Department of Psychiatry and Behavioral Sciences, University of Miami Miller School of Medicine and Research Service, Miami VA Healthcare System*

Background: Schizophrenia is associated with social and functional impairment which can be difficult to treat, may not correlate with improvements in psychotic symptoms, and has been associated with poor long-term patient outcomes. Lumateperone is a mechanistically novel, FDA-approved antipsychotic to treat schizophrenia and depressive episodes associated with bipolar I or bipolar II disorder. In a Phase 3, randomized, double-blind, placebo-controlled trial (Study 301, NCT02282761), lumateperone 42 mg significantly improved symptoms of schizophrenia compared with placebo and had a favorable safety profile in patients with an acute exacerbation of schizophrenia. This post hoc analysis of Study 301 evaluated the effects of lumateperone 42 mg on social and functional impairment associated with schizophrenia.

Methods: Eligible adults (18-60, inclusive) with schizophrenia who were experiencing an acute exacerbation of psychosis were randomized to 28-day inpatient treatment with lumateperone 42 mg or placebo. Improvements in functioning were assessed by the Personal and Social Performance Scale (PSP); this scale ranges from 1-100 with higher scores representing better function. Analyses were conducted using an analysis of covariance. The percent of patients that met improvement criteria for minimally clinically important differences (MCID) in PSP, defined as a 10-point improvement from baseline, was also assessed. Evaluations were conducted in both the intent-to-treat (ITT) population and in patients with marked or severe dysfunction (baseline PSP score ≤ 50).

Results: The ITT population comprised 289 patients (placebo, n=141; lumateperone 42 mg, n=148), of which 283 had evaluable baseline PSP data (placebo, n=137; lumateperone 42 mg, n=146). Mean baseline PSP total score was 47.7 for patients in the placebo group and 47.8 for the patients in lumateperone 42-mg group. For patients in the ITT population, lumateperone 42 mg treatment significantly improved compared with placebo in the PSP total score at Day 28 (least squares mean change [SE], 11.0 [1.13]; least squares mean difference vs placebo [LSMD], 3.3; P LESS THAN .05). A greater percentage of lumateperone patients (41.1%) than placebo patients (35.0%) met criteria for MCID improvement at Day 28.

At baseline, 59.4% of the patients in the ITT population with PSP data (placebo, n=83; lumateperone 42 mg, n=85) had marked or severe impairment in social and personal function

(PSP score ≤ 50). Mean baseline PSP total scores in this subgroup were 40.2 (lumateperone) and 40.5 (placebo). In patients with baseline PSP total score ≤ 50 , there was significantly greater improvement with lumateperone 42 mg compared with placebo in the PSP total score at Day 28 (least squares mean change [SE], 16.9 [1.63]; LSMD, 5.8; P LESS THAN .05). The percent of patients that met criteria for MCID improvement was greater with lumateperone (50.6%) than with placebo (38.6%) at Day 28.

Discussion: Lumateperone 42 mg treatment was associated with significant and clinically meaningful improvements in social and personal function in patients with an acute exacerbation of schizophrenia. Improvements were greater in those with marked or severe social and functional impairment at baseline. These results suggest that lumateperone benefits schizophrenia symptoms associated with social and personal function.

S84. MAINTAIN THE EFFICACY AND SAFETY IN TREATMENT OF SCHIZOPHRENIA AFTER SWITCHING TO LONG-ACTING INJECTABLE ARIPIRAZOLE FROM ORAL ATYPICAL ANTIPSYCHOTICS (MAESTRO)

Euitae Kim^{*1}, Seoyoung Kim¹, Sung-Wan Kim², Beom-Woo Nam³, Kyoung-Uk Lee⁴, Bong Ju Lee⁵, Seung-Hee Won⁶, Chang Hwa Lee⁷, Christoph Correll⁸, Jun Soo Kwon⁹, MAESTRO study group¹⁰

Background: Schizophrenia is a chronic, severe mental illness characterized by psychotic symptoms such as hallucinations and delusions, often coupled with cognitive and social impairments. Although clinical remission is not rare with adequate antipsychotic treatment, most patients experience recurring psychotic relapses along the disease course that result in clinical deterioration and functional impairments. Poor drug adherence is a serious concern in the treatment of schizophrenia since it increases the psychotic relapse risk. Long-acting injectable (LAI) antipsychotic drugs, which ameliorate the daily burden of taking oral medication and prevent psychotic relapse from poor adherence, have been introduced.

Aripiprazole has a unique receptor profile as a dopamine partial agonist and has been demonstrated to be safe and effective in the treatment of schizophrenia. LAI aripiprazole has also proved useful for treating schizophrenia, improving treatment adherence and, ultimately, treatment outcomes. However, some patients treated with aripiprazole did not show a favorable response. Indeed, patients exhibited a diverse clinical response to aripiprazole, including symptomatic aggravations. It could be related to the dopamine partial agonism of aripiprazole, which could affect the treatment outcome more when changing antipsychotic drugs from dopamine antagonists to aripiprazole. The variation in the clinical response when changing

antipsychotic drugs to aripiprazole prompts clinical studies about the efficacy and safety in switching to long-acting injectable aripiprazole.

We conducted a clinical trial to evaluate the efficacy and safety in switching oral atypical antipsychotic drugs to LAI aripiprazole according to the pharmacological characteristics.

Methods: The study was based on an open-label, parallel-group study design. Patients with schizophrenia treated with oral antipsychotic drugs who were clinically stable were enrolled. Their symptomatic changes and treatment-emergent adverse events (TEAEs) were evaluated after switching to LAI aripiprazole.

Results: All the patients showed better responses to LAI aripiprazole in terms of PANSS scores. PANSS scores decreased after switching to LAI aripiprazole. Patients who were previously treated with oral aripiprazole (Group I) showed a larger reduction in PANSS score compared to patients who were previously treated with oral antipsychotic drugs other than aripiprazole (Group II).

In the aspects of TEAE, Group II showed higher incidences of sleep disturbance and psychotic symptoms when switching to LAI aripiprazole. However, the two TEAEs were subsided, comparable to Group I.

Discussion: Switching to LAI aripiprazole did not worsen the psychiatric symptoms in clinically stable patients with schizophrenia, regardless of prior antipsychotic drugs. A strategy for managing temporary sleep disturbance and psychotic symptoms when switching from oral antipsychotic drugs with dopamine antagonism to LAI aripiprazole is required to be developed.

S85. RELATIONSHIPS BETWEEN AKATHISIA AND PSYCHOTIC AGITATION AS EVALUATED BY CONSISTENCY CHECKS FOR THE BARNES AKATHISIA RATING SCALE IN A LARGE CLINICAL TRIALS DATASET

Kazunori Tatsumi*¹, Selam Negash¹, Cong Liu¹, Christopher Poppe¹, Mark Opler¹

¹*WCG Clinical Endpoint Solutions*

Background: Akathisia is one of the most debilitating side effects related to antipsychotic drug use. It is characterized by subjective feelings of inner restlessness and mental distress and objective motor restlessness caused by an urge for continuous movement. Although atypical antipsychotics are less likely to cause akathisia, the propensity of individual atypical agents to cause akathisia varies. Accurate information on the side effect burden of commercially available drugs is important to guide treatment selection and clinical management. Consequently, accurate assessment of akathisia is critically important in clinical trials to ascertain the safety profile of investigational products.

The Barnes Akathisia Rating Scale (BARS) has been commonly used in clinical trials and also in clinical practice. It consists of four items designed to systematically assess both subjective and objective aspects of akathisia. Failure to understand scoring rules and item anchor descriptions may result in misclassification of symptoms. Side effects associated with the atypical antipsychotics often overlap with signs and symptoms of psychiatric illness. In particular, psychosis related psychomotor agitation may resemble the symptoms of akathisia. While consistency checks to improve precision of measurement have recently been developed for psychiatric rating scales (e.g., PANSS), their importance and utility in adverse effect measures have not been explored. In this analysis, we propose consistency checks for the BARS based on the scoring rules, theoretical, and clinical frameworks. The objective of the

current study is to investigate how accurately BARS raters assess akathisia by examining the frequency of flags and to evaluate the correlations between the PANSS Marder excitement factor score and the BARS global total score in a large dataset derived from multiple schizophrenia trials.

Methods: A total of 11,077 BARS assessments were derived from five large multicenter schizophrenia clinical trials investigating the efficacy and safety of atypical antipsychotics. A set of consistency checks developed to monitor data quality for the BARS and PANSS were applied to the data, and flag rates were calculated. The data were stratified into two groups based on the design of study to see if blinding plays a role in the evaluation of the side effect. To examine how well raters are differentiating psychomotor agitation from akathisia, a 2x2 table is presented to demonstrate unlikely rating patterns between the scales, and the Kendall's rank correlation coefficient was calculated to measure the correlations between the PANSS Marder factor scores and the BARS global score.

Results: Concordant with the concept that akathisia occurs less frequently in atypical antipsychotic treatment, a substantial number (GREATER THAN 91%) of BARS global score in studies of atypical drugs and novel agents are rated=0. To address the uneven distribution of scores, assessments in which BARS global score=0 were excluded from the analysis of flag rate. A total of 968 assessments were rated with a global score greater than or equal to 1. In comparing the groups, the open-label group showed a significantly higher overall flag rate (33.7%) compared to the double-blind group (26.7%); $t = -2.06$, $df = 10031$, $p \text{ LESS THAN } 0.05$. The percentage of assessments with at least one flag was also significantly higher for the open-label group (31% vs 19%, $t = -3.87$, $df = 7750$, $p \text{ LESS THAN } 0.0001$), while assessments with two or more flags did not differ between the two groups (3% vs 5%; $t = 1.69$, $df = 11209$, $p = 0.0092$). The flag designed to identify incorrect use of scoring conventions was the most frequently flagged error for both studies. When both the BARS and PANSS were administered together at the same visit, approximately 2.3 – 2.5% of time both akathisia and agitation defined as PANSS-EC GREATER THAN 14 and PANSS-AF GREATER THAN 17 were present. The correlation between the PANSS Marder excitement factor and the BARS global total score was low ($r=0.06$, $p \text{ LESS THAN } 0.01$), and it was almost identical ($r=0.07$, $p \text{ LESS THAN } 0.01$) when BARS=0 was excluded from the correlational analysis.

Discussion: The results suggest that the most common error among BARS raters participating in schizophrenia clinical trials of new generation of antipsychotics is incorrect classification of pseudoakathisia. According to the scale author, a rating of 0 is given for the global item if there is a positive score on objective akathisia but a 0 rating on subjective items. The reason for the rating error may not only stem from the lack of awareness of the scoring rule, but also that raters may be misclassifying psychomotor agitation with akathisia as well. A similar rating error seems to be manifested when examining the relationship between two measures. The correlation between the BARS global score and the PANSS Marder hostility/excitement score was very low. This, in turn, suggests that unexpectedly strong correlations between the two measures could be an indicative of imprecise measurement. Lastly, the open-label study design seems to be more prone to rating errors. While both syndromes theoretically can occur at the same time, application of flags and monitoring of higher correlations of the BARS global score and PANSS factor score may help identify rating errors and misclassification of symptoms.

S86. CLINICAL BENEFIT AND RISK PROFILE OF TV-46000 FOR PATIENTS WITH SCHIZOPHRENIA AS ASSESSED BY NUMBER NEEDED TO TREAT (NNT) AND NUMBER NEEDED TO HARM (NNH)

Leslie Citrome¹, Orna Tohami², Nir Sharon², Ayellet Jehassi², Eran Harary², Mark Suett³, Kelli R. Franzenburg⁴, Christoph U. Correll⁵, Orna Tohami^{*6}

¹New York Medical College, Department of Psychiatry and Behavioral Sciences, ²Teva Pharmaceutical Industries Ltd., ³Teva UK Limited, ⁴Teva Branded Pharmaceutical Products R and D, Inc., ⁵The Zucker Hillside Hospital, Northwell Health, Department of Psychiatry,; Donald and Barbara Zucker School of Medicine at Hofstra/Northwell, Department of Psychiatry and Molecular Medicine,; Feinstein Institutes for Medical Research, Institute of Behavioral Science,; Charité – Universitätsmedizin Berlin, Department of Child and Adolescent Psychiatry, ⁶Teva Pharmaceutical Industries, Ltd.

Background: TV-46000 is a long-acting subcutaneous antipsychotic that combines risperidone and an innovative, copolymer-based drug delivery technology. TV-46000 was approved by the Food and Drug Administration in April 2023 for administration once monthly (q1m) or once every 2 months (q2m) in adult patients with schizophrenia. The Risperidone Subcutaneous Extended-release (RISE; NCT03503318) study was a phase 3, double-blind, placebo-controlled, randomized, relapse prevention study. Compared with placebo, TV-46000 prolonged time to impending relapse (TV-46000 q1m, hazard ratio [HR] 0.200 [95% CI 0.109–0.367], P LESS THAN .0001; TV-46000 q2m, HR 0.375 [0.227–0.618], P LESS THAN .0001). Number needed to treat (NNT) and number needed to harm (NNH) are important metrics that can help healthcare professionals understand the benefits and risks of treatments and thus inform their clinical decision-making.

Methods: NNT estimates versus placebo were calculated for TV-46000 in the treatment of schizophrenia using data from the RISE study. NNH estimates versus placebo were calculated for adverse events of interest based on common second-generation antipsychotic side effects (akathisia, somnolence, weight increased $\geq 7\%$) using safety data from the RISE study.

Results: In the RISE study, 543 patients were evaluated for efficacy (TV-46000 q1m, n=183; TV-46000 q2m, n=179; placebo, n=181) and safety (TV-46000 q1m, n=183; TV-46000 q2m, n=179; placebo, n=179). NNT estimates for impending relapse were 5 (95% CI 3.4–6.9) for TV-46000 q1m and 7 (4.1–12.2) for TV-46000 q2m. NNT estimates for other efficacy endpoints (impending relapse rate at week 24 and proportion of patients who maintained stability) were also robust for TV 46000 q1m (range, 4–5) and TV-46000 q2m (range, 5–6). NNH estimates for akathisia, somnolence, and weight increased $\geq 7\%$ were GREATER THAN 10, indicating a favorable tolerability profile with weight increased $\geq 7\%$ (10 and 16 for TV-46000 q1m and TV-46000 q2m, respectively) having the highest risk, and akathisia (64 and 60) and somnolence (37 and 30) having a lower risk.

Discussion: In the phase 3 RISE study, TV-46000 administered q1m and q2m exhibited a favorable efficacy and safety profile as expressed by NNT and NNH. The robust, single digit number of patients needed to be treated to see a positive effect on risk of impending relapse and symptomatic stability supports the efficacy of TV-46000 in patients with schizophrenia. The high NNHs calculated for selected safety assessments suggest TV-46000 was well tolerated. TV-46000 NNTs and NNHs may provide clinicians with clinically meaningful information when considering the use of long acting injectables for patients with schizophrenia.

S87. SCHIZOPHRENIA PLATFORM FOR IMPROVING RECOVERY WITH INTEGRATED TRIALS (S.P.I.R.I.T.).

Dan Siskind*¹, Urska Arnautovska², Andrea Baker³, Mike Trott², Rebecca Soole², Ravi Iyer⁴, Julia Lappin⁵, Anthony Rodgers⁶

¹*Metro South Addiction and Mental Health Service*, ²*Faculty of Medicine, The University of Queensland*, ³*Queensland Centre for Mental health Research*, ⁴*Swinburne University*, ⁵*University of New South Wales, Sydney, Australia*, ⁶*George Institute, Sydney*

Background: Adaptive platform trials, demonstrated extremely successfully in other health domains like COVID-19, streamline evidence generation by addressing multiple questions rapidly and much more efficiently. Platform trials offer an efficient approach, by using one standardised control arm, while comparing outcomes across multiple parallel treatment arms. Throughout the trial, predefined interim analyses assess the viability of treatment arms, informing whether treatment arms should be terminated early and facilitating enrolment of participants to more promising treatment arms, or to newly added treatment arms. This optimised use of control data reduces the overall sample size required, minimising recruitment time and resource expenditure compared to traditional individual RCTs. This design has promise for trials among people with schizophrenia.

Methods: Rather than ‘intervention focused’, our proposed platform will be ‘schizophrenia focused’ and will use adaptive randomisation techniques to simultaneously evaluate multiple interventions, generate separate effects across subgroups, and minimise trial downtime. In this study, a Master Protocol will be established to guide all trial operations, focusing on four core health domains identified through consumer consultation for treating schizophrenia. Domain-specific primary outcomes are defined: Cardiometabolic (weight), Psychotic symptoms (PANSS), Cognition (BACS), and Social functioning (SF-36). An integrated, cloud-based data management system will be implemented for secure, standardized data collection and automated quality control. A Bayesian statistical framework will be used for data analysis, incorporating prior knowledge for a comprehensive assessment of treatment efficacy. Interim analyses will allow for modifications such as dropping or introducing treatment arms based on predefined criteria.

Results: Our first SPIRIT platform trial randomisation SWiMS (Schizophrenia Weight, Metformin and Semaglutide). This trial will compare semaglutide (2.0mg subcutaneous, weekly) to placebo injections over 52 weeks among 188 people with schizophrenia on antipsychotic medications and obesity. The primary outcome will be change in body weight (percent). Secondary outcomes include changes in metabolic syndrome components, proportion of participants with GREATER THAN 5%, GREATER THAN 10% and GREATER THAN 15% loss of body weight, visceral/hepatic adiposity, cognition, quality of life and psychosis from baseline to 52 weeks. Early stopping will be non-binding, considered only once sufficient data has been accrued, and in consultation with the trial steering committee. Sufficient data will be defined as occurring once 30 participants have been enrolled and adhered to protocol (completed all outcome assessments) for 24 weeks. If one of the arms of this trial meets our predefined futility stopping rules, we will add tirzepatide and a new treatment arm.

Discussion: Through the creation of world’s first schizophrenia platform trial, we will improve the efficiency of clinical trials, with multiple interventions tested simultaneously against a single control group. As ineffective treatments within schizophrenia domains are identified, they can be dropped, and new interventions added without needing to start a new trial. This will lead to immediate consumer benefit, with a higher probability of receiving an effective treatment since there are multiple active treatment arms. Moreover, as ineffective treatments are dropped and effective ones are identified more quickly, patients benefit from better

treatments sooner and more efficient treatment can be more rapidly translated into better health care for this population group.

S88. CANCLOZ: CANNABIDIOL FOR CLOZAPINE RESISTANT SCHIZOPHRENIA - A MULTI-CENTRE RANDOMISED, PLACEBO-CONTROLLED, DOUBLE-BLIND, PARALLEL-GROUP TRIAL

Dan Siskind^{*1}, Andrea Baker², Nicola Warren³, Shuichi Suetani², Claudia Bull³, Mike Trott³, Urska Arnautovska³

¹*Metro South Addiction and Mental Health Service*, ²*Queensland Centre for Mental health Research*, ³*Faculty of Medicine, The University of Queensland*

Background: Schizophrenia affects approximately 1% of the global population, with about a third of these individuals having treatment-resistant schizophrenia (TRS). Clozapine is the most effective known antipsychotic for TRS, yet only 40% of TRS patients show adequate response to clozapine. Existing augmentation strategies for clozapine are limited in effectiveness. Cannabidiol (CBD) has shown promise in reducing positive psychotic symptoms in schizophrenia but has not been tested specifically in clozapine-resistant schizophrenia.

Methods: This study is a 12-week randomised, placebo-controlled, double-blind, parallel-group trial. Forty individuals with clozapine-resistant schizophrenia will be randomly assigned to receive either 1,000mg of CBD daily or a placebo. Participants will be aged 18-64, meet DSM-IV criteria for schizophrenia or schizoaffective disorder, have a PANSS score ≥ 60 , and be on a stable dose of clozapine for at least 18 weeks with a blood level of GREATER THAN 350ng/ml. The primary endpoint is the change in total PANSS scores at 12 weeks. Secondary endpoints include measures of depression, anxiety, sleep quality, quality of life, alcohol consumption, weight change, metabolic syndrome components, neurocognitive functions, and safety and tolerability of the treatment.

Results: We will present results regarding any potential significant reduction in total PANSS scores in the CBD group compared to the placebo group at week 12. Secondary outcomes will be presented on changes in sleep quality, anxiety, neurocognitive measures, depression scores, metabolic syndrome components, or alcohol consumption between the CBD and control group. Tolerability of CBD will be reported.

Discussion: The study will explore whether CBD could be an effective and safe adjunctive treatment for individuals with clozapine-resistant schizophrenia. If it shows promise in improving psychotic symptoms it has the potential to be a safe augmentation agent for people with clozapine resistant schizophrenia.

S89. OXIDATIVE STRESS RELATES TO NEGATIVE SYMPTOMS IN A GLUTEN SENSITIVE SCHIZOPHRENIA SUBGROUP

Deanna L. Kelly^{*1}, Eunkyong Kim², Sidney Redwood³, William Eaton⁴, Valerie Harrington⁵, Daniel Roche⁵, Daniela Cihakova⁶, Monica V. Talor⁶, Donna Dadkhoo⁵, Shuo Chen⁵, Matthew Glassman⁵, Stephanie Kulaga⁵, Fang Liu⁵, Bruce Patterson⁷, Gregory F. Payne²

¹*University of Maryland Baltimore, Maryland Psychiatric Research Center*, ²*University of Maryland College Park - Institute for Bioscience and Biotechnology Research*, ³*University of*

Maryland College Park, ⁴Johns Hopkins Bloomberg School of Public Health, Department of Mental Health, ⁵Maryland Psychiatric Research Center, University of Maryland School of Medicine, ⁶Johns Hopkins Bloomberg School of Public Health, Department of Pathology, ⁷Johns Hopkins University

Background: In individuals with schizophrenia-related disorders (SRD), negative symptoms are enduring and persistent, contribute more to loss of function than positive symptoms, and may be the most significant predictor of poor long-term outcomes. Understanding of their pathophysiology and discovery of new treatments have been elusive, as evidenced by the current lack of Food and Drug Administration-approved medications for negative symptoms associated with SRD.

We have identified and characterized a subgroup of people with SRD, representing about 33-38% of all people with SRD, with an immune and inflammatory response to gliadin, a protein found in wheat, barley and rye. Specifically, this subgroup has high antigliadin antibodies (AGA IgG) correlated to peripheral and central markers of inflammation. Notably, we have found negative symptom improvements in this subgroup when on a gluten-free diet compared to a gluten-containing diet (Cohen's D=0.53) in a 5-week randomized, double-blind, inpatient clinical trial (N=16).

Oxidative stress (OxSt), a marker of excess production of reactive oxygen species (ROS) vs. antioxidants, has been linked to negative symptoms and inflammatory markers in SRD. Our group has developed a global peripheral measure of OxSt that we previously found to be increased in SRD. Consumption of gluten by people with gluten sensitivity induces the overproduction of ROS, triggering a cascade of reactions that cause OxSt at both the small intestinal mucosa and the systemic level. Yet, it is unclear how OxSt relates to negative symptoms in this SRD subgroup with elevated AGA IgG.

Methods: We assayed the initial and 5-week end-point serum samples from the 16 participants in the aforementioned gluten-free diet trial. All participants had an SRD diagnosis and AGA IgG GREATER THAN 20 U (i.e., were gluten sensitive). Serum samples were frozen at -80 °C and analyzed for cytokines (IL-23) and a peripheral measure of oxidative stress (OxSt) using an Ir-reducing capacity assay (Ir-RCA). Iridium (Ir) probes "chemical space" for global information of a sample's oxidation levels, is especially sensitive to the oxidation state of sulfur-based metabolites (e.g., glutathione and protein cysteine residues), and yields results in conveniently measurable optical and electrochemical signals. Triplicate measurements of these samples showed an Intraclass Correlation Coefficient (ICC) of 0.84 which indicates good reproducibility. Negative symptoms were measured at baseline and endpoint using the Scale for the Assessment of Negative Symptoms (SANS).

Results: In this small underpowered sample, the gluten free diet, vs. the gluten containing diet, reduced OxSt over 5-weeks of treatment ($\chi^2 = 3.834$, $df=1$, $p=0.050$, $F=9.85$, $df=1,13$, $p=0.10$). (Cohen's D= -0.71). Critically, reductions in OxSt over these 5 weeks were correlated with improved negative symptoms ($r=+0.518$; $p=0.039$) and gastrointestinal (GI) symptoms ($r=+0.642$; $p=0.007$) and trended toward being associated with decreased IL-23 ($p=0.089$).

Discussion: We have identified an SRD subgroup for which a gluten-free diet appears to improve GI and negative symptoms, and these improvements may be related to reductions in OxSt. In this subgroup, a gluten-free diet may attenuate gut permeability by preventing breakdown of the tight junction barriers stimulated by IL-23 and a resultant immune-inflammatory/OxSt response in the gut and possibly the brain. These results extend our previous work showing the Ir-RCA is a sensitive, global measure of OxSt that can objectively characterize differences in psychiatric populations. In gluten sensitive individuals with SRD,

OxSt may serve as an important biomarker and help elucidate the pathophysiologic underpinnings of negative symptom pathology.

Funding Source: This work was funded in part by NIMH 1R01 MH113617-01 and NIMH R34MH100776 (PIs Eaton and Kelly).

S90. DAILY-LIFE STRESS REACTIVITY AND RECOVERY FOLLOWING VIRTUAL-REALITY-BASED COGNITIVE BEHAVIOURAL THERAPY IN PATIENTS WITH A PSYCHOTIC DISORDER

Elise van der Stouwe^{*1}, Sanne Booi², Chris Geraets¹, Roos Pot-Kolder³, Anna Kuranova¹, Mark van der Gaag⁴, Wim Veling¹

¹University Medical Center Groningen, ²Groningen University, ³The University of Melbourne, ⁴VU University Amsterdam

Background: Studies have consistently demonstrated increased stress sensitivity in individuals with psychosis. Since stress sensitivity may play a role in the onset and maintenance of psychosis, this could potentially be a promising target for treatment. The current study was the first to investigate whether reactivity to and recovery from daily-life stressors in psychosis change in response to treatment, namely virtual-reality-based cognitive behavioural therapy (VR-CBT).

Methods: 116 patients were randomized to either VR-CBT or the waiting list control group (WL). Pre-treatment and post-treatment participants completed a diary ten times a day during six to ten days. Multilevel analyses were used to model the time-lagged effects of daily stressful events on negative affect (NA) and paranoia symptoms to examine reactivity and recovery.

Results: There was a significant difference in NA reactivity. VR-CBT showed higher NA at post-treatment compared to pre-treatment than WL (bpre=0.14; bpost=0.19 vs bpre=0.18; bpost=0.14). There was a significant difference in NA recovery and paranoia recovery between the groups at lag 1: VR-CBT showed relatively lower negative affect (bpre=0.07; bpost=-0.06) and paranoia (bpre= 0.08; bpost=-0.10) at post-treatment compared to pre-treatment than WL (bpre=0.08; bpost=0.08; bpre=0.04; bpost=0.03).

Discussion: Negative affect and paranoia recovery improved in response to treatment. Increased NA reactivity may be explained by a decrease in safety behaviour in the VR-CBT group. The discrepancy between reactivity and recovery findings may be explained by the inhibitory learning theory that suggests that an original threat reaction may not erase but can be inhibited as a consequence of exposure therapy.

S91. PHARMACOKINETIC SIMULATIONS OF ARIPIPRAZOLE 2-MONTH READY-TO-USE LONG-ACTING INJECTABLE TO INFORM ADMINISTRATION IN ADULT PATIENTS WITH SCHIZOPHRENIA

Yanlin Wang¹, Matthew Harlin^{*1}, Frank Larsen², Xiaofeng Wang¹, Wansu Park³, Benjamin Rich⁴, Jogarao V. Gobburu⁵, Arash Raoufinia¹

¹Otsuka Pharmaceutical Development and Commercialization, Inc. (OPDC), ²H. Lundbeck A/S, ³Alnylam Pharmaceuticals, ⁴InnoMx Inc., ⁵University of Maryland

Background: Ongoing symptom control in patients with schizophrenia relies on long term, consistent antipsychotic treatment. However, a meta-analysis of available data for adherence to oral antipsychotics in patients with schizophrenia suggests that adherence rates are ~70% (range: 50–78%), which is below the 80% threshold widely used to define satisfactory adherence (1). Aripiprazole 2-month ready-to-use 960 mg (Ari 2MRTU 960) is a novel long-acting injectable formulation of aripiprazole for gluteal intramuscular administration once every 2 months. Ari 2MRTU 960 was developed to extend exposure to aripiprazole concentrations within the established aripiprazole therapeutic window from 1 month (with aripiprazole once-monthly [AOM]) to 2 months. Extending the dosing interval beyond 1 month may reduce treatment burden for patients and clinicians and improve adherence. A combined population pharmacokinetic (popPK) model for oral aripiprazole, AOM, and Ari 2MRTU was developed. Use of this model to explore dosing with Ari 2MRTU in scenarios relevant to the European clinical context is reported herein.

Methods: Aripiprazole plasma concentration–time profiles were simulated for various Ari 2MRTU initiation and maintenance scenarios. Simulations were performed using Pumas v2.0 in a population of 1,000 virtual patients. Model covariates were assigned to virtual patients by resampling from the total patient population used to develop the popPK model; individual random effects were obtained by resampling from patient subgroups with the most relevant/robust information for each PK parameter of interest. Poor metabolizers of CYP2D6, in whom the PK profile of lower-dose Ari 2MRTU 720 mg was studied, comprised 5% of the virtual population, except for simulations requiring all patients to be normal or poor CYP2D6 metabolizers.

Results: Across multiple simulated initiation scenarios, Ari 2MRTU 960 resulted in aripiprazole concentrations that were comparable to AOM 400, and within the established aripiprazole therapeutic window (95–534 ng/mL) (2,3). This was the case for:

- initiation of Ari 2MRTU 960 after a direct transition from AOM 400
- initiation of Ari 2MRTU 960 plus 14 days of overlapping oral aripiprazole 10 or 20 mg/day following stabilization on oral aripiprazole 10 or 20 mg/day, and
- initiation of Ari 2MRTU 960 on Day 28 after administration of AOM 400 on Day 0 plus 14 days of overlapping oral aripiprazole 20 mg/day following stabilization on oral aripiprazole 20 mg/day.

In maintenance scenarios, median trough concentrations were 191, 144, 110, and 80.1 ng/mL after an Ari 2MRTU 960 dosing delay of 2, 4, 6, and 8 weeks, respectively, increasing in these groups to 231, 217, 205, and 196 ng/mL, respectively, 56 days after Ari 2MRTU 960 was given (plus 14 days of oral aripiprazole 10 mg/day overlap in the last scenario). In CYP2D6 poor metabolizers, Ari 2MRTU 720 mg showed steady-state aripiprazole concentrations comparable to AOM 300 mg. Compared with Ari 2MRTU 960 without a CYP3A4 or CYP2D6 strong inhibitor, aripiprazole concentrations were similar with Ari 2MRTU 720 plus a CYP3A4 strong inhibitor and higher with Ari 2MRTU 720 with a CYP2D6 strong inhibitor.

Discussion: Discussion Model-based simulations across a variety of dosing scenarios relevant to the European clinical context showed that aripiprazole plasma concentrations over the 2-month dosing interval with Ari 2MRTU 960 were comparable to those for AOM 400.

S92. OUTCOMES OF THE CLINICAL TRIAL ETRO TO EVALUATE AN SMARTPHONE APP-BASED TREATMENT PROGRAMME FOR ADOLESCENTS AT ADOLESCENTS AT CLINICAL HIGH RISK FOR PSYCHOSIS

Nina Traber-Walker*¹, Miriam Gerstenberg², Fabian Probst³, Camille Bertossa³, Claudia Bühlmann³, Lukasz Smigielski⁴, Susanne Walitza², Maurizia Frascini²

¹Psychiatric University Hospital Zurich, ²University of Zurich, Department of Child and Adolescent Psychiatry, ³Psychiatric University Hospital Zurich, Department of Child and Adolescent Psychiatry and Psychotherapy, ⁴University of Zurich, Switzerland

Background: The goal of preventing psychotic disorders has led researchers to focus on the early identification of individuals at clinical high risk (CHR) for psychosis and to treat CHR symptoms. CHR symptoms usually appear during adolescence and young adulthood. This is a very sensitive developmental period and the CHR condition is associated with increasing functional impairment. Age-appropriate treatment approaches are needed that address youth-specific concerns, complex symptomatology, associated distress and functional impairment. However, there is a lack of research on treatment strategies for this vulnerable age group. To address this gap, the combined treatment programme "Robin" (standardised manual and smartphone app) has been developed. The treatment programme targets CHR symptoms, comorbid symptoms as well as improvement of quality of life and daily functioning. The "Robin Z" smartphone app is an additional treatment tool to support patients between the therapy sessions. While a number of studies on smartphone-assisted interventions have shown promising effects in adult psychosis patients, little is known about their use with minor patients. "Robin Z" is one of the first smartphone apps designed for adolescent patients with CHR or full-blown psychotic symptoms.

Methods: The ETRO study is a prospective, naturalistic follow-up study. A total of 40 help-seeking CHR adolescents (65% female, mean age 15.31) were recruited for the intervention group (16 weekly individual sessions + 4 family sessions). For the control condition (treatment as usual TAU), 72 participants (34% female, mean age 15.07) from a previous study have been included. CHR-symptoms, comorbid symptoms, functioning, self-efficacy and quality of life will be monitored at six time points (baseline, during the treatment period, immediately after intervention, and 6, 12 and 24 months later) and compared with the respective measures of the active control group.

Results: The group comparison of the transition rate to psychosis shows (Fisher's exact test, p LESS THAN 0.1) that there are statistically significantly fewer transitions in the intervention group (n=1, 2.5%) than in the control group (n=10, 16.9%).

An initial analysis of the control group showed a significant improvement in global functionality (F=11.88, p=0.001) compared to baseline at one-year follow-up. In terms of self-efficacy, there was a statistical trend towards improvement across the follow-up time points (F=4.02, p=0.053). However, there was no statistically significant improvement in quality of life over time.

The follow-up data of the intervention group are currently being analysed and prepared for the congress in Florence.

Discussion: An initial comparison showed that the rate of transitions to psychosis was significantly lower in the intervention group than in the control group. First evaluations of the data from the control group with treatment as usual already demonstrated treatment effects. We assume that the data from the intervention group will differ from the control group and that even more treatment effects can be expected.

To our knowledge, our clinical trial is the first to evaluate a therapy manual with a smartphone app for adolescents at clinical high risk. The results are therefore of high importance for research in early intervention and smartphone-based treatment programmes.

S93. USING COMPUTATIONAL MODELLING OF P300 RESPONSES TO INVESTIGATE CIRCUIT CHANGE IN CLINICAL HIGH-RISK FOR PSYCHOSIS: INSIGHTS FROM THE NAPLS-2 SAMPLE

Julia Rodriguez-Sanchez^{*1}, Daniel J. Hauke¹, Rick Adams¹, Catalina Mourgues-Codern², Tyrone Cannon², Daniel Mathalon³, Albert Powers²

¹University College London, ²Yale University, ³University of California, San Francisco

Background: Hallucinations and delusions have been primarily studied in the context of fully-formed psychosis. However, the neurobiological mechanisms underlying the development of these symptoms remain unclear. Recent evidence suggests that the majority of patients experience delusions prior to hallucinations. Understanding the circuit changes that accompany the onset of different symptoms like hallucinations and delusions is crucial for identifying targeted preventative strategies. We investigated effective connectivity in young individuals meeting clinical high-risk criteria for psychosis (CHR-P) with dynamic causal modelling (DCM) of electroencephalography (EEG) recorded during an auditory oddball paradigm. Notably, individuals at CHR-P have been shown to exhibit diminished P300 responses to oddball stimuli (Hamilton et al., 2019, JAMA Psychiatry), an effect which is also observed in patients with schizophrenia and has been linked to clinical outcomes.

Methods: Baseline data from 571 CHR-P participants, including 77 participants who converted to psychosis during the 24-month follow-up, and 241 healthy controls were collected as part of the North American Prodrome Longitudinal Study (NAPLS-2). We defined five different subgroups among CHR-P participants based on symptom onset: 130 with only delusions at baseline, 28 with only hallucinations, 219 with both delusions and hallucinations, 131 with both delusions and hallucinations who developed delusions first, and 63 with both delusions and hallucinations who developed hallucinations first. We modelled EEG responses to standard and target tones in the superior temporal gyrus (STG)-auditory frontoparietal network. Each region comprised superficial and deep pyramidal cells, spiny stellate cells and inhibitory interneurons. Additionally, we explored a longitudinal subsample of 20 CHR-P participants who presented with only delusions at baseline, including 10 participants who developed hallucinations during the follow-up period and 10 matched controls.

Results: Reduced P300 amplitude in CHR-P was explained by increased superficial pyramidal cell self-inhibition (decreased synaptic gain) in the STG (posterior probability $P > 0.95$). Converters, but not non-converters, showed increased self-inhibition across the STG-auditory frontoparietal network, as well as increased forward connectivity from the STG and superior parietal cortex compared with controls ($P > 0.95$). Among CHR-P subgroups, participants with both hallucinations and delusions ($p = .01$, $d = 0.24$) and participants who developed delusions before hallucinations ($p < .001$, $d = 0.41$)

had significantly reduced P300 amplitudes compared with controls, while baseline P300 responses in participants with only delusions were similar to those of controls. Consistent with this, longitudinal data from CHR-P participants who presented with only delusions at baseline showed P300 amplitude reductions following the onset of hallucinations ($p = .02$). Self-inhibition within the STG ($P > 0.95$) and backward connectivity from the superior frontal cortex ($P > 0.99$) were both increased at 12 months relative to baseline in this group.

Discussion: Our findings reveal widespread circuit abnormalities in CHR-P individuals who later convert to psychosis and provide preliminary evidence for changes in bottom-up and top-down connectivity as hallucinations develop. They also highlight alterations in cortical excitability in CHR-P, aligning with aetiological theories of schizophrenia that implicate disturbances in excitatory/inhibitory balance (Krystal et al., 2017, *Biol Psychiatry*). This approach holds promising potential for investigating circuit changes in emerging psychosis non-invasively and may aid in identifying specific mechanisms associated with primary versus secondary symptoms of schizophrenia, ultimately improving clinical outcomes.

S94. CONVERGING EVIDENCE FOR INCREASED PRIOR WEIGHTING IN PSYCHOSIS RISK AND EARLY PSYCHOSIS

David Benrimoh^{*1}, Catalina Mourgues², Jai Shah³, Al Powers⁴

¹*McGill University*, ²*Yale University School of Medicine*, ³*Department of Psychiatry – McGill University – Montreal – Canada*, ⁴*Yale University*

Background: There is increasing empirical evidence for the finding that psychotic symptoms in schizophrenia, such as hallucinations, are driven by a hyper-precision of prior beliefs compared to incoming sensory evidence. However, it remains unclear whether this increased prior precision is a secondary or compensatory process, or if it is a primary process which drives the development of psychotic symptoms. This distinction is relevant as there may be different neural processes involved depending on the sequence of information processing changes, suggesting different potentially effective intervention strategies. In addition, understanding the timing of computational changes will be important if they are to be useful for generating novel staging methods in early psychosis and psychosis risk.

Methods: I will examine evidence from two recent studies which suggest that increased prior weighting may be present early in psychosis. In the first study, we studied responses to a linguistic version of the conditioned hallucinations (CH) task in an online sample of 88 participants from the general population without psychosis diagnoses. In a separate dataset of 695 patients with first episode psychosis who retrospectively reported their prodromal symptoms from PEPP-Montreal, we examined whether hallucinations or delusions were more likely to be reported as first symptoms, and determined which symptom type was more persistent over time.

Results: In the online CH study, higher CH rates were observed both in those with recent hallucinatory experiences as well as participants with high hallucination proneness; CH rates were positively correlated with increased prior weighting; and increased prior weighting was related to hallucination severity. Participants with recent hallucinatory experiences as well as those with higher hallucination-proneness had higher stimulus thresholds, lower sensitivity to stimuli presented at the highest threshold, and had lower response confidence, consistent with lower precision of sensory evidence. In the PEPP dataset, most patients reported delusion-

spectrum rather than hallucination-spectrum symptoms as their first prodromal symptom (22% vs. 7%) and their first psychotic symptom: (62% vs. 22%). In addition, after psychosis and treatment onset, delusions tended to persist at a higher level than hallucination symptoms.

Discussion: It has often been hypothesized that altered perceptual experiences are the first symptoms in incipient psychosis, with delusions forming as compensatory beliefs to explain away these experiences. These results suggest that if this occurs, it is in a minority of patients, with delusions-type symptoms usually being the first psychotic symptoms and remaining present at threshold for longer, potentially serving as priors which help to drive hallucinatory experiences. These two different studies help to establish the likely important role of altered priors in the generation of psychotic experiences early in the illness, while at the same time continuing to highlight the importance of altered sensory precision. Further longitudinal studies are needed in order to determine the precise sequence of information processing changes which lead to psychosis, and to identify potential subgroups within the psychosis risk population which may experience different trajectories- and therefore may have different underlying neurobiology and treatment considerations.

S95. CHANGES IN THE USE OF PRIOR SEMANTIC KNOWLEDGE RELATIVE TO SENSORY INFORMATION IN PATIENTS IN ACUTE PSYCHOSIS AND PSYCHOTIC REMISSION AND THE LINK TO HALLUCINATIONS: A LONGITUDINAL APPROACH

Franziska Knolle*¹

¹*Technical University of Munich*

Background: Schizophrenia is associated with a wide range of language alterations. Interestingly, the recent predictive coding account does not only provide a testable theory for the explanation of positive symptoms in schizophrenia, but is also one of the most promising theories of language processing. Experimental evidence of the predictive coding account of psychosis suggests that an overweighing of sensory likelihood may occur at lower levels (e.g., early sensory processing areas) due to increased dopamine activity causing aberrant salience and leading to delusions, while an overweighting of prior beliefs at higher levels, potentially caused by altered glutamatergic receptor signalling, may cause hallucinations. The interplay of prior information and sensory likelihood can be tested efficiently during language processing, due to its predictive nature. This study therefore investigates (1) how the use of prior knowledge relative to sensory information in a predictive language task changes when patients with schizophrenia transition from acute psychosis to psychotic remission, and (2) whether an overreliance on prior semantic knowledge induces conditioned hallucinations in a state of acute psychosis, but not in a state of psychotic remission.

Methods: Using a longitudinal approach, we assessed 20 patients with schizophrenia first during a state of active psychosis and then, after approximately three months, in a state of psychotic remission. Controls were assessed at two similarly delayed time points. All participants completed a predictive language paradigm in which they listened to sentences of varying predictability (e.g., high predictability: “Goethe was a famous German ... poet”; low predictability: “Next to the window was a ... hole”). The final word of each sentence (e.g., “poet” or “hole”) was degraded in clarity using a noise vocoding algorithm; degradations were available in four levels from fully unintelligible to fully intelligible. After listening to the full sentence, participants were asked to report the word they perceived, assessing conditioned hallucinations. We fitted a linear Bayesian regression model to estimate the prior weight which

presents the relative strength of the prior over the sensory input. Using a repeated measurement model, we compared prior weights and conditioned hallucinations across time points and groups. Furthermore, we correlated those with positive symptoms at both time points.

Results: The modelling results revealed that prior knowledge relative to sensory information was overweighed in patients compared to controls, but especially during the first time point, when patients were in a state of acute psychosis. The same relationship was detected for conditioned hallucinations. Furthermore, patients with stronger psychotic symptoms perceived more conditioned hallucinations, but this positive correlation was only present during the acute psychotic state and absent during the state of remission.

Discussion: This study shows that prior knowledge was overweighted during a language perception task in schizophrenia patients during an acute state of psychosis, and less so during psychotic remission. Importantly, overweighting prior knowledge and stronger psychotic symptoms were linked to experiencing more conditioned hallucinations. Taken together, this study provides novel evidence of how alterations in predictive language processing change when schizophrenia patients change from an acute to a remitted state of psychosis and how this contributes to the formation of hallucinations.

S96. NARRATIVE COMPLEXITY INDEX AS A SCREENING TOOL FOR SOCIAL COGNITION LOSS IN THE CONTEXT OF PSYCHOSIS

Bárbara Malcorra^{*1}, Marina Ribeiro², Tamara Meletti¹, Luísa Jensen¹, Natália Mota³

¹*Mobile Brain*, ²*Mobile Brain*; *Universidade Federal do Rio Grande do Norte (UFRN)*,

³*Mobile Brain*; *Universidade Federal do Rio de Janeiro (UFRJ)*

Background: Schizophrenia patients present a range of functional and social impairments that affect their daily performance and impair their quality of life. Among the possible contributing factors to this drop in patients' functional performance are impairments in social cognition. However, such social deficits still need to be well established. Based on this, the present study aims to investigate the application of narrative complexity (a measure based on word-recurrence graphs weighted by years of education and compared to a normative curve) as an indicator of loss of social cognition in adults' speech compared with their educational path, considering the importance of seeing the deterioration of this population's communication skills.

Methods: Narratives from 232 Brazilian Portuguese-speaking individuals were collected. One hundred sixty-seven (167) typical subjects and 65 patients with psychotic symptoms (age from 2 to 60; years of education from none to 20 years of education) were requested to produce emotional narratives (such as dream reports and stories based on affective pictures chosen from the IAPS database). The narratives were then represented as word-recurrence graphs, in which a node represents each word, and the sequence between them is represented by edges (directed arrows). We used sliding windows of 30 words to control for verbosity differences, with a 50% overlap between windows. We then calculated the number of Nodes (proxy to lexical diversity), repeated edges – RE (or short-range recurrence), nodes inside the largest strongly connected component – LSC (connectedness or long-range recurrence), and average shortest path – ASP (graph size). A multilinear correlation between word-recurrence graph attributes and years of formal education defined narrative complexity (NC). The combination of graph attributes linked to the individual's level of education makes up the narrative complexity index. We then produced a normative curve for each year of education and calculated the values of the narrative complexity index and its respective percentile.

Results: The multilinear correlation between word-recurrence graph attributes and years of education was significant and explained 36% of data variance ($R^2 = 0.36$, $p < 0.001$). We compared the mean and standard error of the two measures (narrative complexity index and its percentile) between the typical and atypical groups. The results demonstrate that the raw values of narrative complexity do not differ between the two groups (typical group: mean = 5.24, standard error = 0.18; atypical group: mean = 5.22, standard error = 0.29; $p = 0.5846$). However, when adopting the percentile perspective, the loss related to education can be seen (typical group: mean = 68.65, standard error = 2.24; atypical group: mean = 50.14, standard error = 4.81; $p = 0.0015$).

Discussion: These results demonstrate the potential relevance of narrative complexity to discriminating between controls and psychosis patients, pointing to the tool's effectiveness when considering the percentile values of the participants' narrative complexity index. Therefore, it can be applied as an initial step to screening the risk of loss of social cognition in the context of schizophrenia.

S97. BRAIN GROWTH CHARTS: A NORMATIVE MODELLING APPROACH TO INVESTIGATE BRAIN DEVIATIONS IN PATIENTS WITH SCHIZOPHRENIA AND FIRST-DEGREE RELATIVES

Francesco Massari^{*1}, Thomas Wolfers², Gabriele De Agazio¹, Annalisa Lella¹, Roberta Passiatore¹, Giuseppe Blasi³, Aaron Goldman⁴, Teresa Popolizio⁵, Antonio Rampino¹, William Ulrich⁴, Daniel R. Weinberger⁴, Alessandro Bertolino⁶, Giulio Pergola⁷, Pierluigi Selvaggi⁸

¹Università degli Studi di Bari "Aldo Moro", ²University of Tübingen, ³Università degli Studi di Bari Aldo Moro; Azienda Ospedaliero-Universitaria Consorziale Policlinico di Bari, ⁴Lieber Institute for Brain Development - Johns Hopkins Medical Campus, ⁵IRCCS "Casa Sollievo della Sofferenza", San Giovanni Rotondo, ⁶Università degli Studi di Bari "Aldo Moro"; Azienda Ospedaliero-Universitaria Consorziale Policlinico di Bari, ⁷Università degli Studi di Bari "Aldo Moro", Lieber Institute for Brain Development - Johns Hopkins Medical Campus, ⁸Università degli Studi di Bari "Aldo Moro"; Institute of Psychiatry, Psychology and Neuroscience, King's College London

Background: Case-control studies have shown structural and functional brain alterations in patients with Schizophrenia (SCZ) and familiar high-risk individuals (FHR) who share part of the genetic risk. However, this approach carries the risk of settling an artificial symmetry between Healthy Controls (HC) and patients, which might not reflect the heterogeneous biology of the disease. Recently, the Normative Modelling (NM) approach has been proposed to parse neurobiological heterogeneity in psychiatric disorders by estimating individual deviations from the normative population through covariate distribution (i.e. age, gender). Previous NM studies in SCZ showed a pattern of heterogeneous increased negative deviations from the norm with respect to HC. To date, it is still unclear to what extent brain deviations identified with NM are linked to genetic risk or to disease-state factors. To fill this gap of knowledge we used NM to investigate deviations in brain structural metrics in SCZ, FHR, and HC. We hypothesized that FHR share a pattern of deviations with SCZ. We also investigated the association between genetic risk and brain deviations through the Polygenic Risk Score for Schizophrenia (PRS) in areas suggestive of an intermediate phenotype.

Methods: We applied a validated normative model based on a large set of structural Magnetic Resonance Imaging (MRI) data (N= 58,836, Age range= 2-100 years) to predict brain features in our test sample (HC= 834, FHR= 166, SCZ= 255) obtained merging 2 datasets (i.e., University of Bari and Lieber Institute for Brain Development). FHR group included unrelated and unaffected siblings and parents of SCZ. We processed T1-weighted MRI images using the FreeSurfer recon all command, extracting brain structural metrics by applying the Destrieux atlas for cortical regions and Fischl atlas for subcortical areas. The segmentation resulted in 150 Regions of Interest (ROI) of cortical thickness, cortical surface, and 14 ROIs of subcortical volumes. We marginalized the site effect through an adaptation sample (HC= 100). Quality check through Euler number was performed to remove artifact images (N= 27). Consistently with previous studies in patients with SCZ, we focused on negative deviations only. We computed Z-scores that quantitatively assessed brain feature differences between the estimated normative trajectory and each subject's true measure. We computed extreme deviations (Z-score LESS THAN -2.6) for each subject and ROI and we counted how many subjects extremely deviated from the norm. Then we normalized the count to the group size, obtaining the percentage of extremely deviating subjects per ROI. We performed permutation-based ANOVA and post-hoc t-tests for extreme and mean Z-scores between-group comparisons. We tested the association between Z-scores and PRS through ANCOVA. False Discovery Rate (FDR) and Bonferroni method were used to correct for multiple comparisons where needed.

Results: SCZ showed a higher number of extreme deviations in cortical thickness and subcortical volumes than FHR (pBONF FHRvsSCZ= 0.0033, pBONF FHRvsSCZ= 0.0049, respectively) and HC (pBONF HCvsSCZ = 0.0001, pBONF HCvsSCZ= 0.008, respectively). Descriptively, FHR showed a higher number of extreme deviations as compared with HC but differences were not significant (pBONF HCvsFHR GREATER THAN 0.085). We found an overlapping percentage of extreme deviations in brain regions in SCZ around 4-6%. FHR had a significantly higher mean of negative Z-scores than HC in the surface of the right middle frontal sulcus (pBONF= 0.0024) and in the thickness of the whole right hemisphere cortex (pBONF= 0.0034), left fusiform gyrus (pBONF= 0.0037), right lingual gyrus (pBONF= 0.0086) and right anterior collateral transverse sulcus (pBONF= 0.0022). SCZ showed higher negative deviations than HC in the same regions, without significant FHR/SCZ differences. Higher PRS5 negatively correlated with right hemisphere thickness Z-scores in the whole group (Pearson's $r = -0.108$, pFDR= 0.037). No significant PRS by group interaction was found ($F = 0.096$, $p = 0.9$). No significant main effect of PRS or PRS by group interactions on Z-scores from other ROIs were found (all pFDR GREATER THAN 0.174).

Discussion: Our findings suggest that part of the heterogeneity in brain structural metrics, evaluated as deviations from the normative distribution, is shared between SCZ and FHR. However, the small effect sizes detected in the FHR-HC comparison and in the association with PRS suggest that heterogeneity in brain structural metrics is only modestly explained by variability in genetic risk. Future studies should investigate the impact of state-dependent variables (e.g. treatment effects, disease severity) on brain morphology heterogeneity in SCZ.

S98. SEMANTIC SPACE CONTRACTS IN PSYCHOSIS AND REVEALS NEUROFUNCTIONAL CHANGES IN THE HIERARCHICAL ORGANIZATION OF COGNITION

Rui He^{*1}, Claudio Palominos-Flores¹, Han Zhang¹, María Francisca Alonso², Lena Palaniyappan³, Wolfram Hinzen¹

Background: Atypical forms of discourse in psychosis were conceptualized early on as revealing ‘loosening of associations’, quantified as the decrease in semantic similarity between consecutive word pairs using embeddings from large language models. Recent studies have contradicted this, revealing a contraction of the semantic space as indexed by higher semantic similarity. In this presentation, we give a comprehensive view of the alterations in the structure of meaning, using different language models in a hypothesis-driven way, and across multiple metrics and languages, followed by correlations with neurofunctional changes measured using 7T resting-state fMRI.

Methods: Analyses were performed on picture descriptions from twenty-nine untreated first-episodic psychosis (FEP) patients, matched to twenty-nine healthy controls (HC) on age, gender, and education. Firstly, five language models, FastText, Infsent, BERT, SBERT, and CLIP, which differ in their sensitivity to context and grammar, were used to quantify semantic distances crossed between successive tokens/utterances, and semantic perplexity indicating unexpectedness in continuations. Finally, we explored the structure of meaning as graphs, using thresholded semantic affinity matrices from similarities between lexical entities and utterances. These semantic and syntactic measures were correlated with a functional gradient across the whole cortex and within a semantic network comprising the left default mode and limbic regions. Parts of these analyses were replicated in datasets in other languages, including Chilean Spanish, Taiwan Mandarin, and German.

Results: FEP showed higher mean semantic similarity as computed from FastText, Infsent, and SBERT, but lower from BERT. Their descriptions showed lower similarities to the picture stimuli as quantified with CLIP, as well as being more perplexing (higher entropy). Semantic graphs, from both lexical categories and utterances, highlighted higher centrality and lower small-worldness coefficients in FEP. Such shrinking of the semantic space was also observed in free speech samples from chronic schizophrenia in Chilean Spanish, and picture descriptions in both Taiwanese Mandarin and German. These semantic measures predicted the dispersion between the visual and default mode networks in the first cortical gradient. FEP patients also exhibited alterations in the argument structure, with fewer and simpler noun phrases, but more and longer verb phrases.

Discussion: These results reveal that the traditional intuition of a ‘looser’ semantic space is not born out by crosslinguistic data using a variety of lexically-oriented language models, while metrics of perplexity at the grammatical level do vindicate this intuition. Alternations of the semantic space may act as a promising read-out of neuropathological changes in the hierarchical organization of cognition in the brain.

S99. SPEECH AND LANGUAGE MODELS PERFORM BETTER IN WOMEN WITH A SCHIZOPHRENIA SPECTRUM DISORDER THAN IN MEN

Janna de Boer¹, Alban Voppel², Silvia Ciampelli¹, Hugo Corona Hernández¹, Sanne Schuite-Koops¹, Iris Sommer¹, Silvia Ciampelli*³

¹University Medical Center Groningen, ²McGill University, Department of Psychiatry,

³University of Groningen, University Medical Center Groningen

Background: Natural language processing (NLP) and speech processing techniques have proven effective in a range of applications in psychosis. However, recent studies suggest that these models may depend largely on demographic and social characteristics, rather than providing a reflection of symptoms. An obvious source of variation in language analyses is sex. A men's voice is for example much lower in pitch than the voice of a women, but also semantic sex differences have been reported. Recent work from our group suggests that syntactic language analyses are different for men and women with a schizophrenia spectrum disorder (SSD). More specifically, women with SSD had lowest syntactic scores, while female controls had highest scores, compared to men with and without SSD. This resulted in higher diagnostic classification accuracy in women compared to men. The aim of the current study is to analyze whether this sex-specific pattern also applies to other forms of language and speech processing techniques.

Methods: The current study reused data from two previously published studies by our group. In both studies, voice recordings were made via a semi-structured interview lasting at least five minutes. Part 1 included 142 patients with SSD and 142 healthy controls (HC) matched for age, sex and parental education. Acoustic parameters were extracted from the audio recordings with OpenSMILE, using the extended Geneva Acoustic Minimalistic Parameter Set (eGeMAPS), which includes standardized analyses of pitch (F0), speech quality and pauses. Part 2 included 94 patients with SSD and 73 HC matched in age, sex and parental education. The voice recordings were manually transcribed and used to calculate semantic word similarity using word2vec. In both parts, random forest classifiers were trained separately on the women and the men. Because the accuracy generally increases in a smaller sample due to overfitting, the analyses were repeated in non sex-specific samples of the same size. 10-fold cross-validation was used for each model.

Results: In part 1, the original classifier had an accuracy of 86.1% in distinguishing between patients with SSD of both sexes and healthy controls. When the classifier was trained only on the female sample, the accuracy increased to 89.6% (n = 48 SSD and n = 47 healthy controls) while in the males it reduced to 83.5% (n = 94 SSD and n = 93 healthy controls). In the non sex-specific subsamples the respective accuracy rates were 87.4% (n = 95) and 89.8% (n = 187). In part 2, the original diagnostic accuracy in the full sample was 80.0%. In the female sample the accuracy increased to 87.2% (n = 26 SSD and n = 24 healthy controls), while in the males it reduced to 77.8% (n = 68 SSD and n = 49 healthy controls). In the non sex-specific subsamples these were 81.5% (n = 50) and 83.3% (n = 117).

Discussion: Our results indicate that there are substantial differences in language-based classification performance between men and women. Sex-specific classifiers based on speech and language processing perform better in women than in men, because the differences between controls and patients with schizophrenia spectrum disorder are greater in women than in men. These findings confirm and extend previous research by our group by showing that this applies to a range of speech and language processing techniques (i.e., syntactic analyses, acoustic analyses and word2vec analyses). The results also show that the performance improves in smaller samples, as expected, most likely due to overfitting. Future studies should incorporate sex in NLP classifiers, either by training separate classifiers or by including sex as a confounder in the model.

S100. TRANSPROGNOSTIC PREDICTION MODELS IN CHRONIC SCHIZOPHRENIA

Fiona Coutts*¹, Christoph Correll², Paris Lalouis¹, Nikolaos Koutsouleris³

¹King's College London, Institute of Psychiatry, ²Charité - Universitätsmedizin Berlin,

³Ludwig-Maximilian-University, KCL

Background: Individuals with psychotic disorders have highly heterogeneous clinical and functional outcomes. There is large body of research in early psychosis populations dedicated to understanding this heterogeneity and predicting individual outcomes in order to target those with the highest risk with early interventions. Far less research has focused on outcome prediction in chronic schizophrenia, even though knowing a patient's future response to medication, long-term functioning, or relapse risk could guide decisions relating to the type of care they require. The aim of my research is to develop accurate models predicting symptomatic outcomes in chronic schizophrenia, and to see if these models are influenced by how far into the future we wish to predict.

Methods: The sample consists of 680 individuals with chronic schizophrenia from the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) clinical trial, split into a discovery sample (596 individuals from 48 sites) and a validation sample (84 individuals from the remaining 7 sites). Participants were included in the study if they were between 18 and 65 years of age, did not have major contraindication to any of the study drugs, had more than one episode of psychosis and more than two years since their first psychotic episode.

In the discovery sample, machine learning models using baseline clinical, sociodemographic, and cognitive variables will predict symptom severity, defined as the Positive and Negative Syndrome Scale (PANSS) total score at 3 months and 12 months after baseline, and a binary measure of symptomatic remission defined by the Remission in Schizophrenia Working Group criteria. Any models above 65% will be replicated in the validation cohort. Machine learning analyses will be performed in Neurominer 1.2: all models will have a 10-by-10 nested cross-validation structure. Support vector regressions will be used for the continuous symptom severity outcomes, and support vector machines will be used for the binary symptomatic remission outcomes. Model performances will be assessed by Pearson's r for linear models, and Balanced Accuracy for classification models.

Results: The discovery sample had a mean age of 41.3 years, 72.8% of the sample were male, and the mean PANSS score at baseline is 75.6. The mean age of the validation sample was 41.8, 86.9% of this sample were male, and the mean PANSS total score at baseline was 69.1. Gender and PANSS total scores were significantly different between the discovery and validation samples ($p < 0.05$).

In the discovery sample, at 3 months after baseline the mean PANSS total score was 67.4, and 69.6% of the sample were in non-remission. At 12 months the mean PANSS total score was 65.3, and 65.6% of the sample were in non-remission. In the validation sample, at 3 months after the mean PANSS total score was 64.3, and 69% of the sample were in non-remission. At 12 months the mean PANSS total score was 62.1 and 59.5% were in non-remission. The 12-month PANSS total score was significantly lower in the discovery sample ($p=0.049$), but there were no significant differences in the other outcomes.

Preliminary results using a subset of the final feature space show that symptom severity at 12 months can be predicted by baseline quality of life, years in education, functioning, depressive symptoms, and risperidone use ($r=0.53$, $p=1.39 \times 10^{-55}$). The PANSS positive ($r=0.34$, $p=1.7 \times 10^{-22}$), PANSS negative ($r=0.48$, $p=2.1 \times 10^{-45}$), and PANSS general ($r=0.49$, $p=1.8 \times 10^{-47}$) subscales were also significantly predicted.

Discussion: These initial results suggest continuous symptomatic outcomes can be well-predicted in chronic schizophrenia patients. Further analyses will determine whether this prediction is affected by the time that the outcome was measured.

S101. EXPLORATORY NETWORK ANALYSIS OF INDIVIDUAL AND GROUP-LEVEL SOCIAL PROCESSES IN SCHIZOPHRENIA USING INTENSIVE LONGITUDINAL DATA

Joseph Maimone^{*1}, Gil Grunfeld¹, Jasmine Mote¹, Kim Mueser¹, David Gard², Daniel Fulford¹

¹*Boston University*, ²*San Francisco State University*

Background: People with schizophrenia (SZ) can experience acute social deprivation, resulting in severe impacts on mental and physical well-being. Interventions designed to improve social connection in this population have limited efficacy, possibly due to observations that mechanisms supporting social connection are heterogeneous and idiosyncratic. We propose that rigorous understanding of individual patterns of social processes in SZ may set the stage for more targeted treatment approaches.

Methods: In this study, 31 individuals (median age = 48 years, range 22 to 65; 52% male; 55% non-White) diagnosed with schizophrenia or schizoaffective disorder completed an eight-week intervention designed to enhance social goal attainment through smartphone-delivered social skills and motivation training. The app prompted them twice a day to engage with tailored training content, and to complete a brief ecological momentary assessment (EMA) battery about their social motivation (e.g., “How much would you like to talk to or interact with someone right now?”), appraisals of recent social interactions (e.g., “How well do you think you communicated in those conversations”), and affect (e.g., “How [happy, sad, excited, calm, anxious, angry] did those conversations make you feel?”). In the current analysis, we seek participant-specific patterns between social motivation, social appraisals, and affective states to study individual differences in social connection. We use group-iterative multiple model estimation (GIMME) to achieve this goal. GIMME produces directed network plots for each individual, which show whether a relationship between any two nodes exists, as well as the relationship’s magnitude, sign, and direction. An advantage of this approach is that it also produces a group-level network plot by selecting those relationships that are significant and present for a majority (at least 75%) of the sample. This approach enables comparison between individual and group-level patterns to see (1) what node-to-node relationships the sample has in common and (2) how individual processes differ from one individual to the next above and beyond the group relationships.

Results: GIMME requires at least 60 observations per individual to produce reliable results; 16 individuals (median age = 48 years, range 22 to 65; 44% male; 63% non-White) met this threshold (mean observations = 95; range: 64-115) and are included in this analysis. Inspection of variances demonstrated sufficient variability within each individual across all variables for GIMME analysis. Some participants showed inter-item correlations ≥ 0.90 , primarily within positive affect variables or negative affect variables, suggesting a single positive affect node and single negative affect node will be appropriate for network analysis. Final data preparation is under way; once ready, the results will characterize individual- and group-level networks of social processes, providing insights into the presence, direction, and strength of relationships among social motivation, appraisals, and affect in those with SZ over time.

Discussion: Intensive longitudinal data that shed light on idiographic associations between momentary measures of social processes and affect could be useful for approaches to individualized interventions to improve social connection in SZ. For example, models may show that for one participant, positive affect is strongly tied to social motivation; another individual's model may show that social appraisals play a more central role. Differences such as these might suggest different and potentially more effective targets for treatment for each individual. Final results will allow for a comprehensive description of these possibilities and implications for intervention will be discussed.

S102. DOPAMINE 1 RECEPTOR (D1R) MECHANISMS FOR HALLUCINATIONS AND WORKING MEMORY DEFICITS IN SCHIZOPHRENIA: A PRELIMINARY COMPUTATIONAL MODELLING STUDY OF DLPFC

Tsvetoslav Ivanov^{*1}, Mark Slifstein², Jared Van Snellenberg², Rahul Gupta¹, Matt Jones¹, Anissa Abi-Dargham², Sean Froudish-Walsh¹

¹University of Bristol, ²Stony Brook University

Background: Current medications mainly treat positive symptoms of schizophrenia (SZ), like hallucinations. However, patients remain impaired by cognitive symptoms, e.g., working memory (WM) deficits, thought to have a separate cause. Identifying shared mechanisms for hallucinations and WM deficits may lead to drugs that promote full remission in patients showing both symptoms.

Notably, SZ patients exhibit lower than typical dopamine (DA) release in the dorsolateral prefrontal cortex (dlPFC) (Slifstein et al., 2015), which may counterbalance the higher than typical dlPFC D1R expression reported in unmedicated SZ patients (Abi-Dargham et al., 2012). These landmark findings suggest that dysregulation of D1R activation in dlPFC is one common factor underlying hallucinations and WM deficits.

Crucially, dlPFC D1R activation forms an inverted U-shaped relationship with the maintenance of persistent activity during the delay period of WM tasks. Optimal D1R activation enables distractor-resistant persistent activity, while too low or too high D1R activation causes transient, non-persistent activity, only during stimulus presentation.

Likely, the increased dlPFC D1R expression in SZ shifts the inverted U to lower levels of D1R occupancy (i.e., the fraction of active, DA-bound D1Rs). Thus, assuming dlPFC DA release varies in time, albeit around a lower mean, SZ patients should still experience episodes of optimal D1R activation and good WM but also too low D1R activation and poor WM. Too high D1R activation may cause hallucinations. Specifically, this upregulation of D1R activation may be overcompensating for the widely reported downregulation of the inhibitory output of parvalbumin (PV) cells and the excitatory output of pyramidal (E) cells in dlPFC (Dienel and Lewis, 2019).

Methods: To link microcircuit physiology and SZ symptoms, we designed a spiking network model of a visuospatial WM task where we first present a brief target stimulus and later a brief distractor stimulus at a different location (Compte et al., 2000). The model featured E cells and two functional PV cell types – PV_NEAR and PV_OPP – with near- and opposite-feature selectivity (Kuan et al., 2022). E cells are arranged uniformly on a ring according to the angle

of the stimuli for which they fire the most. PV cells are also arranged uniformly based on the angle of the E cells from which they receive the strongest excitation. The microcircuit has E-E, E-PV, PV-E, and PV-PV synapses. E cells send their strongest glutamatergic projections to cells at the same angle. PV_NEAR cells send their strongest GABAergic projections to cells also at the same angle, while PV_OPP cells – to cells located 180° away on the ring.

We studied the propensity of cell type-specific D1R expression profiles to induce pathology in three networks where E cells and, respectively, PV_NEAR (Net.1), PV_OPP (Net.2), or both PV_NEAR and PV_OPP (Net.3) expressed D1Rs. D1R activation modulated G_NMDA and G_AMPA conductances and the firing thresholds of D1R+ PV cells (Durstewitz et al., 2000; Kröner et al., 2007). In particular, across networks, from low to optimal D1R activation, we (1) fitted a 40% increase in G_NMDA for synapses with D1R+ target cells and a 20%, synapse-unspecific, decrease in G_AMPA, and (2) decreased the thresholds of D1R+ PV cells, to facilitate a transition from non-persistent to noise- and distractor-resistant persistent activity regime, thus simulating the inverted U's increasing phase and peak. The G_NMDA value for low D1R activation was the highest G_NMDA that did not support persistent activity. Towards high D1R activation, the thresholds of D1R+ PV cells continued to decrease to simulate the inverted-U's decreasing phase until the model reached a non-persistent activity regime. For sub-optimal D1R activation, the magnitudes of the G_NMDA, G_AMPA, and threshold modulations were intermediate, relative to the low and optimal D1R activations. For supra-optimal D1R activation, the magnitudes of the modulations were also intermediate, but relative to the optimal and high D1R activations.

Results: When PV_OPP cells express D1Rs (i.e., in Net.2 and Net.3), as expected, low and high D1R activation cause non-persistent activity, while optimal D1R activation enables noise- and distractor-resistant persistent activity. The sub-optimal D1R activation elicits distractible persistent activity (i.e., the model holds target stimuli in WM after they disappear, but the persistent activity trace jumps to the location of the distractor when it appears). The supra-optimal D1R activation elicits a hallucinatory persistent activity regime where noise-driven activations occur at non-stimulus locations but still give rise to persistent activity traces with coherent structure. On the other hand, grid searches over the D1R-mediated modulations of the G_NMDA's, G_AMPA's, and the D1R+ PV thresholds revealed no parameter sets in Net.1 that elicit hallucinations, suggesting that its D1R expression profile is closest to biology in health.

Discussion: Our model links cellular, molecular, and microcircuit changes in SZ with hallucinations and WM deficits and suggests mechanistically targeted treatments for the disorder, e.g., partial D1R antagonists that reduce the effects of DA binding on D1Rs.

S103. REFINING THE PHENOTYPE OF MENSTRUAL PSYCHOSIS: SYSTEMATIC REVIEW OF CASE REPORTS

Thomas Reilly*¹, An Hsu², Adam Al-Diwani³, George Gifford⁴, Philip McGuire³, Ian Brockington⁵

¹*Institute of Psychiatry, King's College*, ²*Royal College of Surgeons of Ireland*, ³*University of Oxford*, ⁴*Department of Psychiatry, University of Oxford*, ⁵*University of Birmingham*

Background: Psychotic episodes linked to the menstrual cycle have been described for over 200 years. A proposed definition of 'menstrual psychosis' classifies it as: (i) acute onset; (ii)

episodes of psychosis, mania, catatonia or confusion; (iii) in synchrony with the menstrual cycle; (iv) with complete recovery within two weeks. There have been many cases reports describing this phenomenon, but these have never been systematically reviewed and quantitatively analysed.

Methods: A search of electronic databases was conducted using MEDLINE, Embase and PsycINFO. Search terms were [psychosis OR psychotic OR schizoaffective OR bipolar affective OR bipolar disorder OR mania OR manic OR catatoni*] AND [menstrua* OR catamenia* OR monthly OR cyclic OR menses OR menarche]. This was supplemented with historical case reports and unpublished cases. Cases were included if they described brief episodes of psychosis, mania, or catatonia, synchronised with the menstrual cycle, with complete recovery between episodes. Reports of menstrual exacerbation of chronic mental disorders were excluded. Demographic and clinical characteristics were extracted. The AMDP system was used to extract individual symptoms from case reports. The study was pre-registered with PROSPERO: CRD42023408345.

Results: A total of 10,558 records were retrieved from the electronic database search. After assessing 149 full texts for eligibility, 82 studies were included, consisting of 112 individual patients. An additional 218 published cases (including historical cases) were identified from previous reviews, as well as 100 anonymised unpublished cases. The total number of cases for analysis is 418. Most episodes had onset in the premenstrual (55.9%) or menstrual (22.3%) phase. The most common clinical diagnosis reported was bipolar disorder (40%), followed by schizophrenia spectrum disorder (18.9%). The modal age of onset was 14, and the median was 19 (interquartile range 15-26). Of all cases, 71 experienced episodes during the postpartum period, with 50 of these being the index episode. Four cases were associated with termination of pregnancy or miscarriage, and three cases were associated with weaning. Menarche was the other reproductive event associated with cases, with 59 cases having onset at this time. The most common individual symptom was depressed mood (36.0%), followed by motor restlessness (32.0%), auditory hallucinations (28.1%), euphoria (25.7%), clouded consciousness (25.4%). The most common symptom domain was disturbance of affect (69.3%), followed by disorders of drive and psychomotor activity (58.3%), disorders of consciousness (33.6%), disorders of perception (33.6%), and delusions (30.7%).

Discussion: This study is the first systematic review of menstrual psychosis and the largest analysis to date. Menstrual psychosis is predominately a disorder of adolescence, with a modal and median onset before the age of 20. Indeed, 59 cases were associated with menarche, suggesting this time of hormonal fluctuation confers higher risk of psychotic episodes. The phase of onset of episodes was either premenstrual or menstrual in most cases, which is similar to the time of increased risk of psychosis relapse. The psychopathology of menstrual psychosis suggests a strong affective component, with the most reported symptom domain being disturbance of affect while the most common individual symptom was depressed mood. In keeping with this, the most common clinical diagnosis in cases was bipolar disorder. A link is suggested with postpartum psychosis, which is also characterised by affective symptoms, sudden onset, and subsequent development of bipolar disorder. Postpartum psychosis is a more widely recognised, but similarly rare condition. It is therefore striking that one in six cases of menstrual psychosis also experienced episodes during the postpartum period.

S104. 49 SYMPTOMS OF PSYCHOTIC-LIKE EXPERIENCES: ESTIMATING OVERLAP BETWEEN PSYCHOTIC-LIKE EXPERIENCES MEASURES

Mariia Goncharova^{*1}, Clement Donde¹, Hans Ijzerman¹, Catherine Botolon¹

Background: Psychosis is characterized by hallucinatory and delusional experiences. Conventionally, it was mostly considered to be present among clinical populations. However, attenuated variations of psychosis can be found in the general population and are referred to as psychotic-like experiences (PLEs) (Kelleher and Cannon, 2011). Limited reviews currently exist on the quality of the assessment methods designed to evaluate psychotic-like experiences in the general population (Lee et al., 2016). None of them assessed whether the existing instruments measure the same construct and, consequently, neglected problems associated with the "jingle-jangle fallacy" (Weidman et al., 2017; Flake and Fried, 2020). This fallacy might account for contradictions in the literature, as well as, issues with generalizability of the results. Thus, the goal of our study is to better understand the agreement between different instruments assessing psychotic-like experiences by calculating item overlap (Fried et al., 2017).

Methods: We conducted a systematic search of the scales assessing psychotic-like experiences and schizotypy personality traits among the general population (i.e., hallucinations, magical thinking, and delusions), excluding negative symptoms. Labels for the different psychotic experiences were created based on their definition in literature by the first authors and subsequently revised by another researcher. Different experts provided feedback on these labels and definitions. Two researchers coded each item independently of each other. A third researcher then revised the items that were disagreed upon. Further adjustments were made after discussion. We then estimated to which extent any item overlaps with any item from the other scale included in the analysis. Finally, we used Jaccard index to assess similarities between sets (from 0 with no overlap among scales) to 1 (complete overlap). The analysis was done in R and Excel.

Results: For 12 scales of psychosis proneness, 49 labels were identified with a mean overlap of 0.14. We used network analysis to visualize the data. The most commonly mentioned items for the psychosis scales were paranormal (mentioned in 9 scales) depersonalization (7 scales), suspiciousness, visual hallucinations, and grandeur (each in 6 scales). There were 16 idiosyncratic items. The highest overlap between scales measuring psychosis were SPQ and Prodromal questionnaire-brief (0.34). Lowest mean overlap — BQSPS (0.03), which only had four items, which led to 2 labels.

Discussion: The results demonstrate a poor overlap between the scales. CAPE scale stands out as one having the most overlap with other scales (0.19), which is consistent with previous results (Bernardin et al., 2023). Even though these scales were supposed to measure psychotic symptoms, they might be tapping different, although related, phenomena or, at least, different ways of conceptualizing psychotic experiences (and PLE). Thus, future studies need to acknowledge the issue of defining PLE and be transparent about what is considered a PLE in any study. Our results also point to the lack of content validation during scale development. Future studies should include both bottom-up (e.g., qualitative studies) and top-down (e.g., theory based) strategies for scale development.

S105. DISTINCT CHARACTERISTICS OF RECENT-ONSET PSYCHOSIS WITH AUTISTIC SYMPTOMS

Kyuyoung Lee^{*1}, Jae Hoon Jeong²

¹*Nowon Eulji University Hospital*, ²*Department of Psychiatry, Eulji University Eulji Hospital*

Background: Although autism and schizophrenia have been classified as distinct illnesses, a number of studies have investigated the similarities between them. Patients with psychosis with prominent autistic symptoms were known to generally have lower cognitive and functional level of life. We intended to investigate the differences in clinical, cognitive, and functional characteristics according to the severity of autistic symptoms in recent-onset psychosis.

Methods: The participants were 671 patients with recent-onset psychosis enrolled in the Korean Early Psychosis Cohort Study (KEPS). To evaluate the severity of autism symptoms, PANSS Autism Severity Score (PAUSS) was used, dividing the subjects into three different groups: “Autistic group” (PAUSS $\geq$ 30), “Non-autistic group” (PAUSS $\leq$ 10) and “Moderate group” (10 LESS THAN PAUSS LESS THAN 30). The baseline sociodemographic and clinical characteristics, cognitive functions and emotional recognition were compared by group.

Results: The rate of diagnosis of schizophrenia was highest in autistic group and found to be a significant predictor of autistic group. Regarding the presence of comorbid psychiatric disorders, lowest incidence was shown in autistic group. In the group with more severe autistic symptoms, non-autistic symptoms and functional outcomes measured by PANSSminusPAUSS and SOFAS were also worsened. These two measures also significantly predicted the autistic group. In cognitive functions and emotional recognition, the more severe the autistic symptoms, the more severe the impairments.

Discussion: Autistic symptoms have a significant impact on overall symptoms and functions on patients with recent-onset psychosis. There seems to be an overlap between psychosis and autism.

S106. INTERACTION OF BDNF WITH IL-18 IS ASSOCIATED WITH COGNITIVE DEFICITS IN CHRONIC SCHIZOPHRENIA

Dongmei Wang*¹

¹*Institute of Psychology, Chinese Academy of Science*

Background: The interaction between cytokines and neurotrophic factors may contribute to the etiology and psychopathology of schizophrenia. Accumulating evidence suggests that both BDNF and IL-18, an important and pleiotropic cytokine modulator of immune responses may be involved in the psychopathological symptoms and cognitive deficits of schizophrenia. However, the possible interaction between BDNF and IL-18 has not been examined.

Methods: We recruited 40 chronic schizophrenic patients and 38 healthy control subjects and examined the Repeatable Battery for the Assessment of Neuropsychological Status (RBANS) as well as serum BDNF and IL-18 levels in both groups. Schizophrenic symptoms were assessed using the Positive and Negative Syndrome Scale.

Results: Compared to the control group, the patients exhibited a significant decrease in BDNF levels, but a significant increase in IL-18 levels. In patients, but not in controls, we observed a significant negative correlation between BDNF and IL-18. Furthermore, the interaction between BDNF and IL-18 was associated with immediate memory, delayed memory and RBANS total scores.

Discussion: Our results suggest that both altered BDNF and IL-18 levels may be implicated in the pathophysiology of chronic schizophrenia. Their inverse association only in the schizophrenia group may reflect a pathological mechanism involving an interaction of immune

response and neurotrophin dysfunction. Moreover, IL-18 may interact with the BDNF system to influence the clinical symptoms and cognitive impairment in schizophrenia, which is line with the neurodevelopmental hypothesis of schizophrenia.

S107. CONNECTION AND CREATION OF SHARED MEANING IN SCHIZOPHRENIA: A QUALITATIVE INVESTIGATION OF THE PSYCHIATRIST-PATIENT RELATIONSHIP

Melissa Uehling*¹

¹*Emory University School of Medicine*

Background: For individuals experiencing schizophrenia, various facets of engaging with the psychiatric system may be a source of trauma. Experiences such as involuntary hospitalization, loss of autonomy, and paternalistic doctor-patient relationships may limit the effectiveness of psychiatric treatment and may cause further harm. Emerging work in the area of intersubjectivity may offer the potential to re-imagine the psychiatric system as a place that is more consistently centered on meaningful understanding and valuation of the patient perspective. Specifically, theorists have presented the idea of developing an intersubjective understanding between provider and patient, through creation of a shared understanding of the patient's illness experience. Forging a shared understanding and co-creating a path forward departs from the authoritarian psychiatric modality of imposing an external explanation upon the patient based upon the psychiatrist's own conception of reality. Concerns about authoritarianism in medical treatment are particularly relevant for patients with schizophrenia spectrum disorders, as psychiatrists may be less likely to create a shared understanding with patients or attempt to enter patients' psychological framing, which may be assessed as inaccessible and separate from a shared reality.

Methods: Despite the potential utility of intersubjective approaches in psychiatric treatment, limited work has assessed provider perspectives on how shared meaning and relationship development unfolds in psychiatric spaces. Accordingly, this study seeks to characterize the process of how psychiatrists develop shared meaning and connection with patients with schizophrenia spectrum disorders. This study involved open-ended interviews with 24 U.S.-based psychiatrists who currently treat patients with schizophrenia spectrum disorders. Interviews lasted roughly 60 minutes, and interview questions focused on if and how psychiatrists develop shared understandings and connection with their patients, the values and beliefs affecting these relationships, as well as situational characteristics that facilitate or inhibit such processes. I conducted thematic analysis on the data and employed the analytic method of abductive analysis to perform thematic coding and theoretical development throughout the research process.

Results: Interviews revealed that respondents varied greatly in their perspectives on creating shared understandings with patients with psychosis. When discussing what defines a shared understanding, three main modalities emerged across interviews, including: 1) patient and physician joining in an understanding of symptoms and diagnostic information; 2) creating functionality-oriented, shared goals for treatment and life; and 3) creating a shared understanding of the patient's subjective perspective or narrative of their illness. Virtually all psychiatrists interviewed engaged in each method of shared understanding during different circumstances and time points, with the majority of participants aligning most closely with one approach overall.

Many participants reported grappling with balancing their own expertise with centering the patient's perspective, regardless of the approach taken to creating shared understandings. Some clinicians reported using their own perspective as a benchmark for developing a shared understanding, thus prioritizing the clinician's view or opinion. In contrast, some physicians described an approach that attempted to balance both psychiatrist and patient perspectives during clinical practice, with a flexibility to modify the participant's own desired approach or viewpoint in order to engage more effectively with the patient's view.

Furthermore, virtually all psychiatrists interviewed acknowledged the existence of power imbalances with regards to whose expertise or viewpoint is prioritized within these relationships. However, a minority of respondents discussed making a conscious effort to address the imbalances and could name practical approaches to addressing them. Among those who struggled to name concrete, explicit steps they take to minimize power imbalances, they reported facing challenges with knowing exactly how to navigate inequities in clinical spaces. Furthermore, clinicians reported several barriers to developing shared understandings and connecting with patients effectively, including inadequate formal medical training, the pressures of managed care constraints, and lack of trust due to the ubiquity of involuntary hospitalization and coercive treatment in the medical system.

Discussion: Overall, these findings highlight the complexity in the ways in which psychiatrists approach connection and shared meaning when treating individuals with schizophrenia spectrum disorders. Characterizing the process of intersubjectivity may be a path to understanding aspects of the psychiatrist-patient relationship in the context of psychosis, its intersection with multi-level factors, and the associated impacts on treatment. This study provides a basis for developing further understandings of how to build relationships and more thoroughly understand clinicians' perspectives during psychiatric treatment.

S108. PHENOMENOLOGY OF SOCIAL NEEDS AND EXPERIENCES IN PSYCHOSIS: AN EXPLORATORY MIXED-METHODS APPROACH

Gil Grunfeld*¹, Joseph Maimone¹, Jasmine Mote², David Gard³, Kim Mueser⁴, Daniel Fulford¹

¹*Boston University*, ²*Boston University, College of Health and Rehabilitation Sciences*, ³*San Francisco State University*, ⁴*Center for Psychiatric Rehab, Boston University*

Background: Individuals with psychotic disorder often report difficulties with social functioning, ranging from social cognition, to communication, to maintenance of existing relationships. Dissatisfaction with one's social life — especially perceived deficits in connection — can exacerbate psychosis symptoms and potentially delay recovery in functioning. While a host of laboratory methods have been employed to study social processes in psychosis, little naturalistic data exists attending to the social needs of those with lived experience.

Methods: Using a mixed-methods approach, we examined both ambulatory self-report (i.e., Ecological Momentary Assessment [EMA]) and qualitative interview data from adults with a schizophrenia spectrum disorder (median age = 48, range = 22-65; 48% female; 55% non-White). EMA questions were prompted twice a day over an eight-week period to evaluate social goals as well as to collect information on affect following engagement with others ("happy," "sad," "excited," "calm," "anxious," "angry"). Narrative data about self-described

social needs was collected pre-intervention, which we will code and analyze to a sample size of thematic saturation.

Results: Through longitudinal analysis of ecological momentary assessment (EMA) data, we will explore affect experience in the context of social goal-pursuit over the eight-week intervention period. We will also highlight a range of subjective social goals and motivations through thematic analysis of pre-treatment interviews.

Discussion: Tying together longitudinal EMA data to our granular qualitative findings, our work will provide insights on the affective qualities of social goal formation and attainment in psychosis, as well as broadly pointing to methodological implications for idiographic, phenomenological approaches to studying social dynamics in psychosis.

S109. INTRODUCING TWO ADAPTATIONS OF THE PSYCHOTIC SYMPTOM RATING SCALES (PSYRATS): THE ADAPTED RESPONSE SCALE – PSYRATS AND OTHER MODALITIES HALLUCINATIONS - PSYRATS

Wai Fung Tsang¹, Nadine Keen², Emmanuelle Peters*¹, STAR (Study of Trauma And Recovery) Research group³

¹Institute of Psychiatry, Psychology and Neuroscience, King's College London, ²South London and Maudsley NHS Foundation Trust, ³London, Manchester, Newcastle, Oxford and Sussex

Background: The Psychotic Symptom Rating Scales (PSYRATS) are the most widely validated and internationally translated multidimensional assessment of positive psychotic symptoms, including two assessor-rated subscales for auditory verbal hallucinations and delusions. Over time potential areas for refinement have been identified, particularly the discrete descriptions anchoring its five-point severity scale leading to a floor effect for some items, and others lacking sufficient sensitivity for detecting clinical change. There is also growing evidence of the high prevalence of hallucinations in other modalities in psychosis and other populations such as complex post-traumatic stress disorder (PTSD), which are not captured by the current subscales. The present study aimed to validate (i) an Adapted Response Scale - PSYRATS (ARS-PSYRATS), which uses a 0-10 analogue thermometer rating scale; (ii) an adaptation of the auditory hallucinations subscale to assess hallucinations in other modalities, including multimodal hallucinations.

Methods: The study utilized baseline data (N=305) from a randomized controlled trial evaluating an integrated Trauma-Focused Cognitive Behaviour Therapy for Psychosis, the Study of Trauma and Recovery (STAR trial). Participants met criteria for ICD-10 schizophrenia-spectrum disorder (F20-29) and DSM-V PTSD and presented with distressing hallucinations and/or delusions. The construct validity, internal consistency, and concurrent validity of ARS-PSYRATS subscales, including Hallucinations in Other Modalities-PSYRATS, with the original delusions and auditory hallucinations PSYRATS, were assessed.

Results: Principal Components Analysis identified a two-factor structure for the delusion subscale (Emotional, Physical), and a three-factor structure across the two hallucination subscales (Emotional, Physical, Cognitive), replicating a number of previous studies. Cronbach's alpha for total subscales indicated good internal consistency. Correlations showed good concurrent validity with the original scales. Together, psychometric properties were better for the delusion than for the hallucination subscales but were acceptable overall. The hallucinations in other modalities subscale were a highly useful addition, with 80% of the sample reporting such experiences.

Discussion: The ARS-PSYRATS, including the adapted Hallucinations in Other Modalities, are valid and reliable measures and may be particularly useful for future studies or clinical services wanting to assess clinical change over time. The high prevalence of other modalities hallucinations underscores the importance of assessing such experiences.

S110. MEASURING SOCIAL FUNCTIONING IN PEOPLE WITH SMI: A SYSTEMATIC REVIEW

Bouwina Sportel*¹, Elise Bennik², Emke Lantink³, Hettie Aardema⁴, Nynke Boonstra⁵

¹GGZ Drenthe Mental Health Institute, ²University of Groningen, Department of Clinical Psychology and Experimental Psychopathology, / GGZ Drenthe Mental Health Institute, Department of Psychotic Disorders, ³University of Groningen, Department of Clinical Psychology, ⁴GGZ Drenthe Mental Health Institute, Department of Psychotic Disorders, ⁵NHL Stenden University of Applied Science, / UMC Utrecht

Background: Approximately 281,000 people in the Netherlands have a serious mental illness (SMI; Delespaul, 2013). People with SMI experience major problems in their daily lives, including limited social functioning (Howell et al., 2023).

Research shows that people with SMI often suffer from reduced social functioning: experiencing loneliness, social isolation, smaller social network, less social connection and lower social relationship satisfaction. The relationship between social functioning and personal recovery is receiving increasing attention. Social network size and satisfaction with social support are positively related to self-reported recovery (Thomas et al., 2016), and interpersonal functioning is positively related to personal recovery (Watanabe et al., 2021). Social functioning appears to play a mediating role between psychiatric symptoms and personal recovery (Howell et al., 2023). Therefore, improving social functioning is an important goal of treatment and recovery-oriented care for people with SMI. However, to gain more insight into one's social functioning, accurate measuring is crucial. The aim of our systematic review is to map the available patient reported outcome measures (PROMs) for social functioning in people with SMI and their psychometric qualities, resulting in an advise for clinical practice and research on best fitting instruments.

Methods: We systematically searched Embase, PsycInfo and Epub Ahead of Print using the following terms (used synonyms not included): rating scales AND psychometric properties AND social functioning AND serious mental illness. Included articles contained a target population of people with SMI, psychometric properties of instruments, and at least 3 out of 5 domains of social functioning (work/daily activities, living, relationships, recreation, self-care). After several rounds of screening 70 articles on 24 PROMs were included. COSMIN methodology for systematic review of PROMs was then used to further assess the quality of the PROMs.

Results: Several instruments were included, amongst them BSFQ, ICF-Mental-A and P, WHODAS, CAN, SOFI and SIS. Quality of the included instruments varies between low and high, with a large range of present psychometric properties and a large variation in scores on the properties.

Discussion: Advise for clinical practice and research will be presented.

S111. SEX DIFFERENCES IN SYMPTOMS OF PSYCHOSIS: A META-ANALYSIS ACROSS STAGES

Marta Ferrer-Quintero*¹, Clara Serra-Arumí², Ana Echevarría-Bruno¹, Marina Verdaguer-Rodríguez², Renée Douven³, Mia Plenkovic⁴, Susana Ochoa², Covadonga M Díaz-Caneja¹

¹*Institute of Psychiatry and Mental Health Gregorio Marañón*, ²*Parc Sanitari Sant Joan de Déu*, ³*Maastricht University*, ⁴*Sveučiliste u Splitu Medicinski Fakultet*

Background: There is evidence of clinically relevant differences between women and men with psychosis with potential treatment implications. However, sex differences in clinical presentation are still controversial.

In this work, we aim to assess differences in clinical presentation between males and females at different stages of schizophrenia and other psychotic disorders (ultra-high-risk mental state (UHR), first-episode psychosis (FEP), and established illness (EI)).

Methods: Methods of this meta-analysis adhere to the PRISMA guidelines and are registered in the PROSPERO database under the number CRD42021264942. We retrieved published literature from Web of Science, PubMed, SCOPUS, PsychInfo, and Dialnet databases until 2021, with an update in July 2023. Studies were included if reporting results of male and female individuals aged 16–65 years with a diagnosis of schizophrenia or other psychotic disorder (e.g., schizophreniform, schizoaffective disorder, delusional disorder, brief psychotic disorder, recent-onset psychosis, ultra-high risk for psychosis), irrespective of the diagnostic criteria used. We collected positive, negative, general, depressive, or anxiety symptoms measured with a validated scale. Data were analyzed using a random-effects model. The effect size was computed using Hedges g.

Results: Our search strategy identified 36,147 eligible articles. After abstract screening and full-text review, 532 articles were included for data extraction. The search was updated in 2023, identifying 2,897 articles, of which 80 were finally included. This section presents preliminary findings from an analysis of 182 studies, including 4,277 observations of UHR participants, 9,580 observations of FEP participants, and 15,457 observations of EI participants.

In positive symptoms, the meta-analysis did not find significant differences between females and males in UHR (SMD= -0.0166, 95%-CI [-0.1242; 0.0909], p=0.7528), FEP (SMD= -0.0408, 95%-CI [-0.1119; 0.0303], p=0.2549), nor EI (SMD= -0.0317, 95%-CI [-0.1162; 0.0528], p=0.4579).

In contrast, we found that males present more severity of negative symptoms than females at the UHR (SMD= -0.3522, 95%-CI [-0.4523; -0.2521], p LESS THAN 0.0001), FEP (SMD= -0.2362, 95%-CI [-0.2993; -0.1732], p LESS THAN 0.0001), and EI (SMD= -0.2362, 95%-CI [-0.3187; -0.1537], p LESS THAN 0.0001) stages. Heterogeneity was significant and high in UHR ($I^2 = 64.8\%$ [48.4%; 75.9%], $Q = 85.11$, p LESS THAN 0.0001) and EI ($I^2 = 73.5\%$ [67.4%; 78.5%], $Q = 328.54$, p LESS THAN 0.0001).

Discussion: Preliminary meta-analytic results suggest that men with psychosis tend to exhibit more severe negative symptoms than women across all the illness stages. Given the pervasive nature of negative symptoms and limited effectiveness of available treatments to address them, it is likely that men with or at high risk of psychosis need earlier and more comprehensive support to prevent the loss of functionality and autonomy. These findings underscore the importance of sex-sensitive interventions in the management of negative symptoms among individuals with psychosis.

S112. MINOR PHYSICAL ANOMALIES IN SCHIZOPHRENIA: A SYSTEMATIC REVIEW AND META-ANALYSIS

Ekin Sut^{*1}, Özge Akgül², Emre Bora¹

¹Dokuz Eylul University, ²İzmir Democracy University Karabaglar,

Background: Minor physical anomalies (MPAs) are subtle physical abnormalities that manifest early in the first or second trimester of fetal development and endure throughout an individual's life. Extensive research has explored the connection between MPAs and neurodevelopmental disorders, predominantly focusing on schizophrenia patients and their relatives. Most studies have examined total MPA scores or anatomical region scores, there is a need for a deeper understanding of the frequency of specific anatomical regions or individual MPA items associated with schizophrenia. This study aims to shed light on potential endophenotypic markers by providing an updated meta-analysis of the relationship between MPAs and schizophrenia. Thus, further studies specifically examining MPAs associated with schizophrenia and the gestational period in which they occur may provide information about the neurodevelopmental pathogenesis of schizophrenia.

Methods: A literature search was conducted using the databases Pubmed and Web of Science to identify the relevant studies (January 1980 to August 2023) using the keywords as follows: ("schizophrenia" OR psychosis OR psycho*) AND ("minor physical anomalies" OR MPA). Statistical analyses were performed using JAMOVI (Version 2.3.26). Homogeneity of the distribution of weighted effect sizes was assessed by Q test and I²; and publication bias was assessed by Egger's test for funnel plot asymmetry.

Results: In this comprehensive meta-analysis, we incorporated 47 studies comparing Minor Physical Anomalies (MPAs) scores between individuals with schizophrenia and healthy controls. Among these, 43 studies, involving 3780 schizophrenia cases and 3871 controls, provided data on total MPA scores. The observed difference between patients and controls was medium-large ($g=0.78$ [0.63-0.93], p LESS THAN 0.001), accompanied by significant heterogeneity in the distribution of effect sizes ($I^2= 88.62\%$). In our regional MPA meta-analyses, effect sizes ranged from 0.56 to 0.78, with the most substantial difference identified in the area of the mouth ($g=0.78$, CI [0.62-0.94]). This meta-analysis also delved into the investigation of differences in the frequencies of specific MPA scale items between patients and controls. Aligning with the outcomes of regional MPA analyses, the highest rates were observed in palate and tongue anomalies. Notably, items such as fine electric hair (OR=2.22 [1.31-3.77]), hair whorls (OR=2.44 [1.27-4.70]), epicanthus (OR=2.35 [1.36-4.04]), malformed ears (OR=3.71 [2.16-6.36]), low seated ear (OR=2.65 [1.73-4.06]), lower edges backward/upward (OR=3.06 [1.28-7.35]), furrowed tongue (OR=2.73 [1.77-4.22]), tongue with spots (OR=5.63 [1.72-18.37]), high palate mild (OR=2.73 [1.50-4.95]), high palate severe (OR=5.27 [2.74-10.12]), single palmar crease (OR=2.75 [1.41-5.38]), gap between 1st-2nd finger (OR=3.24 [1.88-5.56]), curved 5th finger (OR=2.02 [1.38-2.96]), syndactilia (OR=2.19 [1.22-3.94]) were identified as the most significant.

Discussion: The frequency of MPA is increased in schizophrenia patients compared to healthy controls. Exploring the prevalence of specific minor physical anomalies in particular anatomical regions can provide valuable insights into the timing of dysmorphology and the neurodevelopmental phases in which developmental pathology occurs. In our study, it is observed that frequency of midline anomalies such as high palate, fine electric hair and hair whorls has increased. Evaluating these anomalies provides useful information for comprehending the neurodevelopmental pathology of schizophrenia. These findings

underscore the importance of not only quantifying total MPA scores but also identifying specific anatomical anomalies. In this way, the neurodevelopmental aspect of schizophrenia can be better understood. Additionally, clarifying the specific and characteristic differences for MPAs may point the way for their use as endophenotypic markers. We recommend that future research delve deeper into the biological mechanisms underlying these abnormalities and their connection to schizophrenia.

S113. DYSEXECUTIVE BEHAVIOR IN FIRST-EPISODE SCHIZOPHRENIA

Gricel Orellana Vidal*¹, Andrea Slachevsky¹, Fernando Henriquez¹

¹*University of Chile*

Background: Dysexecutive syndrome is a prominent and functionally significant cognitive feature of schizophrenia. This research studies dysexecutive behaviors in first episode of schizophrenia (FES) patients.

Methods: We evaluated 22 FES patients, from 17 to 29 years of age with a recent history of a single psychotic outbreak only treated with atypical neuroleptics. We also evaluated twenty healthy persons matched by sex, age and educational level with FES patients as a control group. Executive function using Modified Wisconsin Card Sorting Test (MWCST) and Frontal Assessment Battery (FAB) and dysexecutive conducts applying the questionnaires Dysexecutive Index (DEX) and Behavioral Dysexecutive Syndrome Inventory (BDSI) in both groups. This study marks the first application of the BDSI in a sample of FES patients. DEX scores are DEX self-rating (DEX-S), "significant other" (DEX-SO) and the difference between DEX-S and DEX-SO scores reflects awareness of the deficit (DEX-A). The FAB consists of 6 subtests of frontal- lobe functions: (1) Conceptualization and Abstract Reasoning (similarities); (2) Mental Flexibility (verbal fluency); (3) Motor Programming and Executive Control of Action (Luria motor sequences); (4) Resistance to Interference (conflicting instructions); (5) inhibitory control (go/no-go test); and (6) Environmental Autonomy (prehension behavior). Each subtest is scored from 3 (better score) to 0, for a maximum score of 18. [21]. this study marks the first application of the FAB in a FES sample.

Results: We found that FES patients had marked executive function impairments and dysexecutive behavior as compared to controls (table 1, 2).

FAB: Total, Conceptualization, Motor Programming, Resistance to Interference, and Inhibitory Control scores were significantly lower in FES patients than controls (Table 1).

The t-tests showed significant differences between the FES and control participants for BDSI, DEX-SO, and DEX-S total scores. There were no significant differences in DEX-A scores between groups (Table 2).

Discussion: Dysexecutive behavior is common during FES and may be a primary impairment throughout disease progression. The present results could help clinical practice by providing information on some specific characteristics of dysexecutive behavior in FES. Understanding the associations between executive function and dysexecutive behavior helps to explain the social adjustment disorders associated with schizophrenia. This knowledge may be used to improve diagnostic and therapeutic tools; for example, clarifying the implications of specific DEX and BDSI dimensions could increase the efficacy of individual or family psychotherapy interventions.

S114. BEYOND THE VEIL: UNVEILING SEX DIFFERENCES IN PSYCHOSIS PRONENESS MEASURED BY DELTA INVENTORY AMONG NON-CLINICAL INDIVIDUALS

Nadja Maric^{*1}, Goran Knezevic², CoV2Soul.rs Study Group³

¹*Institute of Mental Health, Faculty of Medicine, University of Belgrade*, ²*Faculty of Philosophy, Department of Psychology, University of Belgrade*³*Serbia*

Background: There have been several studies that have shown differences between men and women in a non-clinical population about their Schizotypy, which was assessed using the Schizotypal Personality Questionnaire, or their psychosis symptoms, which are evaluated through a structured psychiatric interview. Recently, Knezevic et al. proposed that proneness to psychotic-like experiences and behaviours can be redefined as a personality trait known as Disintegration (D), which can be measured using the DELTA inventory. This trait indicates a predisposition to perceive, comprehend, and feel connections among factually unrelated phenomena, which can lead to illusory pattern perception (apophenia or false positive detection errors). The concept of D as a personality trait aims to account for individual differences observed in both clinical and non-clinical populations.

The primary objective of this study was to investigate whether there are sex differences in Disintegration within a nonclinical, nationally representative adult sample, using a 20-item version of the DELTA inventory. We hypothesised that women would show more "positive" features, such as magical thinking or mania/depression, while men would exhibit more "negative" features, such as flattened affect.

Methods: The present study was part of a larger cross-sectional observational epidemiological survey, CoV2Soul.rs (registration number NCT04896983), which employed multistage household probabilistic sampling to recruit a representative adult sample (age 18-65) from Serbia (N=1203; mean age 43.7 years (SD = 13.6)). Around 48.7% were male. We calculated the total DELTA score and nine lower-level traits: General Cognitive/Executive Impairment, Perceptual Distortions, Enhanced Awareness, Apathy/Depression, Paranoia, Mania, Flattened Affect, Somatic Dysregulations, and Magical Thinking. The Total D score, along with the scores for the nine subdimensions, was measured using a 20-item Likert-type scale, ranging from 1 (Strongly Disagree) to 5 (Strongly Agree). To test the difference between females and males on DELTA scores, a t-test for independent samples was used. To predict the probability of a binary outcome (female/male) based on all nine Disintegration subdimensions, logistic regression was used.

Results: There were no statistically significant differences between females and males in age (M_{age}=44.30, SD_{age}=13.52; M_{age}=43.08, SD_{age}=13.60; $t(1201)=1.55$, $p = .121$) and education (M_{educ}=3.30, SD_{educ}=1.38; M_{educ}=3.24, SD_{educ}=1.39; $t(1201)=0.78$, $p = .435$). Female participants had a slightly higher total DELTA score than males (M_f=1.56, SD_f=.66; M_m=1.46, SD_m=.60; $t(1198.86)=2.88$, $p < .001$, $\eta^2 = .007$). The DELTA subscales contributing to this difference were General Cognitive/Executive impairments (M_f=1.73, SD_f=.90; M_m=1.53, SD_m=.77, $t(1189.10)=4.03$, $p < .001$), Somatoform Dysregulations (M_f=1.42, SD_f=.80; M_m=1.28, SD_m=.66, $t(1174.31)=3.43$, $p < .001$), and Apathy/Depression (M_f=1.35, SD_f=.74; M_m=1.24, SD_m=.60, $t(1176.86)=2.80$, $p=.005$). A composite (logistic regression), based on the DELTA subscales revealed that for each point increase in General Cognitive/Executive impairments and Somatoform dysregulation scores, there were the odds of 1.46, $p < .001$ and 1.30,

$p = .034$, respectively, of being a female. For each point increase in Flattened Affect and Paranoia, there were the odds of .77, $p = .003$, and .83, $p = .037$, respectively, of not being a female.

Discussion: Acknowledging gender differences in schizophrenia spectrum disorders and schizotypy is crucial for gaining valuable insights into sex-specific aspects of psychosis risk, clinical manifestations, and the potential for delivering gender-tailored treatments and care to patients. The disparities observed in the Disintegration subdimensions are consistent with established findings in various aspects of schizotypy, revealing some innovative perspectives. The current findings are interpreted as providing support for the validity of the newly introduced 20-item DELTA scale.

This work was supported by the Science Fund of the Republic of Serbia, grant number #7528289. The special research program on COVID-19 is financed by a World Bank loan through Serbia Accelerating Innovation and Entrepreneurship Project – SAIGE.

S115. SCHIZOPHRENIA SPECTRUM AND OTHER PSYCHOTIC DISORDERS IN INTRAFAMILIAL HOMICIDE

Dominique Bourget^{*1}, Jiyoung Hwang¹, Shuying Zheng², Pierre Gagné³, Alain Labelle⁴

¹Royal Ottawa Mental Health Hospital, ²University of Ottawa, ³Université de Sherbrooke,

⁴Schizophrenia Program, The Royal Ottawa Mental Health Centre

Background: The homicide of another person due to psychotic symptoms is an uncommon but severe and unfortunate complication of psychotic illness. Psychotic individuals will most often target acquaintances or individuals with whom they interact the most. In this context, close family relatives are more at risk than the general population.

This poster presentation will review and analyse the results of an original study comprising over one-thousand consecutive cases of intrafamilial homicide coroner cases, collected over a period of 32-years in the province of Quebec, Canada, with respect to the impact and role of psychosis in intrafamilial homicide.

Methods: The data presented in this paper is extracted from the Quebec Study, a longitudinal study of domestic homicide from 1991 to the present. The study received approval from an institutional Ethics Board. The coroners' files contain data on both victims and offenders, their main characteristics, the circumstances and manner of death, the spatial location of the homicide, the type of weapon used in each case, the coroner's findings, the police report, the autopsy report, and toxicology report. In addition to the coroners' files, the authors reviewed any other available examination, including expert opinions and legal outcomes, when available. For the purpose of this presentation, we considered the following variables: type of intrafamilial homicide (e.g. filicide, parricide...), gender and age of offender, the number, gender and age of victims, method used, diagnosis of the offender and substance use, and known risk factors.

Results: The presence of a psychotic disorder was identified in a significant number of cases, and particularly in the categories of parricide (the killing of a parent), fratricide (the killing of a sibling) and filicide. In the sample of parricide, two-thirds of offenders were found to suffer from severe psychosis. Their actions were particularly violent and motivated by delusions against one or two parents. The presence of Capgras syndrome was noted in some cases. In the

category of fratricide, substance-induced psychotic disorder was prevalent. In the category of filicide, the presence of a psychotic diagnosis was high when it came to an offender killing several family victims. Risk factors showed the presence of pre-existing pathology and recent deterioration of behaviour, as well as recent psychosocial stressors. Specific numbers will be provided in table form in the poster.

Discussion: This study examines the prevalence and impact of psychosis, including schizophrenia, in intrafamilial homicides in a province of Canada. As forensic psychiatrists, we are often called upon to assess the offenders after the fact. The findings from this study and our own clinical experience reveal that indicators of a potential increased risk of violence in predisposed individuals do exist. Such risk factors include specific delusions, persecutory beliefs, behavioural and mental disorganization, and other clinical characteristics including worsening of psychosis. In an era where access to assessment and treatment are jeopardized by the insufficiency of resources in place, it is imperative, as a society, to reflect on better prevention and protective remedies.

S116. RELATIONSHIPS BETWEEN CHILDHOOD TRAUMA AND PSYCHOPATHOLOGY: A TRANSDIAGNOSTIC NETWORK ANALYSIS

Yi-hang Huang^{*1}, Chao Liu², Jian-biao Zhang², Shuai-biao Li³, Ling-ling Wang⁴, Hu Hui-xin⁵, Min-yi Chu³, Yi Wang⁶, Qin-yu Lv⁷, Simon S. Y. LUI⁸, Zheng-hui Yi⁷, Li Hui⁹, Raymond C.K. Chan¹⁰

¹Neuropsychology and Applied Cognitive Neuroscience Laboratory, CAS Key Laboratory of Mental Health, Institute of Psychology, Chinese Academy of Sciences, ²Nantong Fourth People's Hospital, ³Translational Neuropsychology and Applied Cognitive Neuroscience Laboratory, Shanghai Mental Health Centre, Shanghai Jiao Tong University School of Medicine, ⁴Neuropsychology and Applied Cognitive Neuroscience Laboratory, CAS Key Laboratory of Mental Health, Institute of Psychology; Department of Psychology, University of Chinese Academy of Sciences, ⁵Neuropsychology and Applied Cognitive Neuroscience Laboratory, CAS Key Laboratory of Mental Health, Institute of Psychology, Chinese Academy of Sciences; Department of Psychology, the University of Chinese Academy of Sciences, ⁶Neuropsychology and Applied Cognitive Neuroscience Laboratory, Key Laboratory of Mental Health, Institute of Psychology, Chinese Academy of Sciences, ⁷Shanghai Mental Health Center, Shanghai Jiao Tong University School of Medicine, ⁸The University of Hong Kong, ⁹Suzhou Guangji Hospital, The Affiliated Guangji Hospital of Soochow University, ¹⁰Neuropsychology and Applied Cognitive Neuroscience Laboratory, Key Laboratory of Mental Health, Institute of Psychology, Chinese Academy of Sciences

Background: Empirical evidence suggests that childhood trauma is a significant risk factor for various psychiatric disorders and is associated with a range of psychopathological symptoms. However, the specific mechanism linking childhood trauma to psychopathology remains unclear. There is a lack of transdiagnostic comparisons among different psychiatric disorders. This study adopted network analysis to examine a large cross-sectional transdiagnostic sample of patients with schizophrenia, bipolar disorder and major depressive disorder to investigate such a link utilising network analysis.

Methods: We administered the Positive and Negative Syndrome Scale (PANSS), the Clinical Assessment Interview for Negative Symptoms (CAINS), the Childhood Trauma Questionnaire

- Short Form (CTQ-SF), and the Clinical Global Impression - Severity of Illness (CGI-S) to 318 patients with schizophrenia, 163 bipolar disorder, and 194 major depressive disorder. We constructed a regularized partial correlation network of childhood trauma and psychopathological symptoms at both the dimension and the item levels. Network Comparison Tests (NCTs) were also used to investigate the differences among diagnoses, gender-stratified groups, and patients with and without childhood trauma.

Results: Our results showed that (1) childhood trauma is closely connected with psychopathological symptoms, after controlling for the inter-relationships between all nodes in the network. Different subscales of childhood trauma were distinctly linked to specific dimensions and/or items of psychopathology; (2) Emotional abuse of the CTQ-SF and motivation and pleasure deficits factor of the CAINS showed high expected influence and strength, while emotional abuse and depressive symptom of the PANSS showed high closeness and betweenness in centrality estimation. (3) NCTs revealed that patients who had suffering ed childhood trauma had exhibited greater network connections than those who did not. Schizophrenia patients also exhibited stronger network connections than both bipolar disorder and major depressive disorder patients. However, we did not find any there was no gender impact difference was upon the network structure across the transdiagnostic groups.

Discussion: In summary, this study utilized network analysis to reveal examine the existence of differential subtype effects of childhood trauma types on psychotic symptoms dimensions psychopathologies across a transdiagnostic sample. Notably, our findings underscored the central role of childhood trauma in shaping motivation and pleasure deficits, making them crucial targets for intervention. Additionally, Moreover, our results highlight emotional abuse as the key childhood trauma subtype influencing psychopathology development in patients with schizophrenia, bipolar disorder and major depressive disorder.

S117. IS THERE ANY TRIGGER FOR THE ONSET OF OBSESSIVE-COMPULSIVE SYMPTOMS IN SCHIZOPHRENIC PATIENTS?

Yasushi Okamura*¹, Hirohiko Harima¹, Masafumi Mizuno¹

¹*Tokyo Metropolitan Matsuzawa Hospital*

Background: Previously, it was generally held to be difficult to understand the developmental basis of symptoms and patterns in psychosis. However, psychogenic factors are known to play a prominent role in the development of neuroses. Thus, the two disorders, psychosis and neurosis, were recognized as etiologically disparate groups of diseases. Obsessive-compulsive disorder (OCD) was thought to originate in obsessive-compulsive neurosis, and it is sometimes still suggested that life events may be deeply involved in the onset of typical OCD. In clinical practice, however, schizophrenia and OCD co-occur in many patients. Indeed, Schneider, K. has remarked that obsessive-compulsive symptoms can occur in the early stages of schizophrenia. Recent epidemiological studies describing cases of comorbidity of OCD and schizophrenia have reported that a diagnosis of OCD increases the risk of later schizophrenia development. However, few psychopathological studies have examined whether obsessive-compulsive symptoms in patients with schizophrenia and OCD differ etiologically from those in patients with OCD without psychosis. With the removal of the requirement that patients acknowledge the irrationality of their obsessions or compulsions (i.e., insight) from the DSM-5 diagnostic criteria for OCD, the definition of OCD was broadened to include new forms characterized by delusional insight. The line of demarcation between schizophrenia and OCD increasingly deserves closer, clinical scrutiny.

Methods: This is a secondary analysis of our previously reported study (Okamura et al., 2022) in which some of the patients analyzed in the study are consistent with those analyzed in this presentation and only new psychopathological findings on the onset trigger are described here. The present study aimed to investigate whether there is any difference in the onset of obsessive-compulsive symptoms between patients with schizophrenia and OCD and those with OCD without a psychotic disorder. Between April 2015 and April 2022, 83 patients with OCD at the Department of Psychiatry at Tokyo Metropolitan Matsuzawa Hospital were divided into a group of 25 patients with OCD with a psychotic disorder (schizophrenia) (the OCD+PD group) and a group of 58 patients without any psychotic disorders (the OCD-PD group) based on the Mini International Neuropsychiatric Interview, Japanese version 5.0.0 2003 (M.I.N.I.) (Sheehan et al., 1997; Lecrubier et al., 1997; Amorim et al., 1998; Sheehan et al., 1998; Otsubo et al., 2005; Sheehan et al., 2010) and ICD-10 (World Health Organization, 2005) for cross-sectional comparison.

Results: The OCD+PD group was significantly less likely to have an onset trigger. Thirty-four patients with any trigger were classified and quantified in terms of the causes and severity of stress using the Social Readjustment Rating Scale (Holmes and Rahe, 1967). The causes of stress were Begin or end school (n=5), Change in working hours or conditions (n=5), Personal injury or illness (n=4), Change in health of family member (n=3), Sex difficulties (n=3), Change to a different line of work (n=3), and unclassifiable (n=21). The severity of stress was significantly higher in the OCD-PD group, and female patients were significantly more likely to have illness onset after some life event, especially if it was acute rather than enduring.

Discussion: The fact that the development of obsessive-compulsive symptoms was associated with significantly fewer triggers and a lower severity of stress in the OCD+PD group than in the OCD-PD group might be considered difficult to understand from the developmental perspective as expressed in the term, *genetisches Verstehen*. However, the present study did not use a life event rating scale nor fully examine the possible role of predisposing factors and the child-rearing environment in OCD onset in addition to environmental changes and events. To overcome these limitations, future studies might re-examine the definition of trigger and employ an objective life event scale while also taking into account personality traits, child-rearing environment, and gender differences.

S118. RESISTING INTERNALIZED STIGMA (RIS): ACCEPTABILITY AND FEASIBILITY OF A COGNITIVE BEHAVIORAL BASED STIGMA REDUCTION INTERVENTION FOR EARLY PSYCHOSIS

Francesca Crump^{*1}, Tom Dinzeo², Monica E. Calkins³, Christian Kohler³, Arielle Ered⁴, Kathryn Coniglio³, Riley Capizzi⁵, Bridgette Patton³, Alicia Lucksted⁶, Lawrence Yang⁷

¹Cambridge Health Alliance, ²Rowan University, ³Department of Psychiatry, University of Pennsylvania, ⁴Perelman School of Medicine University of Pennsylvania, ⁵Temple University, ⁶VA VISN 5 MIRECC, VA Maryland Health Care System, ⁷New York University

Background: The clinical high-risk for psychosis (CHR-p) designation was created to identify individuals exhibiting attenuated psychotic symptoms early to improve course of illness. Although there are invaluable benefits to entering specialized treatment programs for early psychosis, CHR-p individuals are likely to experience increased stigma due to the public's perception of receiving mental health treatment. Similarly, those diagnosed with their first episode of psychosis (FEP) are exposed to similar experiences of stigma and discrimination.

Currently, the only stigma reduction strategies implemented in early psychosis treatment contain psychoeducational elements. This study sought to pilot a manualized, cognitive behavioral therapy (CBT)-based stigma intervention for individuals identified as CHR-p and FEP in an early psychosis clinic.

Methods: This study piloted an 8-week, virtual group stigma intervention (RIS) that contained psychoeducation, CBT techniques to challenge stigmatizing thoughts, and anti-bullying strategies to diffuse confrontations. This study took place at the University of Pennsylvania's Psychosis Evaluation and Recovery Center (PERC) and a total of 9 individuals identified as CHR-p and FEP participated in two mixed groups. Qualitative interviews, psychosocial and functional outcomes were administered at baseline and follow-up. Pearson correlations and Wilcoxon Signed Rank Tests were performed.

Results: Overall, acceptability and feasibility of the intervention was established (attendance M=74.5%). Qualitative interviews indicated improvements in sense of purpose, perspectives on taking psychiatric medication, and increased family support. At baseline, correlations were associated with shame. Higher shame was linked to increased depression ($p=0.013$), worse psychological health ($p=0.001$), poor nutrition ($p=0.019$), low sense of purpose ($p=0.001$), and decreased self-esteem ($p=0.002$). At follow-up, most of the associations with shame became non-significant. Instead, most correlations were associated with positive emotions. Specifically, increased positive emotions were related to better emotion identification ($p=0.026$), quality of life for physical health ($p=0.042$), self-esteem ($p=0.006$), and role functioning ($p=0.005$). Wilcoxon Signed-Rank Tests demonstrated a decrease in stigma ($p=0.044$), an increase in positive emotions related to symptoms ($p=0.038$), and an elevation in sense of purpose ($p=0.024$). Furthermore, trend findings indicated increased self-esteem ($p=0.072$) and improved Theory of Mind performance ($p=0.074$) from baseline to follow-up.

Discussion: This is the first CBT-based stigma intervention to be piloted with CHR-p participants and demonstrated appropriate acceptability and feasibility for early psychosis groups. Participants endorsed uptake of CBT techniques to challenge stigmatizing thoughts, which led to increases in positive emotions, sense of purpose, and decreases in stigma. As specialized programs for early psychosis adopt recovery-oriented models, group stigma interventions, such as RIS, could be incorporated into their treatment offerings to improve outlook on course of illness and increase sense of purpose.

S119. RELATIONSHIP BETWEEN BRAIN STRUCTURE AND NEUROMETABOLITES IN THE EARLY STAGES OF PSYCHOSIS

María Ortuño^{*1}, Adriana Fortea¹, Irene Martínez¹, María Muriel¹, Patricia Camprodon¹, Elena De la Serna², Roger Borràs³, Mireia Masias⁴, Daniel Ilzarbe¹, Inmaculada Baeza⁵, Josefina Castro-Fornieles⁵, Gisela Sugranyes¹

¹Fundació Clínic Recerca Biomèdica - Institut d'Investigacions Biomèdiques August Pi i Sunyer, Clinical and Experimental Neuroscience, ²Centro de Investigación Biomédica En Red de Salud Mental CIBERSAM, Child and Adolescent Psychiatry, ³Department of Child and Adolescent Psychiatry, Institute of Neurosciences, University of Barcelona, ⁴BCN-MedTech, Universitat Pompeu Fabra, ⁵Department of Child and Adolescent Psychiatry, Institute of Neurosciences, University of Barcelona

Background: Patients at high risk for psychosis who develop the disorder have been found to present less gray matter volume and cortical surface area in the temporal and anterior cingulate

cortex compared to those who do not transition to psychosis suggesting that changes in brain structure precede the onset of the disorder. Nevertheless, the neurobiological mechanisms underlying these morphological changes are still not fully understood. Adolescence is an important neurodevelopmental period which is thought to be especially informative for understanding deviation in brain metrics associated with disease. The present study aimed to understand the relationship between levels of glutamatergic metabolites and measures of brain structure in adolescent patients with first episode of psychosis (FPE) or with familial high-risk for schizophrenia or bipolar disorder (HR), and controls.

Methods: 34 FPE (mean age 15.21 [7-18], 35% females), 44 HR (offspring of patients with schizophrenia or bipolar, none of whom meeting criteria for these disorders; mean age 14.06 [7-18], 70% females) and 76 healthy subjects (mean age 14.45 [7-18], 55% females) were recruited in the Hospital Clinic of Barcelona and assessed with clinical and brain imaging measures. All participants underwent the acquisition of two magnetic resonance imaging (MRI) sequences on a 3T scanner: a T1-weighted sequence and a magnetic resonance spectroscopy sequence (MRS) in volumes of interest (VOIs) located in the lateral prefrontal cortex (PFC) (2x2x2cm³) and the medial temporal lobe (mTL, 3x2x2cm³). MRS data was processed employing LCModel in order to obtain the creatinine-corrected ratios of glutamate and glutamate + glutamine (Glx). Moreover, the T1-weighted images were processed with Freesurfer (version 7.1) to retrieve cortical thickness, surface area and gray matter volume from frontal and medial temporal regions. Linear models were conducted in R to study the group by age effect on metabolite levels and the group by metabolite effects on structural measures.

Results: In the mTL we found differences between groups in Glx, specifically between FPE and controls ($t = 2.05$, $p = 0.042$) and HR ($t = 1.86$, $p = 0.065$), at a trend level, whereby Glx levels had a negative relationship with age in FPE, which was absent in the other groups. Moreover, we found a positive relationship between the gray matter volume of the left frontal pole and the values of glutamate ($p = .0011$) and Glx ($p = .016$) measured in the prefrontal VOI in all three groups. No associations were found between measures of brain structure at the hippocampal level and neurometabolites measured in this brain region nor metabolite by group effects in structural measures of any of the VOIs.

Discussion: These findings highlight the complex interplay between glutamatergic metabolite changes with age and brain structure in the early stages of psychosis during adolescence. Further studies characterizing high-risk youth according to their outcome and genetic background will provide a greater understanding of the biological changes that precede the emergence of psychosis or protect towards its development.

This study was funded by Instituto de Salud Carlos III co-funded by the EU (PI1800976, PI2100330, PI2100519), and by the EU grant (101057529), TV3_SalutMental_21 (202232-30), Alicia Koplowitz Foundation, CIBERSAM and 2021 SGR 01319.

S120. WHY HOW WE GOT HERE MATTERS: A QUALITATIVE STUDY OF THE IMPACT OF REFERRAL EXPERIENCE TO EARLY INTERVENTION SERVICES ON PERCEPTIONS OF CARE AND ENGAGEMENT IN TREATMENT

Brannon Senger^{*1}, Quinn MacDonald¹, Candice Crocker¹, Alissa Pencer¹, Jean Hughes¹, Philip Tibbo¹

¹Dalhousie University

Background: Background: Most young adults experiencing psychosis enter early intervention services (EIS) via inpatient services and emergency departments. Referral in this manner is often highly distressing for service users, especially considering the high likelihood of involuntary hospitalization and law enforcement involvement during these interactions. These experiences are suggested to impact young adults' trust and confidence in health services as well as their engagement in subsequent treatment, namely EIS. However, limited research has empirically examined the impact of young adults' referral and helpseeking experiences on these outcomes. This study aimed to explore the referral experiences of young adults enrolled in EIS and assess the impact of these on their current views towards healthcare services/providers and engagement in treatment.

Methods: 12 young adults (mean age = 24.83) within 3-12 months following their acceptance to EIS, were engaged in semi-structured qualitative interviews. Interviews were conducted and analyzed using an interpretative phenomenological analysis approach, which emphasizes the importance of understanding individuals' subjective experiences of an event and explores how this subjectivity influences their sense-making. Interview transcripts were analyzed to identify emergent themes in participants' accounts of their experiences. Two researchers independently analyzed interview transcripts to limit the risk of bias in identified themes.

Results: 3 superordinate themes emerged from participants' accounts of their experiences: (1) Navigating the Maze of Healthcare (2) Dignity and (3) Impact of Referral Experiences. Participants with referral pathways involving urgent care services, particularly through involuntary hospitalization described more adversity during their referral pathway and were more likely to

endorse help-seeking experiences as contributing to negative views towards EIS and diminished engagement in treatment.

Discussion: The impact of early negative experiences with healthcare on views towards EIS and engagement is evident in participants' accounts. Participants' perspectives were further contextualized by their illness insight, degree of recovery, and social support throughout their experiences. Participants with negative views towards EIS often described experiencing increased treatment delay, decreased awareness of the illness, residual psychotic symptoms, and decreased social support in addition to their adverse experiences with healthcare. Themes identified in qualitative analysis indicate specific features of treatment experiences predicting negative views that could be potential targets for improvement in health service delivery. Results highlight the need for psychiatric services to emphasize service users' dignity. Providing opportunities for patients enrolled in EIS to discuss and process past negative healthcare experiences may challenge existing negative beliefs about treatment and strengthen engagement in services.

S121. COMPARING THE IMPACT OF DUP ON 6 AND 12-MONTH OUTCOMES IN A PROSPECTIVE COHORT OF FEP CASES ACROSS TWO SITES

Hadar Hazan^{*1}, Bin Zhou², Fangyong Li², Toni Gibbs-Dean², Sumeyra Tayfur², Sneha Karmani², Emily Kline³, Maria Ferrara⁴, Sarah Riley², John Cahill², Cenk Tek², Matcheri Keshavan⁵, Vinod Srihari²

¹Yale Medical School, ²Yale Center for Analytical Sciences, ³Boston University, ⁴Yale Medical School; University of Ferrara, ⁵Harvard Medical School

Background: This study examined the correlation between Duration of Untreated Psychosis (DUP) and treatment outcomes in two Coordinated Specialty Care (CSC) clinics. One clinic implemented Early Detection (ED) strategies (STEP, n = 147), and the other used standard detection methods (PREP, n = 75).

Methods: We examined the correlation of DUP with treatment outcomes across the entire sample (median DUP = 228 days), and within the ED site, where the median DUP was reduced during the ED campaign (median DUP = 169 days). We used repeated measures of ANOVA and logistic regression to test the change in continuous (functioning, symptom severity, quality of life) and binary outcomes (employment status), respectively. The Difference-in-differences method was used to estimate the causal effect of low DUP on the outcome.

Results: In both samples, patients with a lower DUP showed better odds of employment, schooling, or job-seeking activities than those with a higher DUP at both the 6-month and 12-month intervals. In both samples, individuals with a lower vs. high DUP exhibited better global assessment of functioning (GAF) at the 6-month follow-up. However, this improvement was not maintained at the 12-month follow-up in either sample. Across sites, the low DUP group demonstrated a significantly greater improvement in quality of life (QoL) compared to the high DUP group at the 6-month and 12-month follow-ups. The same trend was evident in the ED sample, although it did not reach statistical significance.

Discussion: Despite the notably shorter DUP at the ED site, both samples exhibited similar trends. Functional outcomes appeared to be most consistently associated with DUP in this observational study. We did not find evidence supporting an association between DUP and symptom severity or GF: role and social scores. Individuals with a high DUP in CSC show improvement over time, although their progress seems to be slower.

S122. SEX DIFFERENCES IN PREVALENCE OF STRESSFUL LIFE EVENTS AND RELATION WITH SYMPTOMATOLOGY IN FIRST EPISODE PSYCHOSIS

Alicia Colomer-Salvans^{*1}, Regina Vila-Badia¹, Clara Serra-Arumi¹, Anna Butjosa², Nuria Del Cacho¹, Helena Escobedo-Pareras¹, Judith Usall¹

¹Parc Sanitari Sant Joan de Déu, ²Hospital Sant Joan de Déu

Background: It is described that there is a high incidence of Stressful Life Events (SLEs) in people with psychosis and that they are three times more likely to experience SLEs before the onset (Beards et al., 2013). There are few studies focused on sex differences of SLEs in First Episode Psychosis (FEP) and on the relationship between SLEs and clinical variables such as psychotic and maniac symptoms. However, the literature suggest some differences in women and men (Mansueto and Faravelli, 2022) and some associations with SLEs and symptomatology (Butjosa et al., 2016). The aims of the study are: 1) to study the prevalence and types of SLEs in FEP women and men, 2) to know the relationship between SLEs and symptomatology in FEP women and men.

Methods: This research is part of a longitudinal observational study called 'PROFEP Group' in Catalonia. The patients belong to Mental Health Parc Sanitari Sant Joan de Déu, Hospital Sant Joan de Déu and Hospital Germans Tias i Pujol health care sector. Participants included are 86 FEP patients (26♀; 60♂) and 87 HC (32♀; 55♂). The Stressful Life Events

Questionnaire (QSLE, Butjosa et al., 2017) was used to assess the total of SLE experimented during life and categorize SLE in nine areas: education, work, partner, family, home, legal, finances, social and health. The U Mann-Whitney test was used to evaluate differences in the prevalence of SLE between FEP women and HC women. Additionally, the T Student test assessed differences in the prevalence of SLE between FEP men and HC men. Finally, Spearman correlation and Pearson correlation tests examined associations between SLE and symptomatology in FEP women and men, respectively.

Results: Comparing with healthy controls (HC), FEP women present more SLEs in education ($U=186.500$; $p=.004$) and health ($U=286.000$; $p=.042$) categories, while FEP men experience more SLEs in total SLEs ($t=5.894$; $p < .001$), education ($t=7.083$; $p < .001$), work ($t=4.346$; $p < .001$), family ($t=3.205$; $p=.002$), home ($t=2.723$; $p=.008$), legal ($t=3.068$; $p=.003$), finances ($t=2.190$; $p=.031$), social ($t=3.810$; $p < .001$) and health ($t=4.841$; $p < .001$).

Regarding the relationship between SLEs and symptomatology, women with FEP who reported more SLEs related to health presented greater positive symptoms ($r=.455$; $p=.022$). In contrast, men with FEP who reported more total SLEs experienced more positive symptoms ($r=.400$; $p=.010$), and those who present more SLEs in the legal and social categories presented more positive ($r=.297$; $p=.021$, $r=.307$; $p=.019$, respectively) and excited ($r=.266$; $p=.040$, $r=.276$; $p=.036$, respectively) symptoms.

Discussion: Both FEP women and men experienced more SLEs than the HC, implying a potential association between experimenting SLEs and the onset of FEP.

Sex differences were observed in the relation between symptomatology and SLEs among individuals with FEP. This highlights the importance of incorporating a gender perspective in studies focusing on SLEs and FEP.

It is important to detect SLEs and provide good support, to reduce the stress and discomfort they can generate and the likelihood of developing a FEP.

Detecting SLEs and providing adequate support is crucial for mitigating the stress and discomfort they can generate, thereby reducing the likelihood of developing FEP.

S123. YOUTH MED.INFO - CO-DESIGN OF MENTAL HEALTH MEDICINES INFORMATION RESOURCES FOR YOUTH

Caroline Hynes^{*1}, Ian Kelleher², Sophie Kathryn³, Izzie X³, Charlie X³, Joseph Morning³, Stephen McWilliams⁴, Maria Migone⁵, David Columb⁵, Sarah Donnelly⁵, John Hayden⁶, Judith Strawbridge⁶, Nimantha Gamage⁷, Dolores Keating⁷

¹*Saint John of God Hospital*, ²*University of Edinburgh*, ³*SpunOut*, ⁴*St. John of God Hospital*, ⁵*Lucena Clinic, Child and Adolescent Mental Health Services*, ⁶*RCSI University of Medicine and Health Sciences, Dublin, Ireland*, ⁷*Saint John of God Hospital Ltd*,

Background: Mental health medicines information resources for youth in Ireland and globally are inadequate. Young people and their parents find existing mental health medicines information difficult to navigate as there are few reliable resources available. They also report lack of access to information on mental health medicines as a barrier to treatment adherence. Between 95-100% of those aged 12-17 report owning or having access to a personal smart device, and YouTube, TikTok and Instagram are the most commonly used platforms by this

age group. They are increasingly used by young people as search tools for queries about mental health diagnoses. However, as health information videos on these platforms are not peer-reviewed or aligned to any specific quality standards, search results may often return misleading or incorrect information. Those with content knowledge, are unlikely to possess skills, time or funding to produce high-quality video resources for youth. We aimed therefore to overcome this barrier by bringing clinicians and young people together to co-design a suite of accurate and accessible medicines information videos for use on YouTube, TikTok and Instagram.

Methods: Using an online design platform (www.canva.com) we produced three pilot videos on fluoxetine, olanzapine and methylphenidate. We then engaged in an iterative review process with a panel of expert collaborators including two specialist mental health pharmacists, two academic pharmacists, four consultant child and adolescent psychiatrists, a consultant adult psychiatrist, a child and adolescent psychiatric nurse and a focus group of young people. The clinical information in the videos was sourced from the manufacturers' summary of product characteristics and adapted in line with the experience of the clinical collaborators. In an effort to be inclusive and accessible, we considered racial and ethnic diversity, the needs of neurodivergent young people and those in LGBTQ+ community in the development process. To promote transparency and ensure that viewers are aware that the information is accurate and reliable, we developed a brand – Youth Med.Info with a logo and website: www.youthmed.info and a short trailer video.

Results: Having refined the three pilot videos, we then produced another five videos under the same medicine categories – sertraline, venlafaxine, risperidone, aripiprazole and lisdexamfetamine. These videos underwent the same rigorous review process as the initial three. The final eight videos were then uploaded to YouTube (@YouthMedInfo), TikTok (@YouthMed.Info) and Instagram (@Youth.Med.Info). The videos are also hosted on the website – www.youthmed.info – where there are links to more information resources as well as details of those involved in the co-design project. We then went on to develop another eight videos on mirtazapine, quetiapine, clozapine, guanfacine, atomoxetine, melatonin, promethazine and lorazepam all of which are undergoing the same review process.

Discussion: The format, language and overall accessibility of mental health medicines information resources for the youth of today is not suitable to their needs. Young people find the current information difficult to navigate and want to relate the use of the medicines to their everyday experiences. As the voice of young people matters most in their own mental healthcare, engaging with them as well as the clinicians who care for them when developing medicines information resources is crucial.

Given the growing popularity of social media platforms such as YouTube, TikTok and Instagram as search engines amongst young people, accessible and reliable mental health medicines information resources should be compatible with them. While there is a wealth of content on mental health medicines on these platforms presently, its accuracy is unclear. To our knowledge, our videos are the only mental health medicines information resources produced by young people and mental healthcare professionals working with young people.

S124. CEREBELLAR TRIPLE NETWORK DYSCONNECTIVITY WITH CORTICAL AND THALAMIC NETWORKS ACROSS DIFFERENT RISKS AND EARLY STAGE OF PSYCHOSIS

Minji Ha^{*1}, Inkyung Park¹, Taekwan Kim², Wu Jeong Hwang¹, Sunghyun Park³, Minah Kim³, Jun Soo Kwon³

Background: Cerebellar dysconnectivity is consistently linked to psychosis, alongside disruptions in the thalamus and cortical regions. Interestingly, these disruptions align with the triple network model, explaining psychopathological phenomena through abnormal interactions within the salience network (SAL), default mode network (DMN), and executive central network (ECN). However, the specific pattern of cerebellar functional network interactions with cortical and thalamic networks across different stages of psychosis risk within the triple network model remains largely unknown.

Methods: Resting-state fMRI data from 241 participants, including 37 first-episode psychosis (FEP), 63 clinical high-risk (CHR), 41 unaffected relatives (URs), and 100 healthy controls (HCs), were used. To capture the network properties of the thalamus and cerebellum, we generated parcellated thalamic and cerebellar maps reflecting their functional connectivity (FC) to associated cortical networks. FC between cerebellar and cortical networks, as well as between cerebellar and thalamic networks, was computed across the groups.

Results: Compared to the HCs, FEP showed more widespread network dysconnectivity across different regions, while CHR showed dysconnectivity primarily between the networks within the same region. This pattern of widespread dysconnectivity was more pronounced in FEP group than in CHR group. Also, URs did not show significantly different FC from the HCs.

Discussion: The expansion of the classical triple network model to incorporate cerebellar and thalamic networks, along with their distinct FC patterns, holds potential significance in contributing to early psychosis pathophysiology. Furthermore, it can be inferred that dysfunctional interactions within cerebellar, thalamic, and cortical triple networks may manifest as impaired prediction- and error-based learning and inappropriate information updating.

S125. COGNITIVE FUNCTION AT FIRST EPISODE IN PATIENTS SUBSEQUENTLY DEVELOPING TREATMENT-RESISTANT SCHIZOPHRENIA

Juan Aguirre¹, Camila Diaz², Javiera Vásquez Núñez³, Juan Pablo Ramirez-Mahaluf⁴, Daniella Barbagelata¹, Ángeles Tepper³, Cristian Mena², Ruben Nachar², David Aceituno⁵, Alfonso González-Valderrama⁶, Nicolás Crossley⁷, Nicolas Crossley*⁸

¹Department of Psychiatry, Pontificia Universidad Católica de Chile, Santiago, Chile., ²Early Intervention Program, J. Horwitz Psychiatric Institute, ³Pontificia Universidad Católica de Chile, ⁴Facultad de Medicina, P. Universidad Católica de Chile, ⁵Department of Psychiatry, School of Medicine, Pontificia Universidad Católica de Chile, Chile. King's College London, Institute of Psychology, Psychiatry, and Neuroscience, Department of Health Service and Population Research, ⁶Instituto Psiquiátrico Dr. José Horwitz Barak, Santiago, Chile., ⁷Pontificia Universidad Católica, ⁸Facultad de Medicina, P. Universidad Católica de Chile

Background: This study addresses cognitive differences between treatment-responsive (TRESP) and treatment-resistant (TRESIST) schizophrenia patients when they first become unwell (in their first episode of psychosis). Previous research has predominantly focused on chronic patients, making it challenging to distinguish inherent neuropsychological deficits in TRESIST from those influenced by chronicity, antipsychotic exposure and overall deleterious

illness progression. Exploring whether these cognitive differences emerge early in the course of the illness or evolve progressively, could offer insights into the nature of cognitive performance in Treatment-resistant schizophrenia and be used as potential early markers of treatment resistance.

Methods: Cohort study of eighty-one first-episode schizophrenia patients aged 18-65 from Santiago, Chile. Patients were followed-up (mean = 64.03 weeks; median = 10.14) and were classified as treatment resistant if fulfilling TRRIP criteria on clinical assessment or if they were prescribed clozapine at any point by their treating psychiatrist. Cognitive performance was assessed using the Matrices Consensus Cognitive Battery (MCCB). A multivariable model was used to compare cognitive performance between groups.

Results: 51 (63 %) patients were allocated to the treatment-responsive group (TRESP) and 30 (37 %) to the treatment-resistant (TRESIST) sample. Groups did not differ significantly in age, sex, antipsychotic dose, duration of illness in treatment or duration of untreated psychosis (p GREATER THAN 0.05). However, TRESIST cases scored significantly higher in symptom severity (PANSS total score, $p = 0.002$).

A multivariable model controlling for age and sex, revealed that TRESIST at their first episode patients exhibited worse performance than their TRESP counterparts in speed of processing tasks (BACS, $p = 0.002$; TMT-A, $p = 0.004$), verbal fluency ($p = 0.03$), attention/vigilance (CPT-IP, $p = 0.048$), and working memory (WMS-III, $p = 0.045$), with medium to large effect sizes (Cohen's d GREATER THAN 0.5). After correction for multiple comparisons (Bonferroni), only speed of processing tasks (Symbol Coding; TMT-A) remained statistically significant. When accounting for symptom severity, duration of untreated psychosis, and antipsychotic dose, TRESIST subjects still exhibited a significantly lower performance in the two speed of processing task (BACS, $p = 0.036$; TMT-A, $p = 0.027$), which was not significant after correcting for multiple comparisons.

Discussion: Treatment-resistant schizophrenia patients exhibit impairment in speed of processing compared to treatment-responsive patients during the first episode, although this result is partly driven by other known factors of cognitive performance such as symptom severity, antipsychotic dose, and duration of untreated psychosis.

Speed of processing appears as an early deficit that could help the timely identification of patients presenting a disease trajectory towards treatment-resistance and facilitate the prompt implementation of known effective treatments such as clozapine. Our results are similar to previous studies with similar design (Kravariti et al., 2019; Millgate et al., 2023). This combined evidence highlights the existence of some cognitive differences at illness onset in TRESIST patients, which are in stark contrast to the severe impairment seen later in their illness (Millgate et al., 2022). It is unclear whether this deterioration is secondary to the high doses of antipsychotic medication these patients are exposed to, the environment changes associated to being severely unwell, or associated with a particularly damaging illness progression. Such deteriorating course sets aside TRESIST cases from TRESP.

The relatively small sample size emphasizes the need for larger and more diverse samples in future research to bolster the robustness of the findings. This consideration underscores the cautious interpretation of the results and emphasizes the preliminary nature of the current findings.

S126. AVOLITION IN EARLY PSYCHOSIS: INTERNAL EXPERIENCE AND RELATIONSHIPS WITH SOCIO-DEMOGRAPHIC FACTORS

Sylvia Romanowska*¹, Michael Best¹

¹*University of Toronto Scarborough*

Background: Negative symptoms, prominent in schizophrenia-spectrum disorders, are notably difficult to treat. Thus, a better understanding of mechanisms underlying this class of symptoms is needed. Avolition, or lack of motivation, has been hypothesized to be the primary negative symptom construct, with other domains representing phenotypic expressions of an overall loss of motivation. Avolition has the most direct effect on psychosocial functional decline and has been demonstrated to be the single most important domain to target for global treatment of negative symptoms. The present study examined internal factors related to avolition in the daily lives of young people with psychosis and its associations with goal-directed behaviour in order to uncover how motivation is translated into action. The specific aims were to investigate whether young people with psychosis differ from community controls (CCs) on, (a) quantity and diversity of activities of daily living, (b) intensity and variability of motivation for different types of goal-directed activities.

Methods: This study included one week of ecological momentary assessment (EMA) to assess engagement in goal-directed activities, the internal experience of avolition, and social networks, followed by a remote assessment of demographics, symptoms, and psychosocial functioning. Thirty-eight participants with early psychosis and 51 community controls between the ages of 18-36 were recruited. All participants were prompted to respond to 5 survey notifications per day for the one-week study period. Summary-level data was compared between psychosis and control groups using two-tailed t-tests. The effect size (Cohen's d) and confidence intervals (95%) were calculated to estimate and compare group differences.

Results: Participants with psychosis had reduced overall levels of motivation for current activities, as well as motivation to persist during activities, relative to CCs. However, participants with psychosis did not rate their current activities as being more effortful relative to CCs. Regarding motivation for specific goal-directed activities, participants with psychosis reported less motivation to engage in (or search for) work/school but had similar levels of motivation to engage in social and recreational activities. Participants with psychosis engaged in fewer different categories of goal-directed activities, more often endorsing engaging in "Nothing" or a passive activity and had smaller social networks relative to CCs.

Discussion: The present data demonstrate the importance of assessing motivation for different categories of goal-directed activities rather than approaching motivation as a unitary construct. Standard assessments of motivation overlook potentially intact areas of motivation, such as social motivation, which may be leveraged in treatment. Moreover, although motivation for certain pleasurable activities (e.g., hobbies; socialization) was intact, participants with psychosis still engaged in fewer different types of activities. Awareness that avolition itself may not be the source of lower activity engagement in young people with psychosis may prompt exploration into alternate roadblocks to engagement in such activities.

S127. THE RELATIONSHIP BETWEEN HDL CHOLESTEROL AND COGNITIVE RESERVE IN FIRST-EPISODE SCHIZOPHRENIA SPECTRUM DISORDERS: A TWO-STUDY ANALYSIS

Barbora Keřková*¹, Karolína Knížková¹, Mabel Rodriguez¹

¹*National Institute of Mental Health, Klecany, Czech Republic*

Background: Markers of cardiovascular disease risk can predict cognitive performance, leading to their consideration as components of the so-called cognitive reserve (CR), a hypothetical buffer against psychopathology. Initial evidence suggests that in first-episode schizophrenia spectrum disorders (FES), reduced levels of high-density lipoprotein (HDL) cholesterol may be uniquely related to poorer CR, with this relationship being particularly evident for certain CR proxies, such as years of education. We tested this suggestion in two samples of FES individuals, for whom CR was computed as either a conventional composite score of demographic and cognitive scale proxies, or comprehensively assessed within the Cognitive Reserve Assessment in Health (CRASH) interview.

Methods: Study 1 included a previously described sample of 137 FES individuals (66.4% males, aged 25.93 ± 6.47 years). CR was the regression component score of: years of education, premorbid IQ, and socioeconomic status. For Study 2, we recruited an additional 45 FES individuals (64.4% males, aged 28.53 ± 8.61 years) who completed the CRASH interview, generating a global CR score as well as educational, occupational, and leisure activity subscores. In both studies, we assessed Pearson's correlations between CR and fasting plasma HDL cholesterol levels. Considering the sex differences in HDL cholesterol's predictive value for cardiovascular risk, the data were also reanalyzed after stratifying by biological sex.

Results: Study 1 showed no significant correlations between HDL cholesterol and the CR composite or component scores ($r_s = -.056-.080$, p s GREATER THAN .05). In Study 2, we found a marginal association between HDL cholesterol and the global CR score ($r = .292$, $p = .051$), which reached significance for the educational subscore ($r = .369$, $p = .013$). After sex stratification, these relationships remained significant only in males.

Discussion: HDL cholesterol can correlate with CR and some of its components, provided that these are assessed comprehensively, rather than solely through demographic and cognitive scale proxies. In particular, the link between HDL cholesterol and educational CR might only transpire once educational attainment is considered together with other factors, such as parental education, school performance, or language ability. Additionally, the relationships between HDL cholesterol and CR might be influenced by biological sex. Overall, the specificity and weak-to-moderate strength of the observed relationships are likely to limit the usefulness of HDL cholesterol as a universal component of CR. Further research could investigate whether the effects of HDL cholesterol and CR on cognitive performance in FES are independent or interchangeable.

S128. ASSOCIATIONS BETWEEN ANTIPSYCHOTIC MEDICATION AND DAILY-LIFE EXPERIENCE OF PSYCHOLOGICAL ADVERSE EFFECTS AFTER FIRST EPISODE PSYCHOSIS - A HAMLETT ECOLOGICAL MOMENTARY ASSESSMENT STUDY

Matej Djordjevic^{*1}, Martijn Kikkert², Shiral Gangadin¹, Lieuwe de Haan³, Priscilla Oomen¹, Claudia Simons⁴, Machteld Marcelis⁵, Mark Nijland⁶, Marieke Begemann¹, Hannah Jongsma¹, Wim Veling¹

¹University Medical Center Groningen, ²Arkin Mental Health Care Amsterdam, ³Academic Medical Center, University of Amsterdam, ⁴GGzE, ⁵Maastricht University Medical Center, ⁶Rob Giel Onderzoekscentrum

Background: Pharmaceutical agents acting on dopamine-2 (D2) receptors (i.e., “antipsychotics”) are a cornerstone of the current treatment for psychotic disorders. However, their adverse effects (AE) can pose a significant subjective burden on patients, though evidence from people’s daily-life is scarce.

This study aimed

1.)To investigate the distribution of momentary indicators of psychological AE (i.e., blunted emotional experience, reduced initiative of social contact, avolition, tiredness and difficulty concentrating, and anhedonia) in 56 people in remission of First Episode Psychosis (FEP).

2.)To investigate whether type, dosage or estimated D2 receptor-occupancy of antipsychotic medication are associated with momentary psychological AE throughout the day.

Methods: The current Ecological Momentary Assessment (EMA) study was conducted in 56 people in remission of FEP, as part of the HAMLETT (Handling Antipsychotic Medication: Long-term Evaluation of Targeted Treatment) trial. At baseline, participants were prompted to report on momentary indicators of psychological AE 10x/day for eight consecutive days. Data on the type and dosage of antipsychotic medication were retrieved from the Dutch Foundation for Pharmaceutical Statistics. We grouped the medications based on D2 receptor-affinity, mechanism of action (D2 antagonism versus partial agonism) and H1 receptor antagonism. We performed stepwise multilevel mixed-effects linear regression analyses to investigate average cross-sectional associations between the type and dosage of antipsychotic medication as well as estimated D2 receptor-occupancy and momentary indicators of psychological AE throughout the day, i.e., overall as well as separately in the mornings (first 3 prompts per day), daytime (prompts 4-7) and evenings (last 3 prompts per day). All models were adjusted for fixed effects of age, gender, tobacco and cannabis use in the past month and symptom severity during FEP.

Results: Analyses of 3,005 questionnaires showed that a higher dosage of antipsychotic medication was associated with increased momentary variability in positive affect ($B = 0.23$ [95% CI: 0.04; 0.42]) and with increased levels of momentary anhedonia ($B = -1.12$ [95% CI: -1.99; -0.25]). Moreover, as compared with dopamine antagonists with high D2 affinity (K_i LESS THAN 20), the use of dopamine antagonists with low D2 affinity (K_i GREATER THAN 20) and the use of partial dopamine agonists were associated with decreased levels of anhedonia ($B = 10.68$ [95% CI: 1.23; 20.14] and $B = 13.40$ [95% CI: 2.95; 23.86], respectively). Estimated D2 receptor-occupancy was not associated with psychological AE overall, though higher D2 receptor-occupancy was associated with increased tiredness and difficulty concentrating in the mornings ($B = 0.29$ [95% CI: 0.10; 0.48]) and in the evenings ($B = 0.23$ [95% CI: 0.02; 0.44]).

Discussion: Type, dosage and D2 receptor-occupancy of antipsychotic medication can be associated with daily-life experience of anhedonia, positive affect variability as well as tiredness and difficulty concentrating. More research into underlying mechanisms and consequences for clinical treatment recommendations after FEP is warranted.

S129. LONGITUDINAL TRAJECTORIES OF PLASMA POLYUNSATURATED FATTY ACIDS AND ASSOCIATIONS WITH PSYCHOSIS-SPECTRUM OUTCOMES IN EARLY ADULTHOOD

David Mongan^{*1}, Benjamin Perry², Colm Healy³, Subash Raj Susai⁴, Stan Zammit⁵, Mary Cannon⁴, David Cotter⁴

¹Queen's University Belfast and Royal College of Surgeons in Ireland, ²University of Cambridge, ³Royal college of Surgeons in Ireland, ⁴Royal College of Surgeons in Ireland, ⁵University of Bristol

Background: There is evidence for associations between polyunsaturated fatty acids (PUFAs) such as docosahexaenoic acid (DHA) and psychosis risk, including Mendelian randomisation analyses that support a causal effect for long-chain PUFAs in reducing risk of schizophrenia. However, most population studies have used single PUFA measurements at one point in time, which may overlook dynamic patterns of temporal variability. Longitudinal plasma PUFA trajectories have not been previously characterised in the general population, and associations between such trajectories and psychosis-spectrum outcomes in early adulthood are thus unknown.

The aims of this study were: 1) To characterise, for the first time, longitudinal trajectories of plasma omega-6:omega-3 (n-6:n-3) PUFA ratio and DHA levels in a large general population sample; and 2) To evaluate associations between these trajectories and psychosis-spectrum outcomes in early adulthood.

We focused on n-6:n-3 ratio and DHA because these measures have been associated with psychosis risk in previous studies. We hypothesised that trajectories characterised by higher n-6:n-3 ratio and lower DHA levels would be associated with increased odds of psychosis-spectrum outcomes.

Methods: We examined a cohort of participants in the UK-based Avon Longitudinal Study of Parents and Children who completed psychiatric assessments at age 24 years (n=3635, of whom 2247 [61.8%] were female). Participants provided plasma samples at four timepoints when aged 7 (n=2268), 15 (n=1896), 17 (n=1933) and 24 years (n=3163). Plasma n-6:n-3 ratio and DHA levels (expressed as % total fatty acids) were measured using nuclear magnetic spectroscopy, then standardised by sex.

We examined five psychosis-spectrum outcomes at age 24 years. Presence/absence of psychotic experiences (PEs), At-Risk Mental State status and psychotic disorder were assessed using the Psychosis-Like Symptoms interview, as was the total number of PEs (range 0 to 11). Negative symptoms score (range 0 to 10) was measured using the Community Assessment of Psychic Experiences.

Curvilinear growth mixture modelling was used to derive longitudinal trajectories of plasma n-6:n-3 ratio and DHA levels. Models were adjusted contemporaneously for body mass index at each timepoint. Associations between trajectory membership and binary outcomes (any PEs, At-Risk Mental State status and psychotic disorder), number of PEs and negative symptoms score were evaluated using logistic, negative binomial and linear regression respectively, before and after adjusting for sex, ethnicity, parental socioeconomic class, smoking and alcohol use. Multiple imputation using Bayesian analysis was used to impute missing exposure and covariate data across 10 imputed datasets.

Results: At 24 years, 116 (3.2%) met criteria for PEs; 23 (0.6%) for At Risk Mental State; and 46 (1.3%) for psychotic disorder.

A three-trajectory solution was optimal for n-6:n-3 ratio (stable average, n=3282 [90.3%]; slightly above average, n=61 [1.7%]; and persistently high, n=292 [8.0%]) and DHA (stable average, n=2739 [75.4%]; persistently high, n=245 [6.7%]; and persistently low, n=651 [17.9%]).

Relative to stable average, the persistently high plasma n-6:n-3 ratio and persistently low DHA trajectories were associated with increased odds of PEs and psychotic disorder in unadjusted analyses, but these associations attenuated on adjustment for covariates. There was little evidence for associations with At Risk Mental State status. Conversely, the persistently high n-6:n-3 ratio trajectory was associated with increased number of PEs (adjusted β 0.41, 95% confidence interval [CI] 0.05 - 0.78, $p=0.026$) and negative symptoms score (adjusted β 0.43, 95% CI 0.14 - 0.72, $p=0.004$). Similarly, the persistently low DHA trajectory was associated with increased number of PEs (adjusted β 0.45, 95%CI 0.14 - 0.76, $p=0.004$) and negative symptoms score (adjusted β 0.35, 95%CI 0.12 - 0.58, $p=0.003$).

Discussion: In this first characterisation of longitudinal plasma PUFA trajectories in a large general population cohort, we found evidence for three broad trajectories of n-6:n-3 ratio and DHA levels across childhood, adolescence and early adulthood. Trajectories characterised by persistently high plasma n-6:n-3 ratio and persistently low plasma DHA levels were associated with psychosis-spectrum outcomes in early adulthood, and in the case of number of PEs and negative symptoms, not fully explained by included covariates. Strengths of this analysis include the use of objective plasma PUFA markers in a large, well-characterised cohort with multiple repeated measures over time. However, the relatively small number of individuals who met criteria for At Risk Mental State and psychotic disorder in this general population study may have limited statistical power. Residual confounding is possible, for example, due to other dietary factors. Compared to erythrocyte membrane measures, plasma PUFA levels reflect a shorter timeframe of 1-2 weeks due to higher metabolic turnover. Despite these limitations, these novel findings suggest that optimisation of PUFA status during development warrants further investigation in relation to psychosis-spectrum symptoms in early adulthood.

S130. TARGETING STIGMA IN FIRST EPISODE PSYCHOSIS: SELF-STIGMA AND CORRELATES

Evan Myers^{*1}, Daniel R. Samost², Sheharyar Hussain², Bethany L. Leonhardt³, Philip T. Yanos²

¹Indiana University - Purdue University Indianapolis, ²John Jay College Of Criminal Justice, City University of New York, ³Department of Psychiatry, Indiana University School of Medicine

Background: Self-stigma affects many people with severe mental illness. Research has shown that self-stigma is negatively linked to treatment engagement and both objective and subjective aspects of recovery in adults. Less is known about self-stigma in youth experiencing first episode psychosis. Adolescence and young adulthood are crucial periods of identity formation, which the onset of psychosis can disrupt, and therefore critical times to address self-stigma. In this study, we aimed to identify correlates of self-stigma in youth with psychosis. These correlates may be important to consider in interventions targeting self-stigma in this population and more generally in clinical care.

Methods: Participants were recruited from a first episode psychosis clinic as part of the development of an exploratory group-based intervention to address self-stigma (NIMH grant: #R34MH122500). Prior to enrollment, potential participants completed a screening of self-stigma (Internalized Stigma of Mental Illness Inventory) and were included in the study if they showed elevated self-stigma. Enrolled participants then completed measures of self-esteem

(Rosenberg Self-Esteem Scale), hopelessness (Beck Hopelessness Scale), recovery style (Recovery Style Questionnaire), and symptoms (Positive and Negative Syndrome Scale).

Results: Data collection is ongoing (target $n = 40$), and initial data ($n = 6$) show that self-stigma is positively related to an integrated recovery style ($r = .81$). Results also show self-stigma is negatively related to self-esteem ($r = -.89$) but not hopelessness ($r = .51$). Subscale analyses reveal that recovery style is specifically related to perceived discrimination ($r = .84$) and self-esteem is inversely related to social withdrawal ($r = -.97$). Correlations between self-stigma and symptom dimensions were not significant.

Discussion: Results provide preliminary evidence that among care-seeking youth with first episode psychosis, self-stigma is related to recovery style. That is, people who tend to “seal over” have less self-stigma. Another preliminary finding is that self-stigma is related to self-esteem but not hope. This may suggest that self-stigma may not immediately impact hope, and that youth with psychosis show resilience in this respect. Therefore, it may be important to consider youths’ recovery style when delivering self-stigma interventions and provide opportunities for them to discuss how stigma relates to self-esteem.

S131. INDIVIDUAL DATA QUANTITY HAS A STRONG IMPACT ON THE PREDICTION OF PSYCHOSIS DISTRESS FROM FUNCTION CONNECTIVITY IN THE ABCD STUDY

Alexis Porter^{*1}, Katherine Damme¹, Vijay Mittal¹, Caterina Gratton²

¹Northwestern University, ²Florida State University

Background: Psychosis spectrum disorders typically manifest in adulthood, following prodromal periods in adolescence (Walker et al., 2007). The severity of psychotic-like experiences (PLE) during adolescence may predict the onset of psychosis (Cowan and Mittal, 2020). This developmental phase provides a unique opportunity to pinpoint neural biomarkers and mechanisms associated with emerging PLEs. Adolescence is characterized by the dynamic formation of large-scale functional networks, and machine learning techniques can detect subtle disruptions in these networks that are linked to adult symptoms and deficits. Recent methodological advancements in accounting for individual differences in functional network organization have significantly improved model predictions in clinical populations (Fan et al., 2021). In our study, we aimed to improve machine learning classification through two methods. First, we assessed whether constructing functional connectivity (FC) using more individual-level data (35-50 minutes) enhanced accuracy in predicting symptom course compared to FC matrices built with less data (10-20 minutes). Next, we employed a parcellation method designed to consider individual differences in brain network topography (Kong et al., 2021) and compared its performance with parcellation methods relying on group average approaches. Collectively, these approaches may enable improved precision in identification of relevant mechanisms for emerging PLEs.

Methods: We analyzed a subset of the ABCD Study ($N=1,320$). In the ABCD, participants underwent up to 50 minutes of task and resting state scans during the initial visit, along with annual behavioral assessments of distress related to PLEs. Participants were included in the study if they had at least 35 minutes of combined time series data after standard motion scrubbing procedures (Power et al., 2014). In this study, we investigated whether a machine learning model based on baseline fMRI data could distinguish between high and low PLE distress scores across five different points in time. We developed models using FC derived from task or resting state data (10 minutes) and compared performance to models constructed

using a concatenation of all task and resting state data (35-50 minutes). To assess the impact of parcellation approaches on identifying individual differences in brain networks, we compared FC derived from individualized parcels (Kong et al., 2021) to standard group atlases.

Results: 30-minute models exhibited significantly higher performance at predicting PLE distress than 10-minute models. Through permutation testing, we determined that models based on extended amounts of data could predict PLE distress above chance from the initial year of collection up to two years later. Additionally, we observed that models using individualized parcels showed a small but significant improvement in performance compared to the other three group atlas methods for predicting the initial year of psychosis distress.

Discussion: These findings suggest that emerging differences in FC relate to PLE distress. However, best performance was seen when larger amounts of data were used for FC estimation, likely due to significant improvements in the underlying reliability of FC estimates (Gordon et al., 2017). The use of an individualized parcellation approach also significantly improves the prediction of psychosis distress within the initial year of data collection, but to a smaller degree. This work underscores the importance of collecting larger amounts of data and deep phenotyping at the individual level to extract meaningful biomarkers and mechanisms for early identification of psychosis risk and relevant treatment targets for early intervention.

S132. TRAJECTORIES OF SUICIDAL BEHAVIOR AND THEIR CLINICAL CORRELATES IN THE EARLY PHASES OF SCHIZOPHRENIA SPECTRUM DISORDERS

Amalie Solberg*¹, Akiah Ottesen², Elisabeth Ann Barrett³, Ingrid Kristiansen⁴, Kristin Lie Romm³, Erlend Mork³, Ping Qin⁵, Ingrid Melle⁶

¹*Oslo University Hospital - Psychosis Research Unit*, ²*Norwegian Centre for Violence and Traumatic Stress Studies*, ³*Early Intervention in Psychosis Advisory Unit for South East Norway, Division of Mental Health and Addiction, Oslo University Hospital*, ⁴*Oslo University Hospital - Psychosis Research unit*, ⁵*Natinal Centre for Suicide Research and Prevention*, ⁶*University of Oslo, Norwegian Centre for Mental Disorders Research*

Background: The risk of suicide in schizophrenia spectrum disorders (SSD) is highest in the first treatment years; suicidal behaviors (SB) are also often the trigger of the first treatment contact, and some die by suicide before treatment is initiated. Still, the trajectories of SB have only been investigated from the first treatment contact onwards while many risk factors for SB in SSD (e.g. earlier suicidal attempts, comorbid depression, substance use, low self-esteem, and experience of childhood trauma) may be present before the onset of psychosis. A better understanding of the development of SB and risk factors for early SB trajectories can help to understand the early high risk of SB and aid early interventions. Our aim is to investigate i) different trajectories of suicidal ideation and behavior from the premorbid period until first treatment, and ii) the relationship between early risk factors for SB and different SB trajectories.

Methods: A total of 223 patients with DSM-IV first-episode SSDs were recruited close to treatment start from departments in the Oslo areas. They underwent a structured and comprehensive clinical examination including the Birchwood Insight Scale (subscales awareness of illness and need for treatment), the Childhood Trauma Questionnaire, and the Rosenberg Self-Esteem Scale. We collected retrospective reports of the number of depressive episodes, weeks of untreated psychosis, and the severity of SB in three time periods: Premorbid

(before the onset of psychosis), post-onset (in the period of untreated psychosis), and at/after treatment start. We used K-mean cluster analyses to identify different trajectories of SB over these time points. SB severity was assessed as 0= no SB, 1=suicidal ideation, 2=suicide plans, and 3=suicide attempts (1=mild SB, 2 or 3=severe SB). The highest score for the period was used in the analyses.

Results: We identified four trajectories of SB. Group A (50,2%), consisted of patients with no SB, SB only premorbid or mild SB in untreated psychosis. Group B (23,8%), had mild persistent SB throughout or initially mild but increasing towards the start of treatment. Group C (14,3%), had severe SB during the period of untreated psychosis. Group D (11,7%), had severe SB premorbid and in one or both of the post-onset periods. Compared to group A, group C had statistically significantly more depressive episodes, longer duration of untreated psychosis (DUP), lower self-esteem, and higher awareness of illness; group B had significantly higher awareness of illness and insight into the need for treatment; group D had significantly higher exposure to emotional abuse, more depressive episodes, lower self-esteem, higher awareness of illness, and insight into the need for treatment. There was also a statistically significant difference between groups B and C, with higher DUP and lower insight into the need for treatment in group C. Group B reported significantly lower exposure to emotional abuse than group D.

Discussion: This study shows significant differences in clinical characteristics between different trajectories of SB in SSD. All groups reported higher awareness of illness than group A. The groups with more severe SB (post-onset and severe persistent) had an accumulation of risk factors but with significant differences. Longer DUP was only associated with the post-onset group C, indicating a role of psychotic symptoms for SB. The severe persistent group D reported more exposure to emotional abuse than all the other groups, underlining the role of childhood trauma in the severity of SB and the development of SB before psychosis onset.

S133. EARLY LIFE STRESS AND FUNCTIONAL CONNECTIVITY IN ANTIPSYCHOTIC-NAÏVE FIRST EPISODE PSYCHOSIS PATIENTS

Hillary Patton*¹, Jose Maximo¹, Adrienne Lahti¹

¹*The University of Alabama at Birmingham*

Background: Childhood trauma (CT) occurs at a much higher frequency in psychosis spectrum disorders as compared to the general population. Evidence suggests that CT is a risk factor for psychosis spectrum disorders but the neural mechanisms underlying this association remains unclear. Previous work has identified associations between CT and altered fronto-limbic functional connectivity in psychosis patients, but the research is limited. The objective of this study is to examine the relationship between childhood trauma and functional connectivity in a large sample of antipsychotic-naïve patients with first episode psychosis (FEP).

Methods: Resting state fMRI data from 105 FEP patients and 123 healthy controls (HC) were used. Our regions of interest included bilateral hippocampus, amygdala, and ventromedial prefrontal cortex (vmPFC). Childhood Trauma Questionnaire (CTQ) total and subscale scores (physical and emotional abuse/neglect and sexual abuse) were correlated with the resting state functional connectivity (rsFC) data.

Results: Compared to HC, patients had significantly higher CTQ total and subscale scores and significantly reduced rsFC in L/R hippocampus – vmPFC (p LESS THAN .05) and L/R amygdala –vmPFC (p LESS THAN .05). Partial correlation analyses accounting for age, sex,

and framewise displacement indicated that higher CTQ sexual abuse subscale scores in FEP patients were associated with increased left amygdala—vmPFC rsFC ($r(59) = .27$, $p < .05$) and higher CTQ emotional neglect subscale scores in FEP patients were also associated with increased left hippocampus—vmPFC rsFC ($r(59) = .27$, $p < .05$). Follow-up analysis showed a significant interaction effect of group (FEP and HC) and CTQ score (sexual abuse subscale) on left amygdala—vmPFC rsFC ($\beta = .014$, $p < .05$). Simple slopes analyses showed that higher CTQ sexual abuse subscale scores were associated with increased rsFC in FEP patients ($\beta = .56$, $p < .001$) but decreased rsFC in healthy controls ($\beta = -.56$, $p < .001$).

Discussion: The findings show evidence that the impact of childhood trauma on brain mechanism patterns differ significantly between the general population and individuals with psychosis spectrum disorders. The results also provide support for the long-term differential impact of trauma subtypes on the human brain. Increased connectivity in FEP individuals in response to greater childhood trauma may reflect a compensatory mechanism or neural adaptation in response to early life stress. Overall, the results contribute to the understanding of the neural mechanisms underlying the association between childhood trauma and psychosis spectrum disorders.

S134. COST AND UTILIZATION OF EARLY PSYCHOSIS SERVICES IN CALIFORNIA

Sophie McMullen^{*1}, Merissa Kado-Walton², Heather Garman³, Yi Zhang⁴, Amanda McNamara², Valerie Tryon⁵, Andrew J. Padovani⁶, Sabrina Lourerio⁶, Joy Melnikow⁶, Tara A. Niendam⁷, Todd P. Gilmer², Rachel Loewy⁸

¹University of California - San Francisco, ²Herbert Wertheim School of Public Health and Human Longevity Science, University of California San Diego, ³Department of Psychiatry, Weill Institute for Neuroscience, University of California San Francisco, ⁴University of California Davis, ⁵Department of Psychiatry, University of California, Davis, School of Medicine, ⁶Center for Healthcare Policy and Research, University of California-Davis, ⁷Department of Psychiatry and Behavioral Sciences, University of California, Davis, School of Medicine, ⁸Department of Psychiatry, Weill Institute for Neurosciences, University of California - San Francisco

Background: Although untreated mental illness can be devastating, an individual typically does not qualify for treatment until their symptoms are severe enough to adversely impact their life. In California, specialized early psychosis (EP) programs targeting youth were implemented to attempt to reduce the negative outcomes related to untreated mental illness. Prior research suggests that EP programs are associated with reduced hospitalization costs, emergency department visits, and improvements in quality of life. However, such research is not specific to California and does not consider potential impacts on the counties where the programs are implemented.

Methods: Using administrative data from an electronic health record, we identified youth aged 12-26 who (1) were enrolled in an EP program from January 2017 to July 2022 and (2) received a first diagnosis of psychosis within one year prior to enrollment. We identified a comparison group (CG) of youth with a first diagnosis of psychosis who received at least one outpatient service during the study period, also within one year of receiving their diagnosis. We calculated

the annual number of mental health outpatient visits and inpatient admissions in the one and two years prior, as well as one and two years post-first diagnosis of psychosis. We used regression analysis to examine the relationship between the number of outpatient visits and the probability of having an inpatient admission, controlling for age, gender, and location of initial diagnosis.

Results: We identified 171 youth who enrolled in EP programs and 2,031 CG youth with a first episode of psychosis who received usual care. The mean age was 21 (SD=3.3) and 62% were

male. EP youth were most likely to receive their first diagnosis of psychosis in an outpatient clinic setting: 49% vs. 17% of CG youth. CG youth were most likely to receive their first diagnosis in an emergency or crisis stabilization unit: 41% vs 15% for EP youth.

We found that 2 years prior to first diagnosis, youth averaged 1.8 outpatient visits per year and the probability of inpatient admission was 1.4%; there was no statistically significant difference between groups. In the year prior to diagnosis, the number of outpatient services increased to 6.8 among youth who eventually enrolled in EP programs compared to 1.3 visits among CG youth in usual care (P LESS THAN .001). The probability of inpatient admission is also higher among youth who eventually enrolled in an EP program: 17.9% vs. 4.4%. In the year following diagnosis, the number of outpatient services increased to 61.3 among EP

youth compared to 19.9 among CG youth (P LESS THAN .001); there was no significant difference in inpatient admission. In the second year after diagnosis, both the number of outpatient services

(38.7 vs 11.1, P LESS THAN .001) and the probability of inpatient admission (20.2 vs. 12.7, P LESS THAN .001) remained higher among EP youth.

Discussion: Youth who enroll in EP programs are more likely than youth in usual care to receive their first diagnosis of psychosis in an outpatient program. They also receive more outpatient and inpatient care in the year prior to enrolling in the program, along with significantly more

outpatient care in the first and second years after enrollment. Additional work should examine whether referrals to EP should be increased from emergency settings.

S135. NAVIGATING ADVERSITY: EXAMINING THE INTERPLAY OF ETHNORACIAL DISCRIMINATION, FAMILY SUPPORT, AND PSYCHOTIC SYMPTOM SEVERITY IN LATINXS WITH FIRST EPISODE PSYCHOSIS

Vanessa Calderon*¹, Mirian Vasquez², Carmen Uribe³, Carrie Bearden⁴, Steven Lopez⁵

¹*Semel Institute for Neuroscience and Human Behavior at UCLA*, ²*Children's Hospital Los Angeles*, ³*California State University, San Bernardino*, ⁴*University of California, Los Angeles*, ⁵*University of Southern California*

Background: Discrimination is associated with an increased risk for psychotic symptoms (Bardol et al., 2020). However, limited prior research has focused on the effects of discrimination among clinical populations with psychotic illness. Even less is known about sociocultural protective factors, particularly among U.S. Latinxs with psychotic illness, a population vulnerable to diagnostic and service use disparities (Schwartz and Blankenship,

2014; van der Ven et al., 2020). The present study assessed the relationship between perceived ethnic/racial discrimination and psychotic symptom severity among U.S. Latinxs with first episode psychosis (FEP), along with the moderating effect of family support.

Methods: Individuals with a psychotic illness diagnosis were recruited from an inpatient or outpatient public mental health center as part of a larger study evaluating a psychosis communication campaign (Lopez et al., 2022). They completed a modified version of the Everyday Discrimination Scale (Williams et al., 1997), including 9-items inquiring about the frequency of different types of discriminatory experiences. Participants were also asked to indicate the main reason(s) for those experiences via a checklist of potential attributions, from which a dichotomous score capturing endorsement of racial and/or ancestry-based discrimination was created (i.e., ethnic/racial discrimination). Clinical interviewers administered the Positive and Negative Symptom Scale (Kay et al., 1987) 30-item measure of psychotic symptom severity. Participants completed a qualitative interview from which family support quality was coded on a 4-point scale using concept-driven methods (Miles et al., 2013). Four independent raters achieved good reliability (ICCs ranging from .77 to .89). Measures were administered in English or Spanish depending on participant preference.

Results: Our analysis included 43 participants (mean age 23.47 years; SD = 6.60), with 11.87 (SD = 1.92) years of education. A majority identified as male (69.8%), Latinx (92.3%), U.S.-born (65.1%) and primarily English-speaking (79.1%). Participants reported an average total PANSS score of 2.77 (SD = 0.64), on a 7-point scale. The mean discrimination frequency score was 1.52 (SD = 1.00) on a 6-point scale. Over half (61.9%) endorsed ethnic/racial discrimination. Discrimination frequency was not associated with PANSS symptom severity, $r(43) = .14, p = 0.37$.

A linear regression model with total PANSS symptoms as the dependent variable was statistically significant [$F(1, 33) = 5.27, p < .05$], with significant main effects of ethnic/racial discrimination [$b = 50.21, t(33) = 3.05, p < .05$] and significant interaction effects (discrimination X support quality) $b = -23.69, t(33) = -2.80, p < .05$. All effects remained consistent after adding covariates (i.e., age, sex, education, medication adherence) to the model.

Discussion: More than half of Latinxs with FEP (62%) report ethnic/racial discrimination “a few times per year” or more often. Furthermore, ethnic/racial discrimination endorsement, but not frequency of discrimination, is associated with greater psychotic symptom severity among a clinical U.S. Latinx population. As hypothesized, family support buffers the relationship between ethnic/racial discrimination and psychotic symptoms among those who endorse discrimination; however, an opposite effect was found for those who do not endorse discrimination, such that greater support quality is associated with greater symptom severity. These findings suggest that family support may be protective in the context of ethnic/racial stressors (i.e., discrimination); however outside of the presence of these sociocultural stressors, an excessive amount of family support may be indicative of high emotional overinvolvement, and low caregiver perceived efficacy, which is a risk factor for relapse among Latinxs with psychotic illness (Breitborde et al., 2013). Findings are limited by cross-sectional data; future studies should assess these relationships longitudinally. Clinical and research practice should inquire about perceived ethnic/racial discrimination among marginalized populations with psychotic illness and incorporate family support interventions to cope with social stressors.

S136. SOCIODEMOGRAPHIC AND CLINICAL CORRELATES OF HALLUCINATIONS IN PATIENTS ENTERING AN EARLY INTERVENTION PROGRAM FOR FIRST EPISODE PSYCHOSIS

Samantha Aversa*¹, Joseph Ghanem², Gil Grunfeld², Ann-Catherine Lemonde², Ashok Malla², Srividya Iyer³, Ridha Joobar², Martin Lepage², Jai Shah²

¹Douglas Mental Health Research Institute, ²McGill University, ³McGill University and Douglas Hospital Research Institute

Background: Hallucinations are a core feature of psychosis, and their severity during the acute phase of illness is associated with a range of poor outcomes. Various clinical and sociodemographic factors may predict hallucinations and other positive psychotic symptoms in first episode psychosis (FEP). Despite this, the precise factors associated with hallucinations at first presentation to an early intervention service have not been extensively researched.

Methods: Through detailed interviews and chart reviews, we investigated sociodemographic and clinical predictors in 636 minimally-medicated patients who entered PEPP-Montréal, an early intervention service for FEP, between 2003-2018. Hallucinations were measured using the Scale for the Assessment of Positive Symptoms (SAPS), while negative symptoms were assessed using the Scale for the Assessment of Negative Symptoms. Depressive symptoms were evaluated through the Calgary Depression Scale for Schizophrenia, and anxiety symptoms via the Hamilton Rating Scale for Anxiety. Groups were categorized according to the presence or absence of clinically significant hallucinations, determined by the SAPS global hallucination rating (LESS THAN 3 considered not clinically significant; ≥ 3 regarded as clinically significant). These groups were then compared on relevant sociodemographic and clinical variables using t-tests or nonparametric tests as appropriate, and significant variables were later entered in a logistic regression model.

Results: A majority (n = 381, 59.9%) of the sample presented with clinically significant hallucinations at program entry. These patients had an earlier age at onset, fewer years of education, and a higher severity of delusions, depression and negative symptoms than those without clinical-level hallucinations.

Discussion: These results suggest that individuals with clinically significant hallucinations at admission tend to be younger and have a greater overall symptom burden. This, along with dynamic changes in the prevalence of hallucinations during the first few months of treatment, makes it especially important to monitor this symptom alongside delusions, depression and negative symptoms in order to identify who might benefit from differential targeted interventions. The implications of these findings for early intervention and person-centered care are discussed.

S137. OPEN BOARD

S138. DO NEUROCOGNITION OR SOCIAL COGNITION PREDICT NEED FOR PSYCHIATRIC CARE IN THE YEARS FOLLOWING FIRST PSYCHOTIC EPISODE?

Maija Lindgren*¹, Sebastian Therman¹, Saskia Stigzelius¹, Marjut Grainger¹, Jaana Suvisaari¹

¹Finnish Institute for Health and Welfare

Background: More severe cognitive deficits at psychotic illness onset are linked with a more severe clinical picture and poorer outcomes. Social cognition affects daily functioning and has found to have even larger effects on outcome than neurocognition. Whereas there usually seems to be no further decline in neurocognitive performance after the illness onset, few longitudinal studies have investigated the trajectory of development of social cognition. We therefore wanted to investigate whether social cognitive performance at the time of entering treatment changed during the following years. Secondly, the predictive value of baseline neurocognition and social cognition were studied in terms of intensity of care during the following years.

Methods: A first-episode psychosis (FEP) group, consisting of adults making their first psychiatric treatment contact for psychosis (n=66), as well as matched controls (n=62), were recruited to the Helsinki Early Psychosis Study. Cognitive assessment, including the Hinting Task to measure the theory of mind domain of social cognition, was administered at study entry, and a subgroup (17 FEP, 23 controls) was tested again 6–11 years later (mean follow-up time 9 years). We investigated whether social cognition performance changed between the assessments. Secondly, using data from the Care Register for Health Care, we investigated whether baseline composite neurocognitive factor and social cognition factor predicted 5-year outcomes of outpatient psychiatry visits and psychiatric hospital treatments (n=65 FEP, of which 39 males) before and after controlling for baseline clinical symptoms (BPRS positive and negative symptom sums).

Results: In the FEP group, the Hinting Task raw score was 16.0 ± 3.0 at baseline and 16.0 ± 1.8 at follow-up assessment. Among the controls, the score also remained from 17.4 ± 1.6 to 16.9 ± 1.6 . Spearman correlations between the task raw scores at the two timepoints was .55 in FEP ($p=.022$). The mean number of outpatient visits during the 5-year register follow-up was 98.9 ± 61.3 , with females having more visits than males. On average there were 2.1 ± 2.2 hospital stays and 87.9 ± 204.3 hospital days during the follow-up. None of the register outcomes were predicted by baseline social cognition. Poorer neurocognitive functioning at baseline correlated with higher number of hospitalizations ($r -0.42$, p LESS THAN .001) and number of hospital days ($r -0.31$, $p=.011$) during follow-up. Number of outpatient visit was not associated with baseline cognition. In regression models, controlling for sociodemographic variables and baseline symptom levels, baseline neurocognition was no longer a significant predictor of the clinical outcomes.

Discussion: Hinting Task performance remained unchanged after 9 years, suggesting neither progression nor recovery of social cognitive deficits in the course of the illness at group level. The sex differences and the state/trait nature of social cognition in terms of symptom fluctuations will be more closely inspected.

Social cognition assessment at the beginning of treatment did not provide information on the clinical outcome in FEP. Baseline neurocognitive deficits were associated with hospitalizations during the following five years, indicating more severe symptomatology and possible relapses. However, cognitive testing at baseline did not provide information on the outcomes independently of baseline clinical symptoms. These results add to our knowledge on neurocognitive and social cognitive deficits at illness onset, seen as prognostic markers. The implications to targeting early cognitive deficiencies with interventions will be discussed.

S139. TREATMENT FOR INDIVIDUALS WITH EARLY PSYCHOSIS AND COMORBID CANNABIS USE: A SYSTEMATIC REVIEW OF LITERATURE

Christina Loisel*¹, Carlos Rocha¹, Sarah Btsh¹, Tamare Piersant, PsyD¹

¹*Albizu University*

Background: Cannabis is one of the most commonly used substances for individuals with psychosis (Barrowclough et al., 2014; Johnson et al., 2016). While there seems to be a link between psychosis and cannabis use, there is very little information that exists on the interventions used to help these individuals (Petros et al., 2022; Van der Steur et al., 2020).

Methods: The present systematic review investigated the effects of individual, group, and combined psychotherapy in the treatment of those with early psychosis and comorbid cannabis use. Published studies were identified through a search of electronic databases. Inclusion criteria included peer-reviewed articles since 2010. Studies were considered if they provided data on individuals with early psychosis and the outcome of treatment. Exclusion criteria were articles about individuals younger than adults, those with comorbid psychiatric diagnoses, and articles mainly focusing on either pharmacological treatment or genetics.

Results: Early intervention services are critically important for individuals who have comorbid cannabis use and early psychosis. Interventions include motivational interviewing (MI), cannabis use cessation, cognitive-behavioral therapy (CBT), family therapy, harm reduction, and contingency management (CM) (Kelly et al., 2012). However, there has been a reduction in treatment-seeking rates. Services are impacted by the individuals' frequency of use, stage of change, amount of cannabis used, age of onset of use, and overall history of use (González-Ortega, et al., 2022). Individual psychotherapy based on cannabis cessation has been found to reduce cannabis use severity (Bucci et al., 2010; González-Ortega, et al., 2022). Group psychotherapy did not have the same desired effect that individual psychotherapy had (Madigan et al., 2012). Combining interventions to account for these variables is the most effective for the comorbidity of cannabis use and psychosis (Kelly et al., 2012).

Discussion: The use of cannabis after the onset of early psychosis can have negative consequences, which include higher relapse rates, more prolonged hospital admissions, and increased severity of symptoms (Fusar-Poli et al., 2017; Hammond et al., 2020; Leeson et al., 2012). While there is room for improvement, these findings indicate that a combination of psychotherapies and techniques is essential for the cessation of cannabis use. More research is needed to understand better the interventions that work for these individuals as well as the link between cannabis and psychosis.

S140. VALIDATING COGNITIVE SCREENING FOR FIRST-EPISODE PSYCHOSIS: THE “COGSCREEN” PROTOCOL

Kelly Allott*¹, Alexandra Stainton¹, Shayden Bryce¹, Isabel Zbukvic¹

¹*Orygen and Centre for Youth Mental Health, The University of Melbourne*

Background: Cognitive impairment is common for young people experiencing First-Episode Psychosis (FEP) and can impact everyday functioning. However, clinicians currently have no fast and effective method for determining which of their patients are experiencing cognitive impairments. The “CogScreen” study is a hybrid effectiveness-implementation study which aims to 1) validate a cognitive screening tool for this population from two leading candidates (Screen for Cognitive Impairment in Psychiatry, “SCIP”; and Montreal Cognitive Assessment; “MoCA”) and 2) conduct a comprehensive implementation evaluation to explore the

acceptability, feasibility, barriers and facilitators of adopting cognitive screening into routine treatment for FEP.

Methods: First, CogScreen will use gold-standard classification accuracy methodology to assess the accuracy of the SCIP and MoCA, relative to comprehensive cognitive assessment. Participants will be 350 young people (age 12-25) being treated for FEP across 7 Australian early psychosis services, who will complete a cross-sectional assessment including the cognitive tests and measures of psychopathology and functioning. A subset of participants (n=120) will repeat the screening measures after two weeks to examine test-retest reliability. Second, in the implementation evaluation we will gather both quantitative and qualitative data from key stakeholder groups who are engaged in early psychosis services (young people with FEP, carers or parents, clinicians or service leaders).

Results: Ethics approval has been received and CogScreen started participant recruitment in August 2023. Recruitment will continue for the next 2 years.

Discussion: At the end of this study, we will provide early psychosis services with a valid cognitive screening tool in addition to both general, and local, guidelines for implementing cognitive screening into their routine care for FEP.

S141. TOPUS - A QUASI EXPERIMENTAL TRIAL TO REDUCE DUP

Nikolai Albert^{*1}, Rie Louise Dyhr¹, Stephen Austin², Lene Halling Hastrup³, Carsten Hjorthøj⁴, Marlene Buch Pedersen⁵, Merete Nordentoft⁶, Vinod Srihari⁷, Wenche ten Velden Hegelstad⁸, Erik Simonsen⁹

¹*Copenhagen Research Center for Mental Health – CORE*, ²*Psychiatric Research Unit, Region Zealand, Denmark*, ³*Psychiatric Research Unit, Region Zealand, Slagelse, Denmark*, ⁴*Copenhagen University Hospital, Mental Health Center Copenhagen*, ⁵*Early Psychosis Intervention Centre, Psychiatry East, Region Zealand, Denmark*, ⁶*Mental Health Centre Copenhagen*, ⁷*Yale University*, ⁸*TIPS – Centre for Clinical Research in Psychosis, Stavanger University Hospital*, ⁹*Psychiatric Research Unit, Zealand Region, Psychiatry East, Denmark*

Background: The association between duration of untreated psychosis (DUP) and later outcome in schizophrenia is well established and have been investigated in several meta-analyses. The latest meta-analysis (Howes et. a 2021) found DUP to be associated with a range of psychopathological and functional outcomes. The nature of the association is still not understood. The TIPS study has found evidence of a causal relationship between DUP and functional outcomes up to ten years after initiation of treatment, but else the evidence of causality is scarce. Further, even if there is no causal relationship the suffering of patients with psychotic symptoms makes it an imperative in itself to reduce the DUP, but there are few trials who successfully have been able to accomplish this.

Methods: Region Zealand in Denmark has implemented an early detection of psychosis team. The team uses widespread information campaigns and consists of specifically trained nurses and clinical psychologist, who responds to a hotline that is open to patients, relatives, teachers etc, without the need of a referral from a GP or other professionals. The team do not provide treatment, but can makes referrals, and thereby quickly identifying patients suffering from psychosis and can reduce the time to initiation of treatment. No other region in Denmark has implemented a similar model. The TOPUS study is designed as a quasi-experimental study including 125 patients for Region Zealand (the intervention region) and 125 patients from the Capital Region (the control region) with non-affective psychosis. Patients will be included from

Early Intervention Services in both regions. The DUP of the participants will be assessed using the Nottingham Onset Schedule (NOS). Duration of untreated psychosis at baseline is a continuous variable which in all prior studies have been found to have a skewed distribution. The variable will be logarithmically transformed and analyzed using linear regression with known confounders included as covariates. After inclusion in the study participants will be reassessed at 3, 9 and 20 months after the baseline assessment.

Results: Inclusion will begin early 2024 and will be completed in 2026. The trial aims to investigate whether a widespread information campaign in combination with a well-established early detection team is effective in reducing the DUP, and if so, if this reduction is associated with the clinical and functional outcomes. When concluded the trial will provide new insights into the relationship between DUP and outcome.

Discussion: The presentation will give an overview of the trial and discuss limitations and strengths.

S142. LONGITUDINAL EVALUATION ON NEGATIVE SYMPTOMS IN PEOPLE AT CLINICAL HIGH RISK FOR PSYCHOSIS: A 2-YEAR FOLLOW-UP INVESTIGATION IN A REAL-WORLD CLINICAL SETTING.

Lorenzo Pelizza*¹, Alessandro Di Lisi¹, Emanuela Leuci², Emanuela Quattrone², Marco Menchetti¹

¹Bologna University, ²AUSL di Parma

Background: Negative Symptoms (NS) severely affect real-world functioning in young individuals at Clinical High Risk for Psychosis (CHR-P), already before their first access to specialized mental healthcare services. However, longitudinal studies on beneficial effects of specialized intervention on NS in CHR-P people is still poor and inconclusive, especially in real-world clinical settings. The aims of the present investigation were: (1) to evaluate longitudinal stability of NS in young CHR-P individuals treated within a specialized “Early Intervention in Psychosis” (EIP) program along a 2-year follow-up period, and (2) to examine any relevant association of NS longitudinal change with the specific intervention components (i.e., antipsychotic medication, individual psychotherapy, family psychoeducation, case management) offered within the EIP program.

Methods: One hundred UHR individuals (aged 12–25 years) completed the Positive And Negative Syndrome Scale (PANSS). The PANSS 5-item “Negative Symptoms” factor score proposed by Galderisi et al. (2021) was used because of its better fitting into our CHR-P sample. The Wilcoxon test for repeated measure was performed to evaluate statistically relevant longitudinal change in NS severity levels. A multiple linear regression analysis was also conducted to examine significant associations between longitudinal change in NS severity and EIP treatment components.

Results: Across the 2-year follow-up period, a significant decrease in NS severity was found. This reduction was associated with the intensity of individual psychotherapy sessions offered in the first year of treatment, a shorter duration of untreated illness (DUI) at baseline, and the 2-year longitudinal decrease in positive symptom levels. Our regression analysis result explained 44.6% variance of the explored model. However, at the end of the follow-up, improvement in NS severity levels was predicted exclusively by the longitudinal decrease in positive symptom scores.

Discussion: NS are clinically relevant at the onset of psychosis. The findings of this investigation showed that longitudinal improvement in NS is positively associated with the intensity of individual psychotherapy sessions provided to young CHR-P individuals during the first year of treatment, together with a shorter DUI at presentation and the longitudinal improvement in positive symptom scores. Specific targeted psychosocial interventions on NS in people at CHR-P are thus recommended and to be routinely implemented. Moreover, maintaining an optimal intensity of individual psychotherapy for at least 2 years within specialized EIP programs could further match a more decisive, stable and prolonged over time improvement in NS levels, consequently favoring better long-term outcomes and a fuller personal, functional and social recovery in this young at-risk population.

S143. THE ASSOCIATION OF ANTERIOR CINGULATE CORTEX GLUTAMATE AND CLOZAPINE ELIGIBILITY IN AN EARLY PSYCHOSIS SAMPLE

Kara Dempster^{*1}, Temi Toba-Oluboka², Candice Crocker², Philip Tibbo²

¹*Queen Elizabeth II Health Sciences Center*, ²*Dalhousie University*

Background: The ability to identify patients who may benefit from clozapine at the earliest opportunity is important for maximizing long-term outcomes in schizophrenia and may facilitate stratification of treatment based on neurobiology. Approximately one third of individuals with schizophrenia do not respond appreciably to first-line pharmacological treatment options and meet criteria for treatment resistant schizophrenia (TRS), the majority of whom demonstrate poor response from the first episode of psychosis (FEP). Given first line dopamine blocking medications are essentially ineffective in this subgroup, it has been hypothesized that alternative neural pathways may be implicated. Glutamate, an excitatory neurotransmitter, has been shown to be elevated in individuals with FEP who do not respond to dopamine blocking antipsychotic medications. Despite the considerable evidence of superiority for clozapine in TRS, its use is frequently delayed. There are currently no objective biomarkers available to support clinicians in identifying individuals who may benefit from a clozapine trial. Given the response to clozapine is more robust if used earlier in the illness, there is an urgent need to characterize the neurobiological underpinnings of clozapine eligibility. To date, no studies have investigated the association of elevated glutamate with clozapine-eligibility in a FEP sample, a group in which clozapine initiation may have the most profound impact on long-term outcomes. We hypothesized that elevated glutamate in the Anterior Cingulate Cortex (ACC) would be associated with clozapine-eligibility in an early psychosis sample.

Methods: Clozapine eligible (CE) individuals and treatment responders (TR) with non-affective psychotic disorders from the Nova Scotia Early Psychosis Program (within the first five years of illness onset) underwent magnetic resonance spectroscopy (1H-MRS) to measure glutamate in the bilateral dorsal ACC. 1H-MRS acquisitions were performed using Point RESsolved Spectroscopy (TE=40ms, TR=2000ms; 128 averages). CE individuals continued to have moderate psychotic symptoms on the PANSS, an illness severity of moderate on the CGI-S, and moderate functional impairment, and had undergone at least two trials of non-clozapine antipsychotic medications. The TR group had no more than mild symptoms on all PANSS items and were taking a single antipsychotic medication.

Results: While data collection is ongoing, to date, 37 individuals have completed the study (TR = 20, CE = 17). The TR group (15 males, 5 females) did not differ from the CE group (14 males, 3 females) in terms of mean age (26 for both groups). The CE group had higher PANSS

scores ($M = 69.47$) and a longer duration of untreated psychosis (DUP) ($M = 25$ weeks) than the TR group ($M = 36.70$ for the PANSS and mean DUP of 12 weeks). To date, glutamate levels in the ACC are not significantly different between the CE ($M = 10.05$, $SD = .84$) and TR ($M = 10.47$, $SD = 1.14$) groups ($t = -1.311(35)$, $p = .199$). Up to date results will be presented at the conference with an anticipated final sample size of 50 (25 per group).

Discussion: While elevated ACC glutamate has been associated with poor response to antipsychotic medications in early psychosis samples, this is the first study to examine the association with clozapine-eligibility. The ability to triage clozapine eligibility based on objective neurobiological findings could revolutionize early psychosis care in that some individuals may be offered clozapine after a single failed trial. Contrary to our hypothesis, ACC glutamate was not higher in the CE group. This suggests that while elevated ACC glutamate may be associated with short-term measures of response at discrete intervals, it may not be predictive of long-term treatment resistance. Limitations include the fact that antipsychotic treatment was not standardized, serum levels of antipsychotic medications were not obtained to confirm adherence, and we did not obtain drug tests at the time of glutamate measurement. Further studies are warranted to explore the association of elevated ACC glutamate at baseline and eventual CE in early psychosis samples.

S144. WOMEN ADVANTAGE IN VERBAL MEMORY ASSOCIATED TO RS9896243: A PSYCHOSIS FAMILY-BASED DESIGN STUDY

Rosa Ayesa-Arriola^{*1}, Noelia Rodríguez-Pérez², Víctor Ortíz-García de la Foz¹, Nancy Murillo-García¹, Sergi Papiol³

¹Valdecilla Biomedical Research Institute IDIVAL Research Group on Mental Illness, Marqués de Valdecilla University Hospital, University of Cantabria, ²Grupo de Genómica Evolutiva, Instituto de Biología Evolutiva (IBE), Universidad Pompeu Fabra, ³Max Planck Institute of Psychiatry

Background: There is a growing recognition of sex differences in Schizophrenia Spectrum Disorders. Verbal memory impairment is one of the most prominent cognitive deficits in first episode of psychosis (FEP) patients, but women show an advantage over men on tests that assess this cognitive domain. A previous human genome-wide association study found that one SNP (rs9896243), located in the intron of the NSF gene in chromosome 17, was associated with verbal memory. Exploring this association in a psychosis family-based design study may shed light on the genetic basis of verbal memory and on sex differences.

Methods: Subjects (112 FEP patients, 119 parents, 86 siblings and 169 healthy controls) were participants of the PAFIP-FAMILIES study in Santander (Spain). Verbal memory was assessed by the Rey Auditory Verbal Learning Test, which included measures of immediate recall, short-delay recall, long-delay recall and recognition. DNA genotyping was conducted by CEGEN and mixed-models approaches were performed as a joint GWAS of all participants, adjusting for ancestral background and familial relatedness. A series of one-way analyses of covariance (ANCOVAs), for sex and including age and years of education as covariates, were used to examine differences between the four groups of participants.

Results: The CC genotype was associated with better immediate recall ($F = 7.9$; $p < 0.001$), short-delay recall ($F = 4.92$; $p = 0.03$), long-delay recall ($F = 3.94$; $p = 0.01$) in female controls and sisters than in female FEP patients. No significant differences were found in men. The CG genotype was associated with better immediate recall ($F = 2.95$; $p = 0.037$), short-delay

recall ($F=4.34$; $p=0.007$), long-delay recall ($F=6.54$; $p < 0.001$) in sisters than in FEP patients among women, and on short-delay recall ($F=3.86$; $p=0.031$), long-delay recall ($F=4.5$; $p=0.005$) in controls than in FEP patients among men. Any of the comparisons on GG genotype showed significant differences.

Discussion: The results suggest sex-specific effects of allele C of rs9896243 genotype on verbal memory and provide further evidence of verbal memory genetically relation with schizophrenia. Further discussion is guaranteed. Our findings are excellent basis for further discussion.

S145. ASSESSING SHARED VULNERABILITY AND SEX DIFFERENCES IN PSYCHOTIC DISORDERS USING POLYGENIC SCORING

Background: There is increasing evidence for shared genetic susceptibility between psychiatric disorders. The PGC cross-disorder group has provided molecular evidence for this common genetic architecture clustering schizophrenia (SZ), bipolar disorder (BD) and major depression (MD) in the mood and psychotic disorders group (Lee et al. 2021).

However, although sex differences have been described in relation to clinical features and outcome in psychotic disorders (Riecher-Rössler et al. 2018), sex differences at the genetic level have been so far under-explored.

The aims of this study were: i) to evaluate the association of polygenic scores (PGSs) for SZ, BD and MD with disorders of the psychotic spectrum in a sample of patients with broadly defined psychosis and ii) to test whether sex differences exist in those associations.

Methods: Our study included 1826 patients (33.2% females) with a range of psychotic disorders (DSM-IV criteria) and 1372 healthy controls (45.8% females) from the Spanish

population (CIBERSAM cohort). Samples were genotyped with the Infinium PsychArray (Illumina) and imputation was conducted in the Michigan Imputation Server. PGSs were calculated using PRS-CS tool (Ge et al. 2019) and PLINK 1.9 (Chang et al. 2015) based on the following GWAS: SZ (Trubetskoy et al. 2022), BD (Mullins et al. 2021) and MD (Wray et al. 2018).

Logistic regression models were used to study the association between psychotic disorder diagnosis and the PGSs, including sex and the first ten ancestry principal components as covariates. To quantify the increased risk, the sample was divided into quartiles based on SZ-PGS, BD-PGS and MD-PGS and the odds ratios (ORs) were calculated for affected status in each quartile using the first quartile as reference. Secondary analyses were run stratified by sex. Analyses were run in R v.4.0.4.

Results: We found association between all PGSs and broadly defined psychosis. SZ-PGS explained the highest percentage of the variance of psychotic disorders in the liability scale ($R^2=11.01\%$; $p < 2 \times 10^{-16}$) followed by BD-PGS ($R^2=2.95\%$; $p < 2 \times 10^{-16}$) and MD-PGS ($R^2=0.26\%$; $p=2.73 \times 10^{-4}$).

We observed an increase in the case-control ratio in progressively higher quartile categories using all PGSs. Compared with individuals in the first quartile, those at the highest quartile had an OR for psychotic disorder risk of 7.95 (95% CI:6.34-9.97) for SZ-PGS, 2.67 (95% CI:2.18–3.28) for BD-PGS and 1.36 (95% CI:1.12–1.67) for MD-PGS.

We assessed PGS contribution to psychotic disorders risk stratified by sex and statistically compared prediction in males and females using a bootstrap resampling approach. SZ-PGS and MD-PGS, but not BD-PGS, explained significantly more variance in males than in females (p -values $< 2 \times 10^{-16}$).

Discussion: The association of the PGSs (SZ, BD and MD) with broadly defined psychosis emphasize the reported shared genetic architecture among these psychiatric disorders (Calafato et al 2018; Lee et al. 2021). The sex-stratified results are in line with recent findings suggesting that sex differences in the genetic architecture of neuropsychiatric and behavioural traits exist but are small and polygenic (Martin et al. 2021; Blokland et al. 2022).

The use of transdiagnostic approaches recognises the multidimensionality of psychopathology and enable the investigation of shared genetic risk factors. Moreover, understanding the genetic basis of sex differences in psychiatric disorders, is crucial for developing sex-stratified diagnostics and therapeutics and for paving the way for precision medicine.

S146. UNRAVELLING THE POLYGENIC BURDEN OF TRANSCRIPTION FACTORS IN SCHIZOPHRENIA: THE IMPORTANCE OF THE PRENATAL TRANSCRIPTOME

Gemma Riquelme¹, Maria Guardiola-Ripoll², Carmen Almodóvar-Payá³, Mariona Latorre-Guardia³, Edith Pomarol-Clotet⁴, Belén Ramos⁵, Mar Fatjó-Vilas^{*4}

Background: Schizophrenia (SZ) is a severe psychiatric disorder with a strong genetic component (heritability of about 80%) and a polygenic architecture. Genome-Wide

Association Studies (GWAS) have placed gene expression regulation factors as key pathophysiological elements in SZ, particularly focusing on transcription factors (TF). Several studies have examined genetic variants and expression changes of specific TF genes; however, little is known about the polygenic burden of the TF machinery on the SZ etiological roots. From the neurodevelopmental hypothesis framework, we investigated whether the TF polygenic load influences the risk of SZ, while considering the time of expression of the TF (prenatally or postnatally).

Methods: Our case-control sample consisted of 318 individuals: 193 patients diagnosed with chronic SZ (age 42.9 ± 11.4 ; 73.6% males) and 125 healthy controls (age 38.3 ± 11.7 ; 52.0% males). First, using the available data at the BrainSpan Atlas of the Developing Human Brain (www.brainspan.org), we selected all the TF expressed in the brain across the lifespan (1,954 genes) and selected those differentially expressed prenatally (866 genes) and postnatally (194 genes). Second, based on the most recent GWAS on SZ, we calculated for each individual in our sample three polygenic risk scores (PRSs, following the C+T method): one summarizing the polygenic load of all brain-expressed TF (All-TF-PRSsz, based on 57,596 SNPs) and two others corresponding to the prenatally and postnatally differentially expressed TF (PreN-TF-PRSsz, based on 21,129 SNPs; and PostN-TF-PRSsz, based on 7,640 SNPs). Third, we assessed the risk variance explained by these three PRSs in our sample (logistic regression controlled by sex, age and ancestry).

Results: We observed an association of the All-TF-PRSsz with the risk for SZ ($p=1.30 \times 10^{-5}$, $R^2=9.87$). The PreN-TF-PRSsz also showed an effect on SZ ($p=3.07 \times 10^{-3}$, $R^2=5.62$). No role of the PostN-TF-PRSsz was detected. For all PRSs, patients presented higher scores than healthy controls.

Discussion: We conclude that the genetic variants of the TF-encoding genes show an effect on risk and might contribute to the assessment of SZ susceptibility. Our data also suggest the importance of considering different developmentally informed periods to understand better the disorder's aetiology and to implement genetically driven diagnostic approaches in the future.

S147. EXAMINING THE INTERPLAY BETWEEN GENETIC LOAD FOR NEURODEVELOPMENTAL DISORDERS AND FOR SLEEP ABNORMALITIES AND HEAVY CANNABIS USE ON THE RISK FOR PSYCHOSIS

Edoardo Spinazzola^{*1}, Isabelle Austin-Zimmerman¹, Giulia Trotta¹, Diego Quattrone¹, Robin Murray¹, Marta Di Forti¹

¹*King's College London, IoPPN,*

Background: Heavy cannabis use is consistently reported as a risk factor for psychosis, but the role played by the underlying genetic factors remains complex. Twin studies have shown that there is genetic susceptibility to lifetime cannabis use, cannabis use disorder, and schizophrenia. Genome-wide association studies (GWAS) have uncovered genetic overlap between cannabis use and schizophrenia, as well as other phenotypes like developmental disorders and sleep abnormalities. Mendelian Randomisation (MR) studies have used GWAS data to investigate the direction of causality between schizophrenia and cannabis use. However,

findings have been contradictory and most of these studies have limitations that warrant caution when interpreting their results.

Therefore, we aim to explore whether the genetic liability for neurodevelopmental disorders and sleep disorders might increase the risk of a) heavy pattern of cannabis use and b) psychosis onset among cannabis users.

Methods: Utilising data derived from the EUGEI multi-centre case-control study, we calculated PRSs for all participants with PRS-CSx and Plink 2.0. Data on cannabis use was derived from the modified version of the Cannabis Experience Questionnaire (CEQEUGEI-mv). We examined the association between a newly developed Neurodevelopmental PRSs and a short (≤ 5 hours) and long sleep (≥ 10 hours) PRSs and 1) age at first cannabis use, 2) pattern of use (frequency/potency), and 3) psychosis case-control status. Interaction effects between these traits were also tested.

Results: We included 693 first-episode psychosis patients and 405 controls from the EUGEI study. Ordinal logistic regression models, adjusted for age, gender, site, and ten principal components, showed that neurodevelopmental PRS was not associated with a composite measure of frequency-potency of cannabis use. Conversely, we found that higher levels of Sleep PRS were associated with heavy cannabis use, with potential interaction observed between cannabis use patterns and sleep PRS (OR 1.11, 95% CI 1.01 – 1.23). Neither Sleep PRS nor Neurodevelopmental PRS were associated with case-control status. However, adding these measures to the pattern of cannabis use increased the variance explained for psychosis onset. A multiplicative interaction model, testing the interaction between Sleep PRS and frequency-potency of cannabis use on psychosis case-control outcome did not yield significant results.

Notably, high Sleep PRS appears to have a protective effect against psychosis in daily users of high-potency cannabis.

Discussion: This data highlights the influence of genetic load for neurodevelopmental disorders on individual susceptibility to develop psychosis. Conversely, Sleep PRS is associated with the opposite effect, increasing the risk of developing psychosis in non-users, while potentially reducing the risk in cannabis users. These findings suggest that distinct genetic factors may impact psychosis risk through independent and non-pleiotropic mechanisms not directly associated with psychosis, but influencing environmental factors, such as cannabis use.

Biomedicine Institute of the University of Barcelona (IBUB). CIBER de Salud Mental (CIBERSAM), Instituto de Salud Carlos III. Institut de Recerca Sant Joan de Déu (IRSJD)

Background: Childhood maltreatment (CM), generally defined as parental neglect and childhood physical, sexual, or emotional abuse, is a risk factor for bipolar disorder (BD) that affects around 50% of patients (Garino et al., 2005). CM has been linked with features related to poorer outcomes in BD such as severe and more frequent mood episodes, higher rates of suicide attempts, earlier onset, and comorbid substance misuse (Rowland and Marwaha, 2018). To date, several studies have pointed to the important role of epigenetics, specifically DNA methylation (DNAm) in CM (Rubens et al., 2023). In addition, signs of accelerated aging in BD have been associated with telomere length, increased oxidative stress, and more recently, accelerated epigenetic aging (EA) (Salarda et al., 2021) though, few EA-related studies have focused on CM (Palma-Gudiel et al., 2021).

Thus, this study aims to investigate DNAm patterns and EA in a sample of patients with BD assessed for CM to detect new epigenetic factors associated to CM.

Methods: A sample of 82 bipolar type I (BD-I) and type II (BD-II) patients answered the Childhood Trauma Questionnaire (Bernstein et al., 2003). This retrospective screening self-assessment questionnaire classifies CM into 5 categories: (i) physical abuse, (ii) emotional abuse, (iii) sexual abuse, (iv) emotional neglect, and (v) physical neglect. A total CTQ score, including the punctuation obtained in all five categories, was used as an outcome measure in our association analyses.

Genome-wide DNAm from peripheral blood samples was assessed using the InfiniumMethylationEPICBeadChip (Illumina). Raw DNAm data were processed with ChAMP (Tian et al., 2017). The association between individual CpGs and regions and total CTQ score was tested with a linear regression model adjusted for blood cell counts, sex, age, and smoking score (Bollepalli et al., 2019) by using Limma and DMRcate (Ritchie et al., 2015; Peters et al., 2015). Gene-set enrichment analysis using FUMA (<https://fuma.ctglab.nl>) was conducted for all genes mapped to CM-associated positions and regions, and the BECon web tool (<https://redgar598.shinyapps.io/BECon>) was used to infer blood-brain correlation of significant CpGs. Lastly, EA was estimated using Horvath's calculator (<https://dnamage.clockfoundation.org/>) and Dunedin clock pipeline (Belsky et al., 2022). The

association between EA and total CTQ score was tested for all studied clocks after adjusting for all covariates. For all analyses, Benjamini-Hochberg was used to correct the false discovery rate (FDR), and a p-value of 0.05 was considered for significance.

Results: A total of 28 positions and 2 regions were associated with the total CTQ score (FDR adjusted p-value LESS THAN 0.05), with 20 positions mapped to 24 genes and 1 region to 3 genes. Gene-set enrichment analyses of all mapped genes revealed non-significant results (FDR adjusted p-value GREATER THAN 0.05). Out of all positions, 17 were present in BECon and 3 of them showed strong positive correlations (r GREATER THAN 0.50). As for EA, no statistically significant association was observed (FDR adjusted p-value GREATER THAN 0.05).

Discussion: These findings suggest association between DNAm patterns and CM in BD, with HOXA-AS3 gene having been linked to sexual and physical abuse in a previous epigenome-wide association study (Dunn et al., 2019). Moreover, SAMD12 gene was previously found upregulated in individuals with CM (Cattaneo et al., 2018) and SLC12A2 gene differentially regulated in mice model with postnatal stress (Dayananda et al., 2023). Still, results should be further studied for a better understanding of CM.

S149. EPIGENETIC CHARACTERIZATION OF OFFSPRING AT HIGH FAMILIAL RISK FOR SCHIZOPHRENIA AND BIPOLAR DISORDER

Alex Segura^{*1}, Elena De la Serna², Irene Martínez-Serrano², Gisela Sugranyes², Immaculada Baeza², Isabel Valli², Covadonga Díaz-Caneja³, Nuria Martín³, Dolores M Moreno³, Patricia Gassó¹, Natalia Rodríguez¹, Sergi Mas¹, Josefina Castro-Fornieles²

¹University of Barcelona, ²Hospital Clínic of Barcelona, ³Hospital General Universitario Gregorio Marañón

Background: Subclinical features of schizophrenia and bipolar disorder can be identified before illness onset, often manifesting from a very young age. Their severity and duration are associated with the manifestation of acute symptoms in later life stages (van Os, Linscott, Myin-Germeys, Delespaul, and Krabbendam, 2009). Genetic and environmental factors may act synergically, modulating the pathogenesis of severe mental disorders and leaving characteristic biological marks (Butera et al., 2023). Epigenome-wide association studies (EWAS) have described some of these biological marks as changes in the methylation pattern of CpG dinucleotides, which modulate gene expression, cell senescence and functionality (Brunet and Rando, 2017).

Schizophrenia and bipolar disorder are associated with a shorter lifespan, linked to age-related biomarkers and physiological conditions (Higgins-Chen, Boks, Vinkers, Kahn, and Levine, 2020; Kirkpatrick and Kennedy, 2018), suggesting that patients suffer from the effects of accelerated biological aging. Epigenetic clocks are calculated to assess putative biological aging asynchronicities with chronological age, based on time-dependent methylation changes. Furthermore, EWAS results reporting the association of specific CpGs with exposure to certain external stressors can be used to estimate epigenetic scores, which summarize the overall biological impact of an external stressor.

Methods: For the present study, offspring aged 6 to 17 years of patients with schizophrenia (n=52) and bipolar disorder (n=178), as well as of community controls (n=113) were recruited from two hospitals in Spain. Biological samples were used to obtain the genome-wide methylation levels, and combined with EWAS summary statistics we constructed a) epigenetic clocks to estimate biological age acceleration and b) epigenetic scores reflecting the impact of stressful pre-conception and gestational conditions. Sociodemographic, cognitive, clinical and functioning data was assessed. Our aim was to characterize the epigenetic patterns, in terms of biological age acceleration and epigenetic impact, of the offspring at familial high risk and the controls. Subsequently, we aimed to assess the role of epigenetic clocks and scores on the cognitive, clinical and functioning scales.

Results: The offspring schizophrenia and bipolar disorder patients reported a biological deceleration on one of the assessed epigenetic clocks. Epigenetic scores were increased in the offspring at familial high risk. Biological age acceleration and epigenetic scores were associated with impaired cognition, more severe subclinical symptoms and worse functioning. Stratified analyses revealed that these associations were more prominent in the offspring of schizophrenia and bipolar disorder patients.

Discussion: The assessment of the biological impact of external stressful conditions presents several methodological limitations. However, the quantification of methylation patterns stands out as a promising approach to accurately summarize the impact of environmental stressors at different life stages. The biological consequences of abnormal methylation patterns can thus be studied, examining their effect on the subclinical and clinical status. In this context, the epigenetic constructs estimated with CpG methylation data characterized the biological marks of children at high familial risk for schizophrenia and bipolar disorder and were associated with worse clinical outcomes.

S150. A POPULATION-DRIVEN FAMILY-BASED GENETIC STUDY OF SCHIZOPHRENIA

Nicole Simons^{*1}, Mafalda Barbosa¹, Gavin Hynes¹, Esther Cheng¹, Katherine Keller¹, Janice Morinigo¹, Vibhuti Patel¹, Rachel Jackson¹, Earnest Chen¹, Alice Hashemi¹, Anina Lund¹, Simon Lee¹, Alexander Charney¹, Rene Kahn¹

¹*Icahn School of Medicine at Mount Sinai*

Background: Two landmark genetic studies of SCZ, the severe and highly heritable psychotic illness, recently established that some SCZ cases are caused by a rare protein-truncating variant (PTV) in one of 12 genes including GRIA3, an X chromosome gene that codes for an AMPA glutamate receptor component. Presented here is a process developed to identify individuals affected by rare PTVs in these 12 genes, followed by a case series of a family with seven members affected by a rare PTV in GRIA3.

Methods: Carriers of rare PTVs in the 12 known causal SCZ genes were identified by mining whole-exome sequencing data from the diverse population of New York City. Identified carriers were re-contacted to undergo comprehensive neuropsychiatric assessments and biospecimen collection. Seven members of this family were enrolled in the study.

Results: Six affected family members are carriers of the rare PTV, and 1 unaffected family member is a non-carrier. No affected non-carriers have been identified. The primary psychiatric diagnoses for the carriers were SCZ and neurodevelopmental disorder (NDD). Affected males

in the family exhibited more severe forms of illness than affected females in the family, but having two X chromosomes was not entirely protective.

Discussion: An X-linked pattern of inheritance was identified between the rare PTV and severe neuropsychiatric diseases, providing evidence for causality. Population-driven family-based genetic studies such as the one presented here are a new way to investigate the mechanisms of disease in individual patients, and lead to the development of novel gene-based therapeutics.

S151. GENOME-WIDE DNA METHYLATION RISK SCORES FOR SCHIZOPHRENIA DERIVED FROM BLOOD AND BRAIN TISSUES FURTHER EXPLAIN THE GENETIC RISK IN PATIENTS STRATIFIED BY POLYGENIC RISK SCORES FOR SCHIZOPHRENIA AND BIPOLAR DISORDER

Kazutaka Ohi^{*1}, Mihoko Shimada², Midori Soda³, Daisuke Nishizawa⁴, Daisuke Fujikane¹, Kentaro Takai¹, Ayumi Kuramitsu¹, Yukimasa Muto¹, Shunsuke Sugiyama¹, Junko Hasegawa⁴, Kiyoyuki Kitaichi³, Kazutaka Ikeda⁴, Toshiaki Shioiri¹

¹Gifu University Graduate School of Medicine, ²National Center for Global Health and Medicine (NCGM), ³Gifu Pharmaceutical University, ⁴Tokyo Metropolitan Institute of Medical Science

Background: Genetic and environmental factors contribute to the pathogenesis of schizophrenia (SZ) and bipolar disorder (BD). Among genetic risk groups stratified by combinations of polygenic risk score (PRS) deciles for SZ, BD, and SZ vs. BD, genetic SZ risk groups had high SZ risk and prominent cognitive impairments. Furthermore, epigenetic alterations are implicated in these disorders. However, it was unclear whether DNA methylation risk scores (MRSs) for SZ risk derived from blood and brain tissues were associated with SZ risk, particularly the PRS-stratified genetic SZ risk group.

Methods: Epigenome-wide association studies (EWASs) of SZ risk in whole blood were preliminarily conducted between 66 SZ patients and 30 healthy controls (HCs) and among genetic risk groups [individuals with low genetic risk for SZ and BD in HCs (n=30) and in SZ patients (n=11), genetic BD risk in SZ patients (n=25), and genetic SZ risk in SZ patients (n=30)] stratified by combinations of PRSs for SZ, BD, and SZ vs. BD. Next, differences in MRSs based on independent EWASs of SZ risk in whole blood, postmortem frontal cortex (FC), and superior temporal gyrus (STG) were investigated among our case-control and PRS-stratified genetic risk status groups.

Results: Among case-control and genetic risk status groups, 33 and 351 genome-wide significant differentially methylated positions (DMPs) associated with SZ were identified, respectively, many of which were hypermethylated. Compared with the low genetic risk in HCs group, the genetic SZ risk in SZ group had 39 genome-wide significant DMPs, while the genetic BD risk in SZ group had only six genome-wide significant DMPs. The MRSs for SZ risk derived from whole blood, FC, and STG were higher in our SZ patients than in HCs in whole blood and were particularly higher in the genetic SZ risk in SZ group than in the low genetic risk in HCs and genetic BD risk in SZ groups. Conversely, the MRSs for SZ risk based on our whole-blood EWASs among genetic risk groups were also associated with SZ in the FC and STG. There were no correlations between the MRSs and PRSs.

Discussion: These findings suggest that the MRS is a potential genetic marker in understanding SZ, particularly in patients with a genetic SZ risk.

S152. CLINICAL CHARACTERISTICS OF PATIENTS WITH COGNITIVE IMPAIRMENT ASSOCIATED WITH SCHIZOPHRENIA

Theresa Cassidy*¹, Kira Griffiths², Min Min Chan², Mayowa Oyesanya², Rifqi Alkhatib², Suzanne St Rose³, Rashmi Patel⁴

¹Boehringer Ingelheim Pharmaceuticals, Inc., ²Holmusk Technologies Inc, ³Boehringer Ingelheim, ⁴King's College London, Institute of Psychiatry, Psychology and Neuroscience

Background: Schizophrenia is a severe psychiatric illness characterized by positive, negative and cognitive symptoms. Evidence suggests cognitive impairment (CI) in schizophrenia is common, with nearly all patients having some CI and up to 98.1% falling below premorbid estimates of cognitive performance. Cognitive deficits vary across schizophrenia patients and its domains affecting executive function, attention, reasoning, and social cognition. Despite being a main feature of schizophrenia, no specific diagnostic code or established treatment for CI in schizophrenia exists. Real-world data (RWD) can extend our understanding of CI including clinical presentation and symptom burden within routine mental healthcare.

Methods: Analysis of electronic health records (EHR) examined CI among 8,355 schizophrenia patients using the Holmusk NeuroBlu Database (Version 22R3), a longitudinal behavioral health real-world database containing de-identified, patient-level, clinical data from 25 mental health providers in 15 states in the US. Patients aged ≥ 18 years diagnosed with schizophrenia from 1999 to 2021 were included. Features of cognitive dysfunction recorded within ± 14 days of the first recorded schizophrenia diagnosis (index) were derived from free-text documented during the mental status examination (MSE) and extracted using natural language processing (NLP) models. The NLP models identified specific text strings that are mapped to clinical features in the MSE and social factors. For example, indications of CI included text strings like "poor concentration", "difficulty with attention/focus", "limited reasoning ability". The index was defined as the first-recorded schizophrenia diagnosis and demographic and clinical features were extracted at index ± 14 days (the baseline period). Baseline clinical features including psychiatric comorbidities, treatment patterns, disease severity, functioning and social factors were compared for those with and without at least one recorded MSE clinical feature indicative of CI.

Results: The mean age of patients was 41.6 years (SD=14.8), and the majority were male (63.3%). CI was less frequently documented (27.9%) at first recorded schizophrenia diagnosis than positive (68.0%) and negative symptoms (61.7%). Those with and without documented CI had a similar demographic profile but differences in clinical features were noted between these two. Patients with CI were more likely treated with mood stabilizers (8.5% vs. 6.6%, $p=0.003$) or an analgesic (6.7% vs. 4.7%, $p < 0.001$) compared to those without documented CI. Conversely, those with CI were prescribed a first-generation antipsychotic less often than those with no documented CI (10.7% vs. 12.5%, $p=0.024$). No significant difference was observed when comparing patients with and without CI who received a second-generation antipsychotic (42.8% vs. 44.1%) or an antidepressant (21.0% vs. 21.3%). Also, schizophrenia patients with CI were less likely to receive psychotherapy (15.7% vs. 21.2%, $p < 0.001$). A comorbid diagnosis of substance use disorder, schizoaffective disorder, PTSD, OCD, and ADHD were more likely for those with CI. Patients with documented CI had higher baseline illness severity and lower functioning (based on CGI-S and GAF scores) and were more frequently seen in emergency departments (26.3% vs. 18.8%, $p < 0.001$) and inpatient settings (45.3% vs 27.7%, $p < 0.001$) compared to those without CI. Further, patients with CI were more likely to experience negative social factors in all categories

including family, financial, housing, legal, occupational and academic functioning. Across 18 months post-index, CI was associated with an increased risk of psychiatric hospitalization, significantly higher inpatient visits and total number of inpatient days compared to those without CI.

Discussion: Results show that schizophrenia patients with CI are more unwell, have a higher burden of functional deficits and are more likely to experience negative social factors. Presence of CI was associated with meaningful differences in clinical presentation and other outcomes, providing evidence to support associations between CI and higher illness burden. Higher prescribing of mood stabilizers and analgesic medications for patients with CI suggest additional illness-related features or physical comorbidities among these patients. Yet, while CI is recognized as almost universal in schizophrenia, its recording in this real-world dataset largely underestimated the CI prevalence versus those found in clinical trial studies and prospective research. This is likely due to limited therapeutic treatment options for CI but suggests an opportunity to improve detection of CI through clinician education or digital approaches and therapeutics.

Funding: Funding for the studies presented was provided by Boehringer Ingelheim.

S153. THE BIDIRECTIONAL ASSOCIATION BETWEEN SCHIZOPHRENIA SPECTRUM DISORDER AND SHELTERED HOMELESSNESS

Sandra Nilsson*¹, Theresa Wimberley², Helene Speyer³, Carsten Hjorthøj⁴, Seena Fazel⁵, Merete Nordentoft⁶, Thomas Munk Laursen⁷

¹Copenhagen Research Center for Mental Health - CORE, ²Center for Register-Based Research, Aarhus University, Aarhus, Denmark, ³Copenhagen Research Center for Mental Health-CORE; Mental Health Center Copenhagen, Copenhagen University Hospital, Denmark, ⁴Copenhagen University Hospital, Mental Health Center Copenhagen, ⁵University of Oxford, Department of Psychiatry, ⁶Mental Health Centre Copenhagen, ⁷Aarhus University

Background: Psychiatric disorders and homelessness are related, but temporal associations are unclear. We aimed to explore the overlap between hospital-based psychiatric disorders, focusing on schizophrenia spectrum disorder, and sheltered homelessness.

Methods: This population-based cohort study was conducted using the Danish registers e.g., the Danish Homeless Register and the Danish National Patient Register. The study cohort included all individuals aged 15 years or older, living in Denmark at least one day during 2002-2021 (born 1984-2006). First psychiatric diagnosis was used to define psychiatric disorders and first homeless shelter contact to define homelessness. Adjusted incidence rate ratios (IRRs) and cumulative incidences according to any psychiatric disorder were estimated.

Results: Among 1,530,325 individuals accounting for 16,787,562 person-years at risk aged 15-38 years, 11,433 (0.8%) had at least one homeless shelter contact. Among 1,406,410 individuals accounting for 14,131,060 person-years at risk, 210,730 had at least one psychiatric disorder (IRR 9.2, 95% CI 8.8-9.6 adjusted for sex, age, calendar year, and country of origin). Drug use disorder (IRR 20.6, 95% CI 19.7-21.4) and schizophrenia spectrum disorder (IRR 10.2, 95% CI 9.6-10.8) were associated with highest risk of sheltered homelessness compared with not having these disorders. Ten years after first psychiatric disorder, 3.0% (95% CI, 2.9-3.1) had at least one homeless shelter contact. Individuals experiencing homelessness had increased risk of any psychiatric disorder compared to individuals with no homeless shelter contact (IRR 7.0, 95% CI 6.7-7.4). Especially high risk was found for drug use disorder (IRR

15.3, 95% CI 14.6-16.1) and schizophrenia spectrum disorder (IRR 12.2, 95% CI 11.5-13.0) in individuals experiencing homelessness compared with no history of homelessness. Ten years after first homeless shelter contact, 47.1% (45.3-48.0) had received a hospital-based psychiatric diagnosis. Highest risk of both outcomes was found the year after first schizophrenia spectrum diagnosis or first homeless shelter contact.

Discussion: Strong bidirectional associations between psychiatric disorders and homelessness were identified with highest risk estimates found for drug use disorder and schizophrenia spectrum disorder. Health and social care professionals should be aware of and address these high risks of accumulated psychiatric and social problems.

S154. PROBLEM GAMBLING AMONG PEOPLE WITH PSYCHOTIC DISORDERS: A META-ANALYSIS OF PREVALENCE

Olivier Corbeil^{*1}, Elizabeth Anderson², Maxime Huot-Lavoie³, Charles Desmeules², Lauryann Bachand², Laurent Béchar⁴, Sébastien Brodeur³, Christian Jacques², Isabelle Giroux², Pierre-Hugues Carmichael⁵, Marco Solmi⁶, Michel Dorval⁴, Marc-André Roy³, Marie-France Demers⁴

¹Laval University, ²School of Psychology, Université Laval, ³Faculty of Medicine, Université Laval, ⁴Faculty of Pharmacy, Université Laval, ⁵Center of Excellence on Aging in Quebec, ⁶Department of Psychiatry, University of Ottawa

Background: Psychiatric comorbidities, notably substance use disorders, are prevalent among individuals with psychotic disorders, significantly hindering their recovery. The reclassification of gambling disorder as a behavioral addiction in the DSM-5 underscored its parallels with substance use disorders. Both gambling disorder and problem gambling (PBG) result in adverse financial, social, and psychological outcomes, including an increased risk of suicide. Global prevalence estimates for gambling disorder and PBG vary due to diverse screening tools and methodologies. Despite higher prevalence rates among individuals with mental health disorders, research on PBG among those with psychotic disorders remains limited. This systematic review aimed to determine the prevalence of PBG in individuals with psychotic disorders and investigate how assessment methods and clinical settings influence this prevalence.

Methods: A comprehensive search strategy was conducted in Medline (using Ovid), EMBASE, PsycINFO (using Ovid), CINAHL, Cochrane Central Register of Controlled Trials (CENTRAL), Web of Science, and ProQuest Dissertation and Thesis. Peer-reviewed studies encompassing both correlational and experimental designs involving a representative sample of individuals spanning all age groups, diagnosed with either schizophrenia spectrum or affective psychotic disorders and providing the prevalence data of PBG were included. There was no language restriction applied. The evaluation of the included studies' risk of bias was carried out using the Joanna Briggs Institute (JBI) critical appraisal checklist for systematic reviews of prevalence data. The overall pooled prevalence estimate of PBG was calculated using the Generalized Linear Mixed Model. The presence of heterogeneity was evaluated using a χ^2 test and the I^2 statistic. All statistical analyses were conducted with R software, version 4.3.0 (R Project for Statistical Computing), using the meta and metafor packages.

Results: The systematic review encompassed 14 non-overlapping studies, out of which 12 studies contributed to the meta-analysis. The pooled prevalence of PBG was calculated at 5.15% (95% CI 3.16 - 7.46), with substantial heterogeneity ($I^2 = 74\%$). Notably, among the

factors analyzed, only the risk of bias within the included studies showed a significant association with the observed heterogeneity.

Discussion: Compared to the general population, individuals with psychotic disorders exhibit a significantly higher prevalence of PBG, estimated to be 5 to 10 times more prevalent. However, due to inconsistencies in PBG assessment methodologies across studies and the absence of screening instruments tailored to this specific population, a more precise estimation of the prevalence of this comorbidity remains challenging. Notably, the presence of PBG among individuals with psychotic disorders may potentially worsen psychosis symptoms and hinder the recovery process. Consequently, integrating routine clinical care with screening measures and providing appropriate treatment for PBG in this demographic is crucial to mitigate its adverse impact on their condition and overall well-being.

S155. AN INVESTIGATION OF RECORDED PHYSICAL, DOMESTIC, AND SEXUAL VICTIMISATION AS RISK FACTORS FOR ADVERSE CLINICAL OUTCOMES IN SERIOUS MENTAL ILLNESS: A LONGITUDINAL STUDY

Ava Mason^{*1}, Jyoti Sanyal², David Chandran³, Angus Roberts⁴, Robert Stewart⁵

¹University College London, ²South London and Maudsley NHS Foundation Trust, ³King's College London, ⁴King's College London, Biostatistics and Health Informatics, School of Mental Health and Psychological Sciences, Institute of Psychiatry, Psychology, and Neuroscience, King's College London, ⁵Institute of Psychiatry, Psychology and Neuroscience, King's College London

Background: Associations have been described between childhood victimisation and psychosis, psychotic symptom severity, and global functioning. However, few studies have examined the effect of other forms of victimisation on clinical outcomes relating to disease burden and treatment adherence. Large data resources are accruing from electronic healthcare records, but these have been under-used for research into the impact of violence experiences because these exposures are traditionally recorded in text rather than pre-structured fields. Taking advantage of recently developed and applied natural language processing algorithms for violence ascertainment, we investigated associations of violence victimisation with clinical outcomes in a large clinical population.

Methods: Clinical records of 16,372 patients receiving care from a large South London (UK) mental health service (SLaM) between January 2007 to October 2022 with a primary serious mental illness (SMI) diagnosis (ICD-10; F2*, F31 or F30) were included in this study. Patients were categorised into those with or without at least one general, physical, domestic, and sexual victimisation mention around the first clinical contact using natural language processing algorithms. Logistic and Cox regressions were used to investigate the association between victimisation and the severity of clinical outcomes in the subsequent three months. Outcomes included the number of prescribed antipsychotics, emergency care (A and E and crisis care), psychiatric inpatient care, compulsory detention and mortality. All regressions controlled for age, sex, ethnicity, neighbourhood deprivation, primary F* diagnosis, secondary diagnosis (substance misuse, intellectual disability, personality disorder), symptom severity (positive, negative, manic, disorganised, catatonic symptoms), antidepressant and mood stabiliser prescriptions, prior inpatient care, and prior emergency care.

Results: Adjusting for all covariates, general, physical, domestic, and sexual victimisation were associated (all p LESS THAN .01) with increased likelihood of patients visiting A and E

(HR range=1.20-1.34) and compulsory detention (HR range =1.52-2.03). General, domestic, and sexual victimisation significantly predicted increased number of antipsychotics prescribed ($B=0.05-0.06$, all $p < .01$). Domestic and sexual victimisation increased the likelihood of having an inpatient admission (HR range=1.37-1.71, all $p < .01$). No type of victimisation affected the likelihood of having an emergency visit by the crisis team or mortality rate (all $p > 0.50$).

Discussion: We believe this is the first longitudinal study to examine the relationship between victimisation types and clinical outcomes in patients with SMI using clinical health record data. When adjusting for multiple sociodemographic and clinical variables, general, sexual, and domestic victimisation significantly predicted multiple adverse clinical outcomes.

S156. PATIENT AND CAREGIVER EXPERIENCES WITH TARDIVE DYSKINESIA: EMOTIONS, CHALLENGES, AND UNMET NEEDS IN THE PATIENT JOURNEY

Aviva Levin^{*1}, Erika Kinjo², Rinat Chaijale³, Nayla Chaijale⁴, Ayelet Yaari⁵

¹Teva Pharmaceutical Industries Ltd., International Markets Medical Affairs, ²Teva Farmacêutica Ltda, Medical Affairs, São Paulo, Brazil, ³Teva Pharmaceutical Industries Ltd., Global Health Economics and Outcomes Research, Tel Aviv, Israel, ⁴Teva Branded Pharmaceutical Products R and D, Inc., ⁵Teva Pharmaceutical Industries Ltd., International Markets Medical Affairs,

Background: Tardive dyskinesia (TD) is a drug induced hyperkinetic movement disorder with multidimensional impact on quality of life and functionality. This study aimed to describe the patients' emotional journey from symptom onset to current state and to identify challenges and unmet needs.

Methods: Qualitative interviews were conducted with participants living with TD and caregivers of patients with TD (unconnected to each other) in Brazil, Israel, and China. Web-assisted telephone interviews were based on a pre-defined discussion guide, and TD diagnosis was based on self-report. Questions assessed awareness of TD as a condition, patient journey from onset of symptoms to diagnosis, impact on daily life, treatment, and long-term management. A Blob Tree© (Pip Wilson and Ian Long, 1980) projective exercise that visually portrayed 21 emotions using “blob people” was used to encourage discussion.

Results: Interviews were conducted with 17 respondents (8 patients, 9 caregivers). Mean age at TD diagnosis had a range of 44–48 years. Respondents tended to choose similar “blob people” (ie, emotions) at different points in the patient journey. Many reported feeling alone when symptoms started, as well as confused and powerless. While all had prior antipsychotic treatment (most for 2–3 years before TD onset), none reported having any awareness of TD before diagnosis or knew their risk of developing it; symptoms were often misattributed and multiple consultations were required to receive a diagnosis. At diagnosis, respondents most often reported feelings of sadness and frustration. Diagnosis came as a shock to all respondents, but some were happy to have a diagnosis after living with unexplained symptoms. Upon symptom worsening, hopeless feelings predominated; some respondents reported feeling supported amidst feeling scared and alone. Patients reported feelings of loneliness and isolation in their current state; however, some expressed hope for a useful future treatment.

Respondents reported that onset of symptoms had an immediate impact on activities of daily living, resulting in anger, stress, and withdrawal. Most patients ultimately gave up working and symptoms eventually impacted basic tasks such as walking, eating, and personal hygiene,

leading many to need 24-hour support. TD negatively impacted social interactions and most patients noticed a decline in mental health with feelings of anxiety, depression, embarrassment, and loss of interest in hobbies and social life. Most patients continued taking antipsychotics (often at a reduced dosage) and started TD treatments. Although no specific treatment was mentioned, respondents reported dissatisfaction with available options, and all reported high treatment adherence and satisfaction with information provided for their current treatment. Most respondents received key information from psychologists, psychiatrists, or other physicians. However, some respondents felt there are a lack of resources about TD and would like more official organizations to provide directions to patients to information and support groups. Most patients lived with family members and felt they had a good level of support from close family and friends and mental health professionals.

Discussion: In this international study of the TD patient journey using qualitative interviews, patients and caregivers alike reported substantial impact on patient quality of life and feelings of loneliness, confusion, sadness, frustration, and hopelessness. While many patients had good support systems, there is a need for greater awareness of TD, more accessible information, and more efficient diagnosis routines.

S157. SCHIZOPHRENIA AS A RISK FACTOR FOR CARDIOVASCULAR AND METABOLIC HEALTH OUTCOMES: A COMPARATIVE RISK ASSESSMENT

Suhailah Ali^{*1}, Damian F. Santomauro¹, Alize J. Ferrari¹, Fiona Charlson¹

¹*The University of Queensland*

Background: Cardiometabolic diseases are responsible for the majority of premature deaths in people with schizophrenia. This study aimed to quantify the fatal burden of ischaemic heart disease (IHD), stroke and diabetes attributable to schizophrenia.

Methods: Comparative Risk Assessment methodology from the Global Burden of Disease (GBD) study was used to calculate attributable burden; pooled relative risks (RRs) for IHD, stroke and diabetes were estimated via meta-regression, which were combined with GBD schizophrenia prevalence estimates to calculate the deaths and years of life lost (YLLs) caused by these health outcomes that were attributable to schizophrenia. The proportion of explained all-cause fatal burden and corresponding unexplained burden was also calculated.

Results: The pooled RRs for IHD, stroke and diabetes mortality were 2.36 [95% uncertainty interval (UI) 1.77 to 3.14], 1.86 (95% UI 1.36 to 2.54) and 4.08 (95% UI 3.80 to 4.38) respectively. Schizophrenia was responsible for around 50,000 deaths and almost 1.5 million YLLs globally in 2019 from these health outcomes combined. IHD, stroke and diabetes together explained around 13% of all deaths and almost 11% of all YLLs attributable to schizophrenia, resulting in 320,660 (95% UI 288,299 to 356,517) unexplained deaths and 12,258,690 (95% UI 10,925,426 to 13,713,646) unexplained YLLs.

Discussion: Quantifying the physical disease burden attributable to schizophrenia provides a means of capturing the substantial excess mortality associated with this disorder within the GBD framework, contributing to an important evidence base for healthcare planning and practice.

S158. EXPLORING THE CAUSAL ASSOCIATIONS OF SELF-HARM AND ITS PERSISTENCE WITH PSYCHOTIC EXPERIENCES: A POPULATION-BASED ADOLESCENT COHORT STUDY UTILIZING A MARGINAL STRUCTURAL MODEL

Satoshi Yamaguchi^{*1}, Syudo Yamasaki¹, Mitsuhiro Miyashita¹, Kaori Baba¹, Junko Niimura¹, Naomi Nakajima¹, Shuntaro Ando², Atsushi Nishida¹

¹Tokyo Metropolitan Institute of Medical Science, ²The University of Tokyo

Background: Longitudinal associations between antecedent psychotic experiences (PEs) and subsequent self-harm are well-established. However, recent studies using data from the nationwide registry observed strong relationships between antecedent hospital presentations for self-harm and subsequent psychotic disorder. These findings highlight an urgent need to examine the effects of self-harm on PEs in the general population. This is the first study aiming to explore the causal associations of antecedent self-harm and its persistence with subsequent PEs in a population-based adolescent cohort.

Methods: Data was obtained from a population-based birth cohort (Tokyo Teen Cohort; N = 3,171), consisting of random sampling of adolescents born between 2002 and 2004. A marginal structural model with inverse probability weighting was utilized to examine the association of self-harm at 12y and 14y with PEs at 16y as well as PEs with general psychological distress (GPD), accounting for time-fixed and time-varying confounders. The association of PEs at 12y and 14y with self-harm at 16y was also examined.

Results: Persistent self-harm at 12y and 14y was significantly associated with PEs at 16y (Odds ratio (OR) = 7.28, 95% confidence interval (CI) = 1.34–39.5) and PEs with GPD (OR = 10.1, 95% CI = 1.84–55.8). These associations were stronger than the association of persistent PEs at 12y and 14y with self-harm at 16y (OR = 2.49, 95% CI = 1.30–4.74).

Discussion: Persistent self-harm was strongly associated with subsequent PEs, and especially with PEs with GPD, a more severe phenotype of PEs, suggesting that preventive intervention for persistent self-harm is essential for reducing future psychosis risk.

S159. INVESTIGATING THE INFLUENCE OF PERSONALITY AND COGNITIVE BIASES ON PERCEPTIVE AND NON-PERCEPTIVE CLINICAL HIGH-RISK (CHR) SYMPTOMS FOR PSYCHOSIS IN THE COMMUNITY

Giulia Rinaldi^{*1}, Stefan Lerch¹, Frauke Schultze-Lutter², Stefanie J. Schmidt¹, Marialuisa Cavelti¹, Michael Kaess³, Chantal Michel¹

¹University of Bern, ²Heinrich-Heine University Düsseldorf, ³University of Bern, Airlangga University, ³University of Bern, University Hospital Heidelberg

Background: Beyond their role in predicting psychotic disorders, CHR symptoms influence mental health quality via their associations with psychopathology and impairments in psychosocial and personality functioning. Cognitive biases (e.g., dichotomous thinking, emotion-based reasoning) are also involved in the development of psychosis, and linked to general psychopathology and personality functioning, but their role in the context of CHR is underexplored. Therefore, we investigated the impact of personality functioning,

psychopathology and cognitive biases on CHR symptoms overall, as well as perceptive (P-CHR) and non-perceptive (NP-CHR) CHR symptoms independently, in a community sample. **Methods:** The final sample comprised 444 participants assessed via telephone using clinical interviews and via online questionnaires as part of a larger study. As expected in a community sample, a high proportion of participants had no CHR symptoms, and therefore, we used zero-inflated Poisson (ZIP) models to analyze (i) which factors influenced the likelihood of showing no CHR symptoms versus at least one, (ii) which factors influenced the count and severity of CHR symptoms. To this end, we calculated a CHR, a P-CHR and a NP-CHR sum-score, each representing the outcome variable in a separate ZIP model. In all models, the sum-scores of instruments measuring psychopathology, personality functioning, and cognitive biases were included as predictors, with age, sex and educational level as covariates.

Results: A higher sum-score in cognitive biases and higher impairments in personality functioning correlated with a lower likelihood of having no CHR symptoms. The likelihood of having no P-CHR symptoms also decreased with higher sum-scores in cognitive biases, while the chances of showing no NP-CHR symptoms were lower in women and when impairments in personality functioning were higher. A higher psychopathology sum-score was associated with a smaller probability of having no CHR, P-CHR and NP-CHR symptoms. For CHR symptoms, a higher count and severity correlated with a higher sum-score in cognitive biases, younger age and female sex. In younger participants, P-CHR symptoms' count and severity also tended to be higher. For NP-CHR symptoms, a higher count and severity was associated with a higher sum-score in cognitive biases.

Discussion: Our findings suggest that cognitive biases and personality functioning play a role in the presence, count and severity of CHR symptoms in non-help-seeking populations, influencing their expression and resulting in different patterns of both P-CHR and NP-CHR symptoms. To better understand their impact on CHR and ultimately inform mental health promotion, dedicated prevention, and treatment, future studies should investigate specific cognitive biases and facets of personality functioning individually. Further, our results support existing literature on the association of CHR symptoms with psychopathology, on the influence of age on CHR symptoms and on its differential effect on P-CHR and NP-CHR symptoms. To understand the role of age in CHR in more detail, future research should analyze its interactions with other factors, such as sex. In conclusion, our study highlights the complex interactions of CHR symptoms with other areas of mental health and sociodemographic variables, calling for their further exploration and emphasizing their clinical relevance.

S160. SYSTEMATIC INVESTIGATION OF SHARED AND EXCLUSIVE ASSOCIATIONS OF NON-GENETIC FACTORS WITH INDIVIDUAL PSYCHOTIC EXPERIENCES: EXPOSOME-WIDE ASSOCIATION STUDY IN THE UK BIOBANK

Angelo Arias-Magnasco¹, Bochao D. Lin², Lotta-Katrin Pries², Sinan Guloksuz*¹

¹Maastricht University, ²Department of Psychiatry and Neuropsychology, School for Mental Health and Neuroscience, Maastricht University Medical Centre, Maastricht, the Netherlands

Background: By applying exposome-wide analysis (ExWAS) and Mendelian Randomization analysis to investigate a range of nongenetic factors associated with any psychotic experiences (PE) in the UK Biobank, we have previously shown that ever having experienced sexual assault might be a potential causal risk factor for PE but experiencing a physically violent crime and cannabis use rather appeared to be possible aftereffects of having PE. In this study, we aim to

enhance our understanding of the complex web of non-genetic factors through systematic investigation of individual PE items to reveal shared and exclusive non-genetic factors across PE domains.

Methods: This study analyzed the Mental Health Survey data of the UK Biobank (UKB project number: 55392) to investigate individual items of PE as the outcomes. These four individual items of self-reported PE were: ever believing in an unreal conspiracy against self, ever believing in unreal communications or signs, ever hearing an unreal voice, and ever seeing an unreal vision. Following the quality control, 315 variables were included as predictors in the analyses conducted in two sequential main steps. First, ExWAS of each PE item were conducted in two equally split discovery and replication datasets (Bonferroni corrected $P < 1.59 \times 10^{-4}$). In the second step, variables associated with each of the PE item in the ExWAS were tested by applying a multivariable logistic regression model per PE item.

Results: The study population comprised 155,247 participants (57% females; mean age 55.94 years). Several significant associations were identified across PE items in the discovery dataset. Belief in unreal personal conspiracies was associated with 107 variables (34%). Belief in unreal communications or signs was associated with 66 variables (21%). Auditory hallucinations, such as hearing an unreal voice, were associated with 128 variables (41%), while visual hallucinations were associated with 137 variables (43%). The replication dataset confirmed these associations with high replication rates: 89% for unreal conspiracies, 82% for unreal communications, 78% for unreal voices, and 88% for unreal visions.

The subsequent multivariable models per each PE item demonstrated significant independent associations of 27 variables with unreal conspiracies, 19 with unreal communications, 39 with unreal voices, and 45 with unreal visions. In the final multivariable models, several of these predictors were shared across PE items, whereas others were exclusive to specific PE items. Most remarkably, each of the PE item was associated with both childhood and adulthood traumatic experiences across different domains (e.g. felt hated by family member as a child, victim of sexual assault, belittlement by partner as an adult). Cannabis use was also associated with all PE items but belief in unreal communications or signs.

Discussion: Our study paves the way for a systematically constructed map of nongenetic factors associated with psychopathology dimensions to guide the future work that would also include non-psychotic dimensions and apply up-to-date Mendelian Randomization methods.

S161. IMPLEMENTING VIRTUAL REALITY IN SPECIALIZED MENTAL HEALTH CARE FROM LEADERS' PERSPECTIVES

Trine Sandal¹, **Helen Bull**², **Jan Ivar Røssberg**³, **June Lystad**⁴, **Andreas Seierstad**⁵, **Olivia Schjøtt-Pedersen**⁴, **Alexandra Søhoel**⁴, **Helge Skirbekk**⁶

¹University of Oslo, Ulleral Hospital, Department of Psychiatry, ²Oslo Metropolitan University, ³Institute of Clinical Medicine, University of Oslo, Norway. Division of Mental Health and Addiction, Oslo University Hospital, Norway, ⁴Oslo University Hospital, ⁵Oslo University Hospital, Section for Early Psychosis Intervention, ⁶University of Oslo

Background:

Innovation is an essential part of future mental health care. In line with national and international regulations, health services are instructed to invest in and implement technological solutions in care delivery to better manage sparse clinical resources. Technology in general and Virtual Reality (VR) in particular, has the potential to play a key role in bridging

the gap between demand and supply in specialized psychosis treatment as patients and clinicians call for a more specific focus on functional outcome and social inclusion. Consequently, the healthcare system needs to both explore new avenues for treatment. Experiences however indicate that many innovation projects end up in the “pilot graveyard”. gameChange, developed at the University of Oxford, is a VR application for individuals with psychosis experiencing agoraphobic anxiety and avoidance. It has been validated in a large randomized controlled trial in the UK and has recently been piloted in Norway in the VROslo study, mixed methods feasibility study across seven psychosis treatment units at Oslo University hospital (OUH). Twenty-seven individuals with psychosis have tested the gameChange application. All participants, VR therapists and managers of participating hospital units were interviewed. The aim of the current study was to explore and describe challenges and advantages that managers have experienced during the implementation of VR therapy within specialized mental health services.

Methods: Qualitative semi-structured interviews were carried out, gathering data from seven managers. Interviews were recorded, transcribed, and analyzed using inductive thematic analysis. **Results:** On the basis of the seven interviews, four main themes were identified; preparation for change in work methodology, recruiting staff, prioritizing tasks, and the patient as a catalyst for change. Preparing the organization in terms of presenting the project and providing sufficient information was considered important. Different strategies were applied by managers to recruit resource persons and help them adapt to their project roles, varying from adjusting rotation plans to limiting other clinical tasks. Managers described different approaches to prioritizing the implementation of VR therapy underlining the balancing act between day-to-day clinical tasks and innovation. Divergent views regarding the patient group also emerged with some managers considering individuals with psychosis too ill to receive, adhere to or profit from VR therapy.

Discussion: The findings of the current study highlight that the successful implementation of VR therapy in specialized mental health care requires specific factors at the organizational, individual and leadership level. Analyses of patient and (VR-) therapist perspectives may shed further light on unique barriers and facilitators related to the implementation of VR treatment in mental health services.

S162. POLYGENIC RISK OF SOCIAL ISOLATION BEHAVIOR AND ITS INFLUENCE ON PSYCHOPATHOLOGY AND PERSONALITY

Adam Socrates^{*1}, Niamh Mullins², Ruben Gur³, Raquel Gur³, Eli Stahl², Paul O' Reilly², Avi Reichenberg², Hannah Jones⁴, Stanley Zammit⁴, Eva Velthorst⁵

¹*Icahn School of Medicine At Mount Sinai*, ²*Icahn School of Medicine at Mount Sinai*, ³*Penn Medicine and Children's Hospital of Philadelphia*, ⁴*University of Bristol*, ⁵*Mental Health Organization “GGZ Noord-Holland-Noord”*

Background: Loneliness has been described as an epidemic on par with obesity and tobacco use, linked to a range of psychiatric issues, but the behavioral component that drives social isolation is not well understood. Most genetic studies focus on the subjective aspects of isolation i.e. loneliness and social anxiety as opposed to the behavioral manifestations that lead to objective isolation as a measurable construct. Here, a genome-wide associations study (GWAS) was carried out to identify genetic variants that contribute specifically to social

isolation behavior (SIB) in order to investigate the relationship between genetic predisposition to actual social isolation, and psychosis and other psychopathologies and personality traits.

Methods: An SIB phenotype was devised with 4 traits from the UK Biobank, and a GWAS carried out to identify SNPs which contribute to this trait in up to 449,609 participants from the UK Biobank. Using this social isolation GWAS, polygenic risk scores (PRS) were derived in ALSPAC, an independent, developmental cohort, and used to test for association with friendship quality and social traits. Linkage disequilibrium (LD) score regression using the SIB GWAS was used to test for genetic correlation with schizophrenia and other psychiatric disorders. Mendelian randomization was used to test for causal relationships between social isolation and these psychiatric disorders. Finally, Genomic SEM was applied to investigate relationships between social isolation and psychosis, personality, and psychiatric domains.

Results: 17 loci were identified at genome-wide significance, contributing to a 4% SNP-based heritability estimate. At age 18, friendship scores were associated with the SIB PRS, demonstrating that the genetic factors can predict related social traits in late adolescence. LD score correlation using the SIB GWAS demonstrated genetic correlations with schizophrenia, autism spectrum disorder (ASD), major depressive disorder (MDD), educational attainment, extraversion, and loneliness. Genomic Structural Equation Modeling (SEM) revealed a common personality factor contributing to SIB, neuroticism, loneliness, MDD, and ASD, weakly correlated with a second common factor that contributes to psychiatric and psychotic traits.

Discussion: Our results show that SIB contributes a small heritable component, which is associated genetically with reduced social outcomes such as friendship and extraversion, as well as psychiatric disorders including schizophrenia.

S163. POSTMORTEM STUDY OF BCAS1-IMMUNOREACTIVE OLIGODENDROCYTES IN THE POSTERIOR HIPPOCAMPUS: IMPAIRED OLIGODENDROCYTE REGENERATION AS A BIOLOGICAL UNDERPINNING OF SCHIZOPHRENIA?

Johann Steiner^{*1}, Peter Falkai², Anna Kessel¹, Thomas Schneider-Axmann³, Andrea Schmitt⁴

Background: Structural and functional deficits in oligodendrocytes and impaired myelin integrity have been described in schizophrenia and may disrupt connectivity between disease-relevant brain regions. Notably, a population of breast carcinoma amplified sequence 1 (BCAS1)-expressing oligodendrocytes has been discovered as an important player in the remyelination of brain lesions, for example in multiple sclerosis. The hypothesis of our study was that the population of regenerating BCAS1-positive oligodendrocytes is reduced in schizophrenia as a possible cause of disease-related impairments in cerebral wiring and connectivity.

Methods: Numbers and numerical densities of BCAS1-immunostained oligodendrocytes were determined in the hippocampal subregions CA1, CA2/3, CA4, dentate gyrus and subiculum in postmortem brains from ten patients with schizophrenia and ten matched controls. We examined the same brains as previously, where we had found a reduction in total oligodendrocyte numbers in CA4 in a stereological study of Nissl-stained sections.

Results: Compared with controls, patients with schizophrenia showed a significant decrease in the mean number of BCAS1-immunoreactive oligodendrocytes in CA2/3 and CA4, which was associated with a reduction in the total number of oligodendrocytes in these hippocampal subregions.

Discussion: The observed reduction in BCAS1-immunoreactive remyelinating oligodendrocytes suggests that impaired oligodendrocyte regeneration may be involved in schizophrenia, ultimately leading to reduced total oligodendrocyte densities (Nissl staining) previously described in CA2/3 and CA4. Further insights into the underlying mechanisms may lead to new gliotrophic therapeutic approaches.

S164. MITOCHONDRIAL FUNCTION AND WORKING MEMORY IN SCHIZOPHRENIA: A PET AND TASK-FMRI STUDY

Atheeshaan Arumuham*¹, Ekaterina Shatalina², Thomas Whitehurst², Ellis Chika Onwordi³, Alexander Whittington⁴, Ayla Mansur⁴, Roger Gunn⁴, Sridhar Natesan¹, Matthew Nour⁵, Matthew Wall⁶, Eugenii Rabiner⁶, Oliver D. Howes¹

¹Institute of Psychiatry, Psychology and Neuroscience, King's College London, ²Psychiatric Imaging Group, MRC London Institute of Medical Sciences, Hammersmith Hospital, ³Bart's and The London School of Medicine, Queen Mary University of London, ⁴Division of Brain Sciences, Imperial College London, ⁵University of Oxford, ⁶Invicro

Background: Cognitive impairment is a core feature of schizophrenia affecting multiple domains, including working memory (WM). The aetiology of this impairment has been associated with genetic, environmental, neurochemical and structural brain abnormalities. Mitochondria are essential for cellular energy metabolism, and their dysfunction can have profound effects on brain function and cognition, with multiple lines of evidence suggesting a relationship between mitochondrial dysfunction and schizophrenia. Postmortem brain tissue from patients with schizophrenia have found significant abnormalities in mitochondrial complex 1 (MC1) expression in the dorsolateral prefrontal cortex (DLPFC), a region strongly implicated with WM function, but MC1 expression and its relationship with WM has not been examined in vivo. To address this, we investigate MC1 availability in patients with schizophrenia and examined the relationship with neural correlates of WM function.

Methods: A total of n=59 volunteers took part in the study (36 patients with schizophrenia and 23 matched controls). They received a dynamic, continuous 90-minute PET acquisition using [18F]-BCPP-EF, a selective radioligand for MC1, and determined the volume of distribution (Vt). Following this, participants underwent a functional MRI scan utilising an established WM task, the n-back, to measure task-evoked blood-oxygen level dependent (BOLD) activation. The DLPFC, anterior cingulate cortex (ACC) and hippocampus were defined as a priori regions of interest (ROIs) based on existing literature. Exploratory cluster-based extraction of Vt was performed according to significantly activated clusters identified during fMRI voxel wise analysis.

Results: For the PET data, we found a significant ROI x Group interaction ($F_{1,57}=10.0$, $p=0.002$), with post hoc testing finding significant reduction in mean patient Vt in the ACC ($t_{58}=-2.70$, $p=0.01$), DLPFC ($t_{58}=-2.69$, $p=0.01$), and hippocampus ($t_{58}=-2.26$, $p=0.03$). During ROI analysis of fMRI data, we did not find a significant difference between groups in BOLD activation during the 1 and 2back GREATER THAN 0back task condition, quantified as parameter estimates. Voxel-wise analysis found a cluster that had significantly higher

activation in patients compared to controls for the same task condition, with the local maxima being located within the left hippocampus ($Z=3.78$, $p=0.02$, MNI co-ordinates: $x=-36$, $y=-10$, $z=-18$). ROI correlation analysis did not find a significant relationship between V_t and task-evoked BOLD activation.

Discussion: We found significantly lower [18F]-BCPP-EF mean V_t in patients with schizophrenia compared to healthy controls, which supports existing postmortem literature. Previous studies have found [18F]-BCPP-EF uptake correlates positively with markers of metabolic activity, such as oxygen and [18F]-FDG uptake. Taken together, our findings of reduced MC1 binding in patients with schizophrenia indicates deficits in MC1 may underlie hypometabolism seen in schizophrenia. Furthermore, voxel-wise analysis of WM-evoked activation, found increased activation in patients compared to controls, in a cluster that partially included the left hippocampus. fMRI studies employing the n-back task have found hippocampal activation is associated with higher WM load and plays a vital role in encoding and retrieval during the WM task. Nevertheless, we did not find a significant correlation between tracer uptake and task-evoked BOLD activation in these ROIs. Although there is some evidence of frontal metabolism being correlated with WM impairments, we did not identify this relationship between MC1 and WM-evoked BOLD activations. Methylene blue is a compound that bypasses the rate limiting role of MC1 in mitochondrial respiration. Given the reduced expression of MC1 in patients with schizophrenia, and its potential effect on hypometabolism seen in schizophrenia, methylene blue could be utilised as a pharmacological challenge to elucidate the relationship between MC1 and WM. These findings build on existing literature suggesting the role of mitochondrial abnormalities in the aetiology of schizophrenia, although further studies are required to determine a causal relationship between MC1 and WM.

S165. MOLECULAR MECHANISMS UNDERLYING EXCITATION/INHIBITION BALANCE DEFICITS FOLLOWING MATERNAL IMMUNE ACTIVATION

Francesca McEwan^{*1}, Chiho Kambara¹, James Dal Santo¹, Jarred Lorusso¹, Jocelyn Glazier¹, Michael Harte¹, Reinmar Hager¹

¹*University of Manchester*

Background: Exposure to maternal immune activation (MIA) has been associated with increased risk for neurodevelopmental disorders such as schizophrenia. To establish the mechanistic pathways underlying this link, animal models recapitulate MIA through mid-gestational administration of the viral mimetic poly(I:C), which stimulates an increased cytokine response in the maternal plasma. Offspring exposed to MIA show behavioural changes, which are often translatable to symptoms in patients with schizophrenia. However, the neurodevelopmental mechanisms underlying such symptoms remain poorly understood. The aims of this study were to determine how MIA affects the expression of schizophrenia linked targets essential for the maintenance of excitatory/inhibitory balance (E/I).

Methods: In this study, pregnant rats were injected with poly(I:C) on gestational day (GD) 15 and plasma cytokines were measured 3 h following injection to confirm MIA. Offspring behaviour was assessed at postnatal day (PD) 100 in novel object recognition (NOR) tasks, with a short (2 min; NOR-S) and long (1 hour; NOR-L) inter-trial interval and anxiety behaviour was measured in the open-field task (OFT). All molecular analyses were conducted on the GD21 hippocampus and PD14, 42 and 98 dorsal hippocampus, including the expression

of schizophrenia linked genes (Nrg1, ErbB4, Dtnbp1, Slc12a2) and corresponding proteins, as well as oxidative stress markers MDA and SOD, and global histone modifications.

Results: Molecular dysregulation in the poly(I:C) dorsal hippocampus was predominantly found at the pre-weaning time point (PD14), including changes to oxidative stress markers such as increased MDA activity in poly(I:C) offspring, and increased SOD in poly(I:C) females. There was also a dysregulation of global histone modifications at PD14 such as increased H3k27ac expression in poly(I:C) offspring and decreased H3k27me3 in female poly(I:C) offspring. This coincided with increased expression of GABAergic targets at PD14 including a main effect of poly(I:C) on Dtnbp1 and Slc12a2 mRNA expression and DTNBP1A and DTNBP1C protein expression. There was also increased ErbB4 mRNA and protein expression and NRG1 protein expression in poly(I:C) females. Molecular changes preceded behavioural deficits in poly(I:C) offspring such as decreased performance in NOR-L and reduced exploration during OFT. Offspring could be clustered based on behavioural phenotype, resulting in significantly more poly(I:C) offspring in deficit cluster in contrast to typical cluster. Although there were no changes significant changes to mRNA expression in poly(I:C) offspring at adulthood, when assessed according to cluster, the deficit cluster displayed increased expression of ErbB4 and Dtnbp1.

Discussion: We propose that MIA results in oxidative stress during the pre-weaning time point affecting mitochondrial function, which provides key metabolites required for epigenetic function and hence, results in global changes to histone modifications. This coincides with increased mRNA or protein expression of Nrg1, ErbB4, Dtnbp1 and Slc12a2, which are implicated in E/I balance through GABAergic synapse development. Future work is required to assess synaptic density within the MIA hippocampus. The use of unbiased clustering methods in this study allowed us to assess the molecular phenotype of offspring susceptible to poly(I:C) deficits, with deficit offspring exhibiting dysregulated mRNA expression, reminiscent to that observed in poly(I:C) offspring at PD14. Future research into the molecular mechanisms underlying resilience and susceptibility to MIA are important in the understanding of schizophrenia aetiology and in the identification of preventative targets.

S166. INTERPLAY BETWEEN EXCITATION-INHIBITION BALANCE, RANGE ADAPTATION AND AMOTIVATION SYMPTOMS IN SCHIZOPHRENIA: A COMBINED 1H-MRS, RESTING-STATE AND TASK-BASED FMRI STUDY

Lingling Wang^{*1}, Hui-xin Hu², Yi Wang³, Huang Jia², Huang Yi-hang², Xuan Wang³, Zhen-hua Zhu⁴, Hong-yan Sun⁴, Yuan Cai⁴, Wen-long Hou⁴, Gang Ye⁴, Zhao-peng Kang⁴, Simon S. Y. LUI⁵, Li Hui⁴, Raymond C. K. Chan³

¹Shanghai Normal University, ²Neuropsychology and Applied Cognitive Neuroscience Laboratory, CAS Key Laboratory of Mental Health, Institute of Psychology, Chinese Academy of Sciences; Department of Psychology, The University of Chinese Academy of Sciences, ³Neuropsychology and Applied Cognitive Neuroscience Laboratory, Key Laboratory of Mental Health, Institute of Psychology, Chinese Academy of Sciences, ⁴Suzhou Guangji Hospital, The Affiliated Guangji Hospital of Soochow University, ⁵The University of Hong Kong

Background: Excitation-inhibition (E/I) imbalance plays an important role in schizophrenia (SCZ) patients' amotivation symptoms. The specific pathway that links E/I imbalance with amotivation symptoms is yet fully clear. Range adaptation refers to representing a stimulus value as its relative place. It is associated with amotivation symptoms and correlated with E/I

imbalance. Range adaptation may underlie the relationship between E/I imbalance and amotivation symptoms. This study examined the interplay between excitation-inhibition balance, range adaptation related brain activity and amotivation symptoms in schizophrenia patients.

Methods: A total of forty-six SCZ patients and 37 healthy controls (HC) were recruited to undertake the resting-state brain scans to examine the range adaptation related ventral prefrontal cortex (vPFC) resting-state functional connectivity. A subgroup of 32 SCZ patients and 36 HC further undertook magnetic resonance spectroscopy (MRS) to measure E/I imbalance and another subgroup of 38 SCZ patients and 33 HC further underwent the Monetary Incentive Delay task-Adaptive version fMRI task.

Results: SCZ patients exhibited reduced E/I balance as compared to HCs. The vPFC connectivities were comparable between the two groups. However, during adaptation to expected value of reward, SCZ patients exhibited hypo-activation in the putamen and insula. Regarding the adaptation to expected value of loss, SCZ patients showed hyper-activation in the caudate. They also exhibited hypo-activation in the inferior frontal gyrus during adaptation to outcome value of reward. E/I balance was correlated with resting-state vPFC connectivity. Moreover, the vPFC connectivity and task-based brain activations were associated with amotivation symptoms in SCZ patients.

Discussion: Our results suggest that SCZ patients exhibit E/I imbalance. Range adaptation may link the E/I imbalance with amotivation symptoms in SCZ patients.

S167. A COMPARISON OF AUDITORY AND VISUAL EVENT-RELATED POTENTIALS IN TREATMENT RESISTANT AND ULTRA-TREATMENT RESISTANT SCHIZOPHRENIA

Andor Bodnár^{*1}, Yifan Mo², Claire McCaulley², Arlene Cuerdo², Lilian Zhong², Chloe Bethany², Malaka Harper², Jay Leonard², Frederick Nucifora², Christopher Ross², Russell Margolis²

¹*Johns Hopkins University School of Medicine*, ²*Department of Psychiatry, Johns Hopkins University School of Medicine*

Background: Approximately 30% of patients with schizophrenia do not respond to standard antipsychotic medicines (treatment-resistant schizophrenia, TRS), and of these, 30% or more do not respond to clozapine (ultra-treatment-resistant schizophrenia, UTRS). We hypothesize that UTRS patients will have diminished event-related potentials (ERPs) across multiple sensory modalities, reflecting sensory gating and attentional control deficits. We conducted electroencephalographic recordings to explore potential neural correlates distinguishing these patient categories.

Methods: To preliminarily test this hypothesis, task-induced changes in ERPs of UTRS (N = 7) and TRS (N = 11) patients, ascertained as part of a comprehensive phenotypic investigation of treatment responsiveness in schizophrenia, were measured using frequency and spatial auditory oddball and visual Stroop protocols. 32 electrodes were mounted in a fitted cap with a standard 10-20 layout. Electrodes on the cap were referenced to the electrode at the vertex (FCz). Average electrode impedance was LESS THAN 20 kΩ. The electroencephalography (EEG) data were sampled at 1000 Hz. In EEG preprocessing steps, electrodes were average referenced, and spherical interpolation was limited to 10-15% of electrodes. After epoch rejection, high (0.5 Hz) and low (60Hz) pass filtering was applied to the EEG data.

Results: In the frequency auditory oddball task, P200 (140-180ms) amplitude at central-parietal electrodes was diminished in UTRS compared to TRS, and negatively correlated with PANSS scores. In the spatial auditory oddball task, reorientation negativity response was significantly diminished in UTRS at left frontal electrodes. In the visual Stroop experiment, P300 amplitudes were reduced at central-parietal electrodes for both congruent and incongruent trials and were inversely correlated to PANSS scores.

Discussion: Taken together, these preliminary ERP findings suggest that deficits in sensory gating attention control, and attention reorientation may distinguish UTRS from TRS. The replicability of this result, and the extent to which the findings reflect the presence of symptoms or an underlying neurophysiologic difference between TRS and UTRS, remain to be determined.

This work was funded by T32MH015330, the Abramson Fund, and ABCD Charitable Trust.

S168. CLOZAPINE-INDUCED ALTERATIONS IN BRAIN STRUCTURE AND CONNECTIVITY IN PATIENTS WITH TREATMENT-RESISTANT SCHIZOPHRENIA AND THEIR IMPACTS ON CLINICAL AND FUNCTIONAL OUTCOMES

Hyejin Sim^{*1}, Seoyoung Kim², Wi Hoon Jung³, Euitae Kim²

¹*Seoul National University*, ²*Seoul National University Bundang Hospital*, ³*Gachon University*

Background: Clozapine stands out as the sole effective antipsychotic for patients displaying inadequate response to treatment, suggesting its distinctive mechanism and different pathophysiology. In those with treatment-resistant schizophrenia (TRS) taking clozapine, volume reduction and disruption in functional connectivity have been reported. This study aims to investigate the longitudinal effects of clozapine treatment on brain structure and connectivity, exploring potential associations with various clinical and functional variables.

Methods: Patients diagnosed with schizophrenia who planned to start clozapine were recruited, and non-treatment-resistant schizophrenia (NTRS) were recruited as the control group. and they are prospectively investigated. T1-weighted and resting-state functional MRI data were obtained both before initiation and 18-weeks after the clozapine treatment. Longitudinal changes in gray matter and functional connectivity were evaluated. Measurement included serum levels of clozapine and nor-clozapine, concomitant antipsychotic doses, and assessments of clinical symptoms and cognitive performances pre- and post-clozapine treatment.

Results: Baseline comparisons between the treatment TRS and NTRS group, compared to treatment responders, showed altered striatal-cortico connectivity at baseline (before the clozapine treatment). After switching to clozapine, patients with treatment-resistant schizophrenia presented gray matter reductions in bilateral frontotemporal gyrus, and limbic areas (insula, putamen, caudate, cingulate gyrus) while no such changes were observed in the control group. Decreased functional connectivity was observed between the frontal gyrus and superior temporal gyrus (Heschl's gyrus, planum temporale) with no such changes observed in the control group.

Discussion: Clozapine treatment is associated with cortical/subcortical volume reductions, particularly affecting the mesolimbic dopamine pathway and its downstream regions, aligning with the dopamine hypothesis of schizophrenia. Additionally, group differences in connectivity alterations shows the effect of clozapine. decreased frontal functional connectivity to superior

temporal gyrus, crucial for auditory perception and language processing, potentially explain the observed diminished hallucination and/or language disruptions.

S169. TEMPORAL POLE, 'IMPENDING UNDERSTANDING' ASPECT OF ABERRANT SALIENCE, AND PSYCHOPATHOLOGY

Jun Miyata*¹, Yukako Nakagami², Shuraku Son², Yujiro Yoshihara², Toshiya Murai², Hidehiko Takahashi³

¹*Aichi Medical University*, ²*Kyoto University*, ³*Department of Psychiatry and Behavioral Sciences, Tokyo Medical and Dental University*

Background: The aberrant salience hypothesis (Kapur, 2003) postulates that a hyper-dopaminergic state in the midbrain-striatum causes heightened attribution of salience to ordinary stimuli, leading to the formation of delusion and hallucination. However, the exact neurobiological mechanisms of aberrant salience and delusion are unclear. Using resting-state functional magnetic resonance imaging (MRI) and the Aberrant Salience Inventory (ASI, Cicero et al., 2010), our previous study revealed region-specific functional connectivity between abnormal salience and the brain (manuscript in preparation by Nakagami et al.). In this study, we investigated the structural connectivity between gray matter and aberrant salience and its relevance to psychopathology.

Methods: We recruited 41 patients with schizophrenia and 67 healthy controls. We measured the intensity of subjective aberrant salience experience by using ASI, which consists of 29 items, and calculated scores of five subscales (increased significance, senses sharpening, impending understanding, heightened emotionality, and heightened cognition). We also rated psychopathology using the Positive and Negative Syndrome Scale (PANSS) (Kay et al, 1987) and calculated the negative, positive, excited, depressive, and cognitive factors (Lancon et al, 1998). T1-weighted MRI imaging data were acquired on a 3T scanner and were processed using a voxel-based morphometry pipeline, including segmentation, standardization, nonlinear-only Jacobian correction, and smoothing. Independent component analysis was applied to the resulting gray matter segment images, identifying 10 structural covariance networks (SCN) and calculating each subject's loading on these networks. Using these loadings as dependent variables, we performed multiple regression analyses with diagnosis, age, gender, and five subscales of ASI as explanatory variables, testing 1) the interaction between diagnosis and ASI and 2) the main effect of ASI. The significance level was set at $p < 0.05$ (FWE-corrected for network number, contrast number, and subscale number). When we found significant results, we then explored their correlation with the PANSS five factor scores. This study received approval from the Kyoto University Medical Ethics Committee, and participants provided written and verbal consent after receiving an explanation of the research.

Results: We observed a significant interaction between diagnosis and the "Impending Understanding" subscale of ASI for an SCN involving bilateral temporal poles, amygdala, and hippocampus ($p < 0.018$, FWE). Post-hoc analysis revealed a negative slope in healthy controls and a positive slope in patients. This subscale was correlated with the PANSS positive ($r=0.349$, $p=0.029$) and cognitive ($r=0.335$, $p=0.037$) factor scores.

Discussion: The association between the "Impending Understanding" subscale, which reflects a sense of profound meaning in familiar things, and the temporal pole, a neural correlate of semantic representation, supports the region-specificity of abnormal salience experiences. This association may also indicate the importance of aberrant salience for psychotic symptoms.

S170. DEVELOPING DANTE-PRESS, A SINGLE-SHOT MULTI-METABOLITE-SELECTIVE ¹H-MRS SEQUENCE, TO ACQUIRE ENDOGENOUS MEASUREMENTS OF GLU, GABA, GSH, AND NAA SIMULTANEOUSLY AT 7T

Kesavi Kanagasabai*¹, Lena Palaniyappan², Jean Théberge³

¹University of Western Ontario, ²McGill University, Douglas Mental Health University Institute; Western University, Robarts Research Institute, ³Lawson Health Research Institute, Department of Medical Biophysics, Western University, Robarts Research Institute

Background: Schizophrenia is described to be a complex network of abnormal concentrations of neurotransmitters such as gamma-aminobutyric acid (GABA), glutathione (GSH), and glutamate (GLU). Proton magnetic resonance spectroscopy (¹H-MRS), a non-invasive imaging modality, can quantify the chemical composition of a volume of interest in a living human brain to study metabolite levels. To date, no single-shot metabolite-selective ¹H-MRS pulse sequence has provided high-quality measurements of GLU, GABA, and GSH simultaneously. Currently, metabolite-selectivity is achieved by spectral editing or optimizing acquisition parameters. Both lead to 1) complex spectral modeling, 2) interference from neighboring metabolites, 3) reduced signal-to-noise ratio, 4) face a precision trade-off and 5) increased sensitivity to motion. Therefore, there is an unmet need to implement an effective technique to quantify GLU, GABA, GSH, and NAA precisely and simultaneously to properly investigate the pathophysiology of schizophrenia. One promising technique involves the use of an advanced ¹H-MRS pulse sequence known as Delays Alternating Nutation Tailored Excitation Point RESolved Spectroscopy (DANTE-PRESS). DANTE-PRESS uses a narrow-band radiofrequency pulse to selectively isolate the signal of a molecule of interest in the human brain spectrum. The use of a higher field strength scanner will increase the sensitivity of the measurements of all four neurotransmitters. The objective is to develop, test and validate DANTE-PRESS at 7 Tesla to isolate GLU, GABA, GSH, and NAA in a human brain.

Methods: To complete this, DANTE-PRESS was programmed within the software environment of the 7 Tesla MR scanner at Robarts Research Institute at Western University. An interactive user interface was created to allow users to adjust bandwidth, amplitude modulation, and other features of the pulse sequence in real time to isolate metabolites of interest. An inline display of adjustment loops, to generate accurate frequency profiles to avoid magnetization transfer between metabolites, is a work in progress. Phantoms and healthy volunteers have been scanned to refine scanning protocol for the novel sequence and assess qualitative performance of sequence – isolate metabolite(s) of interest and suppress unwanted signals.

Results: Since this is a novel sequence, there will be echo time phase and magnitude evolution of GLU, GABA, and GSH from 50-150ms. Qualitatively, double DANTE-PRESS was able to isolate metabolites of interest such as NAA, GSH, GABA, and GLU while suppressing unwanted signals in a multi-metabolite phantom and in vivo. To assess within session variability using the GLU-only phantom, GABA-only phantom, and NAA from a multi-metabolite phantom, the mean Cramer Lower Bounds (CRLB) were 0.012, 0.024, and 0.04 respectively. The mean %CRLB were 7.71%, 11.21% and 10.28% respectively. The % coefficient of variance were 18.08%, 9.49%, and 10.29% respectively. We were able to isolate GLU and NAA simultaneously using a multi-metabolite phantom where the mean CRLB, mean % CRLB, and the %CV were 0.04, 10.28%, and 10.29% respectively. Furthermore, DANTE-PRESS can effectively suppress remaining water signal such that water suppression is not required.

Discussion: DANTE-PRESS could provide precise measurements of GLU, GABA, GSH, and NAA to assess disorders affecting excitation/inhibition balance and oxidative stress. Future work involves performing test-retest data in humans. This can be used towards planning a cross-sectional study in schizophrenia.

S171. EXPLORING THE LINK BETWEEN RESTING-STATE FUNCTIONAL CONNECTIVITY AND HEART RATE VARIABILITY IN SCHIZOPHRENIA AND HEALTHY CONTROLS: A COMPARATIVE ANALYSIS

Harsh Pathak*¹, Srinivas Balachander¹, Vanteemar S Sreeraj¹, Swarna Buddha Nayok¹, Bridgit Kaniparambil¹, Chithra Uppinkudru¹, Ketaki Maity¹, Kiran Bagali¹, Makarand Pantoji¹, Nathiya Ezhumalai¹, Rajkumar Krishnamoorthy¹, Rujuta Parlikar¹, Sachin Reddy¹, Saranya Haribabu¹, Vyoma Shah¹, Ashok Jammigumpula², Jithin T Joseph², Manul Das³, Subham Samantaray³, Abhiram Narasimhan purohith², Chandramouli Roy³, Sonia Shenoy², Umesh Shreekantiah³, Samir kumar Praharaj², Nishant Goyal³, Urvakhsh M Mehta¹, Muralidharan Kesavan¹, Jagadisha Thirthalli¹, Ganesan Venkatasubramanian¹

¹National Institute of Mental Health and Neurosciences (NIMHANS), ²Kasturba Medical College (KMC), ³Central Institute of Psychiatry (CIP)

Background: Individuals diagnosed with schizophrenia (SCZ) exhibit symptoms that are associated with aberrant autonomic functioning. Recently, it has been proposed that these dysfunctions play a role in both the onset and exacerbation of auditory verbal hallucinations (AVH). The posterior insula is a key region involved in the processing of interoceptive signals received from autonomic afferents via the posterolateral thalamus. The interoceptive inference theory proposes that the emergence of AVH is linked with prediction error in interoceptive signals, which results in a consistently low-grade arousal state. Studies have shown that a transient increase in arousal state, indicated by reduced RMSSD (root mean square of successive differences between normal beats), is linked with exacerbation of AVH. Other studies have found activation of the insula just before and during AVH. Thus, the dysfunction of the Insula, along with the left temporoparietal junction (TPJ), is implicated in AVH. This association underscores the intricate link between irregularities in autonomic functioning, such as abnormality in heart rate variability (HRV), and the emergence of auditory verbal hallucinations in SCZ. We aim to examine the relationship between the association of HRV measures with the resting state functional brain connectivity between the left TPJ and the insular cortex in SCZ with persistent AVH and healthy controls (HC).

Methods: We analyzed 70 subjects (SCZ - 43, HC - 27, age and gender-matched) for whom HRV data was available. Resting-state functional magnetic resonance imaging (rs-fMRI) was available for 63 subjects (SCZ- 37, HC- 26). rs-fMRI data was pre-processed using fMRIPrep; motion correction was done using aCompCor, and atlas-based connectivity matrices for the Brainnetome regions were derived using ENIGMA-HALFPipe. Our regions of interest included the left TPJ (A41/42), and six sub-regions within the left insular gyrus (dorsal agranular insula, dorsal dysgranular insula, dorsal granular insula, hypergranular insula, ventral granular insula, dorsal agranular insula and ventral granular insula). A 12-minute resting electrocardiogram (ECG) was performed, with the outcome measure for heart rate variability (HRV) being the (RMSSD), calculated through the LabChart software. Regression models were used to examine the relationship between the connectivity of the TPJ with each insular sub-regions, adjusting for age, gender, and diagnosis.

Results: RMSSD was significantly lower in the SCZ group as compared to HC ($d=-0.53$, $p=0.05$). Functional connectivity (FC) of left TPJ was found to be significantly lower with the left hypergranular insula (HI) ($d=-0.17$, $p_{\text{FWE}}= \text{LESS THAN } 0.001$) and the left dorsal granular insula (DGI) ($d= -0.12$, $p_{\text{FWE}}=0.03$). The interaction of FC between the left TPJ and the left DGI and group was significantly associated with the RMSSD ($F=4.592$, $p=0.037$), though the effect of the group alone was not significant.

Discussion: We demonstrate a significant difference in RMSSD and functional connectivity of the left TPJ with left posterior insular subregions in SCZ compared to HC. Moreover, it also highlights the relationship between resting state connectivity of the left TPJ with left posterior insular subregions and the measure of autonomic tone (i.e., HRV). Further studies with a larger sample size may be needed to understand the relationship between the functional connectivity of Left TPJ with the left posterior insula and HRV measures in SCZ. Exploring these may reveal the abnormalities in interoception and enhance our understanding of the underlying mechanisms in the pathophysiology of AVH in SCZ.

S172. MISMATCH NEGATIVITY INDICES AS A PROGNOSTIC FACTOR FOR REMISSION IN SCHIZOPHRENIA

Young-Joon Kwon^{*1}, Won-Myong Bahk², Bo-Hyun Yoon³, Kwanghun Lee⁴, Moon Doo Kim⁵

¹Soonchunhyang University Chunan Hospital, ²Yeouido St. Mary's Hospital, The Catholic University of Korea, ³Naju National Hospital, ⁴Department of Psychiatry, College of Medicine, Dongguk University, ⁵School of Medicine, Jeju National University

Background: Mismatch negativity (MMN) is known to be associated with neuro-social cognition and functional outcomes. Remission and recovery rates are related to the neuro-social cognition of patients with schizophrenia. The present study explored the relationship of MMN with remission in patients with schizophrenia.

Methods: Forty patients with schizophrenia were recruited and divided into two groups, with or without remission, according to the Remission in Schizophrenia Working Group criteria (RSWGcr). Symptom severity (PANSS), cognitive function, functional outcome, and MMN of the patients were evaluated. A regression analysis was used to identify the factors that significantly predicted symptom improvement and remission including MMN at frontal site assessed at baseline, and anticipated clinical variables as predictive factors.

Results: MMN amplitudes in frontal sites were further decreased in the groups without remission compared to the groups with remission. MMN amplitude was significantly correlated with measures of symptom change and functional outcome measurements in patients with schizophrenia. Regression analysis revealed that symptom severity and MMN significantly predicted remission in patients with schizophrenia. Symptom improvement significantly predicted PANSS at baseline, illness duration, and antipsychotic dose, as did MMN amplitude at frontal site.

Discussion: Our results suggest that MMN reflected symptom improvement and remission in patients with schizophrenia. MMN indices appear to be promising candidates as predictive factors for schizophrenia remission.

S173. STRIATAL-CEREBELLAR FUNCTIONAL CONNECTIVITY IN PATIENTS WITH SCHIZOPHRENIA

Xuan Wang^{*1}, Xiao-dong Guo², Xin-lu Cai³, Yi-jing Zhang⁴, Bing-jie Huang⁵, Yi Wang⁶, Cheng-cheng Pu⁵, Xin YU⁷, Raymond C.K. Chan⁸

Background: Impairment of motivation is one of the core negative symptoms of schizophrenia (SCZ). The Cortico-Cerebellar-Thalamic-Cortical (CCTC) Circuit model posits that dysconnectivity between the cerebellar and cerebral regions may underlie the manifestation of amotivation symptoms. However, there is a dearth of studies to support such a claim. This study aimed to test this model through resting-state functional connectivity. We hypothesized that patients with SCZ would show reduced functional connectivity between cerebellar regions and cerebral reward regions compared to healthy controls (HC), and this impairment would be associated with amotivation symptoms in SCZ.

Methods: Sixty-two patients with SCZ meeting the DSM-IV criteria were recruited from Peking University Sixth Hospital and 61 age- and gender-matched HC were recruited from the nearby community. Negative symptoms of patients were assessed using the Scale for the Assessment of Negative Symptoms (SANS). All the participants undertook resting-state fMRI (rsfMRI) scan inside a 3T GE Medical Systems scanner. The rsfMRI data was preprocessed using fMRIPrep, and denoised with CONN. Both theory-driven and data-driven functional connectivity analyses were performed: (1) Driven by CCTC model, cerebral reward regions (i.e., bilateral ventral striatum, caudate, putamen, orbitofrontal cortex, dorsal lateral prefrontal cortex, anterior cingulate cortex), transit regions (i.e., bilateral thalamus and ventral tegmental area), and Buckner's cerebellar 7 networks were taken as regions of interest (ROIs). Group comparisons and symptom-related analyses were performed on ROI-to-ROI functional connectivity. (2) The data-driven analyses were performed based on intrinsic network. Intrinsic network represents a measure of whole-brain centrality at each voxel, defined as the root mean square of correlation coefficients between each individual voxel and all of the voxels in the brain. By applying a general linear model on intrinsic networks, we identified regions whose whole-brain centrality was significantly associated with symptoms. These regions were then used for subsequent ROI-to-voxel connectivity analysis.

Results: Based on the theory-driven analyses, we identified significant decreases in connectivity between the left attention network of the cerebellum and the bilateral putamen in SCZ patients after FDR correction. Besides, SCZ patients also exhibited lower functional

connectivity between the thalamus and caudate. Regarding the data-driven analysis of intrinsic networks, we found that the severity of avolition of SCZ could negatively predict the global centrality of the cerebellar vermis VII region. After extracting the whole-brain connectivity maps of vermis VII, significant between-group differences were observed in bilateral putamen. Moreover, the connectivity between the left putamen and vermis VII was found to be negatively correlated with avolition symptoms in patients with SCZ.

Discussion: Convergent findings from both theory-based and data-driven analyses suggest a reduced dorsal striatal-cerebellar functional connectivity in SCZ. The connection between vermis VII and left putamen was negatively associated with amotivation symptoms in SCZ. These findings support the CCTC model and shed light onto the neural pathophysiology underpinning amotivation in SCZ, and pave way towards improving clinical diagnosis and treatment of related symptoms.

S174. BRAIN-BEHAVIOR PARTICIPANT SIMILARITY NETWORKS AMONG YOUTH AND ADULTS WITH SCHIZOPHRENIA SPECTRUM, AUTISM SPECTRUM, OR TYPICALLY DEVELOPING CONTROLS

Maria Secara*¹, Prashanth Velayudhan², Lauren Lauren Erdman², Lindsay Oliver³, Ju-Chi Yu³, George Foussias³, Erin Dickie¹, Meng-Chaun Lai⁴, Anil Malhotra⁵, Robert W. Buchanan⁶, Aristotle N. Voineskos¹, Stephanie H. Ameis³, Colin Hawco¹

¹*Centre for Addiction and Mental Health, University of Toronto*, ²*Hospital for Sick Children*, ³*Centre for Addiction and Mental Health*, ⁴*Centre for Addiction and Mental Health*, ⁵*Zucker Hillside Hospital*, ⁶*Maryland Psychiatric Research Center, University of Maryland School of Medicine*

Background: Autism spectrum disorder (ASD) and schizophrenia spectrum disorder (SSD) display heterogeneity in brain function and exhibit social cognitive deficits which strongly predict functional outcomes. The objective of the present study was to integrate multiple brain imaging phenotypes and behavioral measures to identify new brain-behavior subgroups across these disorders.

Methods: Multi modal structural MRI, functional MRI, social cognitive and neurocognitive data from 106 SSD, 59 ASD, and 118 controls were examined using meta-similarity network fusion (metaSNF). Meta SNF identifies common patterns of similarity across data types and applies spectral clustering to identify biotypes, iterating models with differing parameters (e.g. including different data types). Left-out Birchwood Social Functioning Scale (BSFS) and Interpersonal Reactivity Index (IRI) were used to identify biotypes with clinically meaningful differences in social function and outcomes.

Results: The top clustering solution identified four transdiagnostic data-driven groups, with between-cluster separation on both BSFS ($p=0.00165$) and IRI ($p=0.00643$), driven by social cognition and cortical surface area. Social cognitive scores and surface area (precuneus, superior frontal, insula, superior temporal, and medial orbitofrontal) comprised the top ten contributing model features driving participant similarity and differences between the groups. A post-hoc analysis revealed between-network resting-state functional connectivity differences in the default mode, dorsal attention, somatomotor, salience, limbic, and visual networks.

Discussion: Our findings open the possibility of studying new data-driven groups that represent individuals with SSD and ASD more similar to each other than compared to traditional diagnostic groups. This has the potential to progress disease subtyping to target

specific neural circuitry among participant subgroups for treatment innovation and support current efforts which aim to expand beyond DSM-based diagnostic groups into transdiagnostic biologically based diagnoses.

S175. CONSTRUCTING THE METABOLIC CONNECTOME BASED ON HIGH-RESOLUTION SPECTROSCOPIC IMAGING TO IMPROVE EARLY DETECTION OF YOUTH AT CLINICAL HIGH RISK

Federico Lucchetti*¹, Edgar Céléreau¹, Martine Cleusix¹, Alessandra Solida², Jean-Baptiste Ledoux¹, Luis Alameda¹, Marco Armando¹, Kerstin von Plessen¹, Philippe Conus¹, Patric Hagmann¹, Paul Klauser¹

¹Lausanne University Hospital and University of Lausanne, ²Centre Neuchâtelois de Psychiatrie

Background: Only a minority of youth identified with a clinical high risk (CHR) state will experience a first psychotic episode and potentially develop schizophrenia (i.e., approximately 20% over two years). Moreover, non-transition to psychosis does not equate to recovery, as less than half of CHR individuals fully recover (i.e., 40% over two years), with many developing other mental disorders like mood disorders. The challenge for clinicians and researchers lies in accurately identifying CHR individuals truly at risk of psychosis or other mental disorders, a crucial step in enhancing early detection and tailoring interventions for youths seeking mental health care. In the pursuit of biomarkers for CHR, neuroimaging studies, while significant, have faced challenges likely due to the subtle and diverse nature of cerebral alterations in the early stages of psychosis. Recent advancements in whole-brain MR spectroscopic imaging (MRSI) offer a solution to address those challenges. Despite facing issues such as limited spatial resolution, suboptimal signal quality for myo-inositol, and extended acquisition times, the latest developments have facilitated the use of 3D high-resolution MRSI techniques whereby enabling comprehensive mapping of brain metabolites with an isotropic resolution of 5mm across the entire brain. The overarching goal of the project is to create a "metabolic connectome" for each individual's brain, based on inter-regional metabolic concentration similarities derived from MRSI. The hypothesis is that brain network analysis (connectomics) of this metabolic connectome will unveil new biomarkers associated with early and subtle changes in CHR. This approach is promising as it takes into account network effects and considers the relationships between brain regions rather than focusing solely on local alterations, which can be highly heterogeneous across individuals and scanning sites.

Methods: In this longitudinal study, MRI brain scans and clinical data have been collected from 42 CHR individuals and 20 matched healthy controls (HC) since 2018 in Lausanne. The MRI protocol included structural, diffusion resting-state functional MRI and MRSI. Metabolite concentrations (i.e. N-acetylaspartate + N-acetyl aspartylglutamate (tNAA), creatine + phosphocreatine (tCre), choline moiety metabolites (Cho), myo-inositol (Ins), and glutamate + glutamine (Glx)) in each voxel were estimated using LCModel with water signal as reference. We relied on pertinent network-based metrics encompassing the pair-wise connectivity matrix based on the Pearson Correlation Index.

Results: First, we show the feasibility of generating stable metabolic similarity matrices from MRSI data in CHR and HC. For each individual, we generated a pair-wise connectivity matrix based on Pearson correlations of metabolites between brain regions. Then, we tested the stability of the generated connectivity matrices. Last, we demonstrate the feasibility of generating a metabolic connectome from the metabolic similarity matrices. We described the topological properties of the metabolic connectome and compared them with natural networks.

Discussion: We present here the first steps of the construction of a metabolic connectome using whole-brain high-resolution MRSI data. From a technical perspective, this project is pioneering, utilizing MRSI data to establish a metabolic connectome. From a neuroscience standpoint, the sensitivity afforded by mapping brain metabolites, coupled with the inter-regional similarity approach, is expected to identify early and subtle brain alterations in CHR. If successful, this method may aid in identifying youths who stand to benefit the most from early intervention.

S176. SYNAPTIC TERMINAL DENSITY AND AMPLITUDE OF LOW FREQUENCY FLUCTUATIONS IN SCHIZOPHRENIA: A RESTING STATE FMRI AND [11C]UCB-J PET STUDY

Ekaterina Shatalina^{*1}, Ellis Chika Onwordi², Thomas Whitehurst³, Alexander Whittington⁴, Ayla Mansur⁴, Atheeshaan Arumham⁵, Tiago Reis Marques⁵, Roger Gunn⁴, Sridhar Natesan⁵, Matthew Nour⁶, Eugenii Rabiner⁴, Matthew Wall⁴, Oliver Howes⁵

¹King's College London, Institute of Psychiatry, ²Bart's and The London School of Medicine, Queen Mary University of London, ³MRC London Institute of Medical Sciences, Imperial College London, ⁴Invicro, ⁵Institute of Psychiatry, Psychology and Neuroscience, King's College London, ⁶Max Planck University College London Centre for Computational Psychiatry and Ageing Research, University College London; Department of Psychiatry, Oxford University

Background: Amplitude of Low Frequency Fluctuations (ALFF) measured during resting state functional Magnetic Resonance Imaging (fMRI) is significantly altered in schizophrenia. Previous work showed that fractional ALFF is related to synaptic terminal density, as measured by [11C]UCB-J Positron Emission Tomography (PET) in healthy controls and that schizophrenia is associated with lower [11C]UCB-J binding. Given that Blood Oxygen Level Dependent (BOLD) contrast measured during fMRI has a synaptic origin, we set out to explore if aberrant ALFF in schizophrenia may be related to differences in synaptic terminal density.

Methods: 22 participants with schizophrenia (unmedicated, mean age $\pm$ SEM 26.65 $\pm$ 1.59 years, mean age of symptom onset 23.8 $\pm$ 1.87 years) and 15 healthy control subjects (mean age $\pm$ SEM 34.87 $\pm$ 3.40 years) underwent a [11C]UCB-J PET scan and an 8-minute resting state fMRI scan. Voxel-wise kinetic modelling of [11C]UCB-J was carried out using the 1-tissue compartment model to produce volume of distribution values, with the centrum semiovale then used as a reference region to produce distribution volume ratios (DVRs). FMRI data were pre-processed using standard methods. ALFF measures were derived using the AFNI 3dRSFC module from data in the 0.01-0.1Hz frequency range and normalized to Z-scores. Second-level analyses compared ALFF between groups at the whole-brain level and were carried out using the FSL FLAME-1 module (Z GREATER THAN 2.3, cluster threshold of p LESS THAN 0.05).

Group differences in ALFF were used as regions of interest (ROIs) to extract ALFF Z-scores and [11C]UCB-J DVRcs values for each subject. Pearson's correlations were used to test relationships between the ALFF Z-scores and [11C]UCB-J DVRcs in each group. Exploratory analyses included whole-brain voxel-wise Pearson's correlations in each group, where resultant r-coefficients were transformed to z-scores and thresholded at Z GREATER THAN 2.3 and cluster threshold of p LESS THAN 0.05 to identify significant correlation clusters in the data.

Results: Compared to controls, the schizophrenia group had significantly higher ALFF in frontal cortical regions, the anterior cingulate and the caudate (Z GREATER THAN 2.3, cluster p LESS THAN 0.05). In this ROI, [11C]UCB-J DVRcs was comparable between the groups and there were no significant associations between ALFF Z-statistics and [11C]UCB-J DVRCS in either group (schizophrenia $r=0.179$, $p=0.425$; controls $r=0.309$, $p=0.244$). Exploratory analyses showed significant correlations between ALFF and [11C]UCB-J DVRcs in the control group in regions spanning the putamen, insular cortex, precentral gyrus, angular gyrus, cerebellum and occipital cortex. In schizophrenia significant correlations were seen in the bilateral dorsolateral prefrontal cortex. Whole-brain comparison of correlation-coefficients showed significant differences in r-values between groups across all brain regions.

Discussion: We report a group difference in ALFF in schizophrenia that is in line with published meta-analyses. Our data suggests these differences in ALFF are not related to synaptic terminal density. Exploratory analyses suggest the relationship between resting state brain function and synaptic terminal density is complex and altered in schizophrenia. Further work should focus on testing whether excitation-inhibition imbalance may be contributing to aberrant ALFF in schizophrenia.

S177. COGNITIVE DEFICIT IN PSYCHOSIS: LINKS TO HIPPOCAMPAL SUBFIELDS AND PREFRONTAL SUBREGION VOLUMES

Simon Evans^{*1}, Erkan Alkan², Veena Kumari³

¹University of Surrey, ²University of Surrey, ³Brunel University

Background: Cognitive impairments undermine functional capacity for most patients with schizophrenia, they are persistent and largely unresponsive to treatment. Thus, understanding their neural substrates is important but the literature is inconsistent. Here, we focus on elucidating the role of hippocampal subfields (in relation to memory task performance), and the role of prefrontal subregions (in relation to executive function) so as to provide more detailed insights into structure-function relationships as compared to previous work. A well-matched control group allowed us to determine whether these relationships are unique to patients.

Methods: The sample included 57 SZH and 32 age and gender-matched healthy controls. Symptom severity was assessed using the Positive and Negative Syndrome Scale (PANSS) and all participants underwent a T1 MRI scan. Various standard memory and executive (Stroop, Wisconsin Card Sorting Test (WCST)) were administered. Brain volumes were derived using Freesurfer and a region of interest analysis (encompassing hippocampal subfields and prefrontal subregions) was conducted to assess correlations with the relevant cognitive performance measures, and PANSS scores.

Results: Reduced brain volumes were observed in the SZH group, for most of the regions under study. In SZH, after FDR correction, volumes in middle frontal regions showed a

relationship with WCST category and non-perseverative errors. Stroop performance correlated with superior frontal, middle frontal, anterior cingulate and certain ventrolateral prefrontal subregion volumes. Memory task performance was seen to correlate with volumes within specific hippocampal subfields. These relationships were only seen in SZH, not the control group. No correlations with symptom severity were observed within any of the regions of interest.

Discussion: Results point to links between specific prefrontal subregions (particularly middle frontal and superior frontal) and executive function in SZH, as well as the role of specific hippocampal subfields in relation to memory performance. These were not observed in controls, suggesting they are unique to patients. Further, no correlations were observed in relation to symptoms, suggesting they reflect mechanisms at least somewhat independent of general disease severity. These results provide important novel insights and adds detail to the literature, as it is the first investigation into the role of prefrontal subregions and hippocampal subfields, based on a single sample with a well-matched control group, using a comprehensive battery of cognitive tasks.

S178. EXPLORING MYO-INOSITOL DISTRIBUTION AS A BIOMARKER OF ASTROCYTIC ACTIVATION IN PATIENTS AT RISK FOR PSYCHOSIS: A PILOT STUDY

Edgar Celereau*¹, Daniella Dwir¹, Martine Cleusix², Jean-Baptiste Ledoux³, Zoé Schilliger¹, Pascal Steullet¹, Marco Armando⁴, Alessandra Solida⁵, Luis Alameda², Philippe Conus², Kerstin Jessica Plessen⁴, Patric Hagmann³, Paul Klauser¹

¹Centre for Psychiatric Neuroscience, Department of Psychiatry, Lausanne University Hospital (CHUV), ²Service of General Psychiatry, Department of Psychiatry, Lausanne University Hospital (CHUV), ³Service of Diagnostic and Interventional Radiology, Department of Medical Radiology, Lausanne University Hospital (CHUV), ⁴Service of Pedopsychiatry, Department of Psychiatry, Lausanne University Hospital (CHUV), ⁵Department of Adults Psychiatry II, Centre Neuchâtelois de Psychiatrie (CNP)

Background: Astrocytes are actively engaged in inflammatory responses, regulation of redox states, and the reuptake of glutamate, which are all pathophysiological nodes previously underscored in research on psychosis. These cells can manifest an "activated" state characterized by heightened pro-inflammatory status. Consequently, reactive astrocytes may exert a significant and early influence on the pathological mechanisms contributing to the onset of psychosis.

Myo-inositol (MI) is a key brain metabolite, mainly regulated by astrocytes, which was found to be increased concomitantly with the presence of reactive astrocytes. Interestingly, meta-analyses demonstrated heightened MI concentrations in individuals diagnosed with psychosis or at risk for psychosis, suggesting a link between activated astrocytes and the disease. The in vivo and non-invasive detection of MI is made feasible through proton magnetic resonance spectroscopy. While the development of whole-brain MR spectroscopic imaging (MRSI) has been underway for 15 years, it was constrained by limitations in spatial resolution, suboptimal signal quality for myo-inositol, and prolonged acquisition times. Notably, a recent promising 3D high-resolution MRSI technique enables comprehensive brain metabolite mapping with a 5mm isotropic resolution across the entire brain (Klauser et al, 2022). We propose the first pilot

study to assess MI in the whole brain of subjects at clinical high risk for psychosis (CHR-P) and healthy controls. The aim of this pilot study is to develop the use of MI measurement in the brain as a biomarker of astrocytic activation in psychosis.

Methods: CHR-P patients and healthy controls were recruited from the Lausanne Psychosis Cohort (33 patients including 9 women, 13 controls including 5 women). Patients were clinically evaluated with the SPI-A/SPI-CY (Schizophrenia Proneness Instrument for Adult or Child/Adolescent) and the SIPS (Structured Interview for Prodromal Syndroms), and all participants were assessed with the Global Assessment of Functioning (GAF) scale. Participants underwent T1-weighted anatomical and MRSI brain scans on a 3T MRI scanner. Metabolic maps were generated with water signal as reference, aligned to the anatomical images and registered in standard space. A voxel-based analysis was performed on the whole brain (gray and white matter) and corrected with a non-parametric cluster-based approach. Clusters were considered significant with a corrected p-value LESS THAN .05. Participants also underwent measurement of a blood inflammatory marker (i.e., sRAGE) in the plasma using an ELISA kit.

Results: We found an association between increased MI concentration in gray matter and altered global functioning in the whole sample as well as in the group of patients. Increased MI concentration in the postcentral gyrus was also associated with the severity of negative symptoms in CHR-P patients. Last, in the significant regions where MI was elevated in the precedent analyses, we found that an increased MI concentration correlated with an increased inflammatory biomarker (sRAGE).

Discussion: These pilot findings suggest the presence of reactive astrocytes in CHR-P patients, especially in those with a low level of functioning. The relatively small sample size / relative lack of statistical power could hinder significant results in group comparisons, and for the correlations with other symptom categories. The association between MI concentration and blood sRAGE also supports the presence of an astrocyte reactivity, which may represent a biomarker and a target for psychosis.

S179. ENHANCED SLOW-FREQUENCY ENTRAINMENT IN PATIENTS WITH SCHIZOPHRENIA – A PARALLEL EEG AND OPM-MEG STUDY

Marion Brickwedde*¹, Fabian Symanowski¹, Tineke Grent-'t-Jong¹, Paul Anders², Peter Krüger², Tilmann Sander², Peter Uhlhaas¹

¹Charité Berlin, Germany, ²PTB, Berlin, Germany

Background: Schizophrenia (ScZ) has been associated with aberrant sensory information processing which can be investigated with psychophysical and electrophysiological methodologies, such as rhythmic sensory stimulation, eliciting steady-state responses (SSRs). Prior research has observed reduced high-frequency visual SSRs in ScZ patients, while findings concerning SSRs at lower frequencies (LESS THAN 10 Hz) remain inconclusive (Krishnan et al., 2005. Clin Neurophysiol.) To further investigate the nature of SSR impairments in ScZ, we employed optically pumped magnetometers (OPMs) in conjunction with EEG to capture visual SSRs at 7.5 and 10 Hz stimulation. OPMs are novel MEG-sensors, which can be applied directly onto the scalp without helium cooling, potentially offering superior signal-to-noise as well as localization accuracy when compared to conventional SQUID-MEG and EEG methods (Brookes et al., 2023; Trends Neurosci.).

Methods: For this study, 20 ScZ-patients as well as 20 age- and gender- matched healthy controls (HCs) were recruited. Visual SSRs were elicited by reversing checkerboard patterns either at 7.5 Hz or at a 10 Hz frequency (total = 100 trials per condition). To control for attention, participants were asked to respond to rare stimuli of one specified colour with a button press. Measurements took place in a magnetically shielded room employing a 56-electrode EEG-system and a 22-channel OPM system. OPM sensors were distributed over occipito-parietal sites. SSRs were analysed using time- as well as frequency decomposition and inter-trial phase coherence (ITPC) measures. Significance was tested using a cluster-based permutation approach.

Results: We observed significantly increased SSRs for both 7.5 and 10 Hz stimulation in ScZ patients compared to the HC group in ITPC analyses. Intriguingly, in the baseline-corrected power spectrum, condition differences between stimulation frequencies were only observable in the HC group. Moreover, within the ScZ group, the presence of ~3-7 Hz activity was observable when stimulating at 10 Hz, which was absent in the HC group. Finally, SSR responses in patients with ScZ were very focal, predominantly measured by a singular lateral occipital sensor, contrasting with the broader distribution of SSR responses across parietal sensors observed in the healthy controls (HCs).

Discussion: Patients with ScZ showed increased SSR responses to 7.5 Hz and 10 Hz stimulation. Importantly, these effects diminished when power-values were baseline-corrected, indicating a potential continuation of entrainment beyond the stimulation period. SSR responses are indicative of cortical excitability (Brickwedde et al., J. Neurosci. Methods) and activity in the theta- (~3 – 8 Hz) and alpha- (~8 – 12 Hz) range to inhibitory processes (Köster et al., 2018. Sci Rep.; Jensen et al., 2014. Trends Neurosci.). Accordingly, heightened responses to rhythmic stimulation within these frequencies could reflect heightened excitability of inhibitory networks. These networks are believed to modulate information processing conveyed by high-frequency activity (Bonnefond et al., 2017. ENeuro). Therefore, an increased activity within these slow-rhythm inhibitory networks would align with the observation of decreased SSR responses to higher frequency stimulation.

S180. SYNAPTIC TERMINAL DENSITY EARLY IN THE COURSE OF SCHIZOPHRENIA: A UCB-J POSITRON EMISSION TOMOGRAPHIC IMAGING STUDY

Ellis Chika Onwordi^{*1}, Thomas Whitehurst², Ekaterina Shatalina³, Richard Carr⁴, Ayla Mansur⁵, Atheeshaan Arumham⁴, Martin Osugo⁴, Ben Statton⁶, Elaine Berry⁶, Marina Quinlan⁶, Declan O'Regan⁶, Tiago Reis Marques⁷, Sameer Jauhar⁸, Susham Gupta⁹, Ravi Mehrotra¹⁰, Eugenii Rabiner¹¹, Roger Gunn⁵, Sridhar Natesan⁴, Oliver Howes¹²

¹²*Department of Psychosis Studies, Institute of Psychiatry, Psychology and Neuroscience, King's College London*

Background: The hypothesis that excessive synaptic elimination underlies schizophrenia pathogenesis has been highly influential. Supporting this, there is evidence for large and widespread deficits in the uptake of [11C]UCB-J, a marker of synaptic terminal density, in patients with chronic schizophrenia compared to healthy volunteers. Moreover, the normal relationship between synaptic terminal density and glutamate levels seen in healthy controls is not present in patients with chronic schizophrenia, suggestive of lower glutamatergic terminal density in chronic schizophrenia. However, it is unclear if these differences are present at the onset of illness in unmedicated patients. Here, we used multimodal imaging to address these questions. First, we investigated [11C]UCB-J uptake in antipsychotic-naïve/free patients with schizophrenia recruited from first-episode services (FE-SCZ) and healthy volunteers (HV). Second, we explored whether SV2A levels are related to markers of glutamatergic function in FE-SCZ and HV groups.

Methods: Forty-two volunteers (FE-SCZ n=21, HV n=21) underwent [11C]UCB-J positron emission tomography to index grey matter [11C]UCB-J volume of distribution (VT) and distribution volume ratio (DVR). Our primary analysis tested for group differences in VT in the frontal cortex (FC), anterior cingulate cortex (ACC) and hippocampus. Exploratory analyses tested for group differences in DVR, and in VT in other brain regions. To adjust for [11C]UCB-J plasma-free fraction (fp), we also tested for differences in VT/fp. In addition, volunteers underwent proton magnetic resonance spectroscopy, estimating creatine-scaled glutamate (Glu/Cr) and glutamate+glutamine (Glx/Cr) in the anterior cingulate cortex (ACC) and left hippocampus. We collected clinical data including PANSS score.

Results: Repeated measures ANOVA revealed a significant region ($F_{2,40}=609.4$, $p < 0.0001$) but not group effect ($F_{1,20}=0.09$, $p=0.77$) on [11C]UCB-J VT. There were no significant group differences in mean [SEM] VT in the FC (HV=19.63 [0.65], FE-SCZ=20.01 [0.65], $t=0.41$, $p=0.69$, Cohen's $d=0.1$), ACC (HV=22.37 [0.70], FE-SCZ=22.37 [0.62], $t=0.004$, $p=1.00$, $d=0.0$), or hippocampus (HV=15.04 [0.50], FE-SCZ=15.46 [0.42], $t=0.65$, $p=0.52$, $d=0.2$). Exploratory analyses revealed significantly lower ACC VT/fp (HV=91.71 [1.93], FE-SCZ=83.79 [2.70], $t=2.38$, uncorrected $p=0.02$, $d=0.7$) and temporal lobe DVR (HV=3.72 [0.11], FE-SCZ=3.35 [0.13], Kolmogorov-Smirnov $Z=1.54$, uncorrected $p=0.02$, $d=0.7$) in the FE-SCZ group. PANSS total score was inversely associated with hippocampal VT in the FE-SCZ group ($r=-0.48$, $p=0.03$). There were no significant group differences in Glu/Cr or Glx/Cr in the ACC or left hippocampus ($p > 0.05$). [11C]UCB-J DVR was significantly positively associated with Glu/Cr in the HV group (ACC: $r=0.46$, $p=0.048$; left hippocampus: $r=0.67$, $p=0.002$) but not FE-SCZ group ($p > 0.05$ in both regions). [11C]UCB-J DVR was significantly positively associated with Glx/Cr in the ACC in the HV group ($r=0.66$, $p=0.002$) but not FE-SCZ group ($p > 0.05$), and there were no significant DVR-Glx/Cr associations in either group in the left hippocampus ($p > 0.05$).

Discussion: These findings indicate that large differences in synaptic terminal density are not present early in the course of schizophrenia, but there may be subtler effects in the temporal lobe and ACC, and lower hippocampal synaptic terminal levels are linked to greater symptom severity. Moreover, they show that the normal relationship between glutamate and synaptic terminal density is lost in vivo early in the course of schizophrenia. When taken with prior in vivo evidence of lower VT in patients with chronic illness, this may suggest synaptic density

changes during the course of schizophrenia, potentially resulting in lower levels of glutamatergic terminals and/or a lower glutamatergic-to-GABAergic terminal ratio.

S181. THE AMYGDALAR SUBREGIONAL CONNECTIVITY STUDY USING RESTING STATE FMRI

Harah Kwon^{*1}, Minji Ha², Sunah Choi², Sunghyun Park¹, Moonyoung Jang¹, Minah Kim¹, Jun Soo Kwon²

¹Seoul National University Hospital, ²Seoul National University

Background: Schizophrenia and Obsessive-Compulsive Disorder (OCD) share many epidemiological and clinical characteristics, and indeed, several neurophysiological and neuroimaging studies have confirmed substantial overlap in their biological mechanisms and, in particular, the brain region that has been receiving notable attention is the amygdala. Recent neural correlate studies have revealed that the distinct functions of subregions within the amygdala in emotional processing contribute to the heterogeneity observed in both OCD and schizophrenia. In this pilot study, our primary focus was to examine the variations in functional connectivity (FC) of these subregions among different symptom phenotypes of OCD within a group of individuals not receiving medication.

Methods: Functional magnetic resonance imaging (fMRI) was performed in resting state on 110 healthy controls (HCs) and 107 OCD patients. Whole-brain FC between OCD patients and HCs, as well as between the different OCD symptom phenotypes, was compared using seeds from the bilateral amygdala's centromedial, laterobasal, and superficial subregions.

Results: Among the three OCD subgroups as well as the overall OCD and HC groups, there were no appreciable differences in core demographic profiles. When comparing symmetry-type OCD patients to HCs, they demonstrated hypoconnectivity between the superior frontal gyrus and left centromedial amygdala. Similarly, when comparing contamination-type OCD patients, they demonstrated hypoconnectivity between the left frontal cortex and left centromedial amygdala.

Discussion: These findings suggest that by impairing the modulation of motor reactions regarding emotional information, hypoconnectivity between the centromedial amygdala and the frontal cortex could be linked to the compulsion-focused phenotype of OCD. This underscores the importance of elucidating changes in FC within amygdala subregions for understanding the heterogeneity of OCD. Furthermore, it suggests that such insights may also be valuable in comprehending the diverse phenotypes of schizophrenia that share the significant neural underpinnings regarding emotional processing with OCD.

S182. THE FUNCTIONAL HIERARCHY OF THALAMOCORTICAL CONNECTIVITY IN CHRONIC SCHIZOPHRENIA

Harin Oh^{*1}, Han Byul Cho², Shinwon Park³, Sunah Choi⁴, Jung-ha Lee⁴, Minah Kim⁵, Seok-Jun Hong⁶, Jun Soo Kwon⁷

University Hospital, Department of Psychiatry, Seoul National University College of Medicine, ⁶Department of Biomedical Engineering, Sungkyunkwan University, ⁷Department of Brain and Cognitive Sciences, Seoul National University College of Natural Sciences, Department of Neuropsychiatry, Seoul National University Hospital, Department of Psychiatry, Seoul National University College of Medicine, Institute of Human Behavioral Medicine, SNU-MRC

Background: Schizophrenia is recognized for diverse heterogeneity, putting pressure on identifying the exact pathophysiology and better treatment for individuals. One of the consistent findings is the disruption of thalamocortical functional connectivity throughout the disease progression, characterized by reduced connectivity (hypoconnectivity) between the thalamus and prefrontal cortex (PFC), and increased connectivity (hyperconnectivity) with somatosensory and motor cortex^{1,2,3}. Recent studies have demonstrated a negative correlation between hyper- and hypo-connectivities, indicating an interconnected relationship between these connectivities and potential dysfunction stemming from a shared mechanism⁴. However, their correlation with specific symptoms or their potential as a diagnostic indicator remains uncertain due to current limitations in analyzing the relationship between multiple regions. Thus, a major focus has been given to identifying the causal relationship between the hyper- and hypo-connectivity patterns. Understanding the functional role of each region is crucial to identify their causal relationship. The prefrontal-thalamic connectivity is heavily implicated in higher-order functions, while somatosensory-thalamic connectivity plays a critical role in sensory processing and motor coordination^{5,6}. To clarify the association between higher-order and sensory processing in chronic schizophrenia, exploring the functional hierarchy and organization of those changes could be the next step to identifying causal relationships between two dysconnectivities. Hence, this study aims to investigate the thalamic functional gradient to identify the association between thalamic dysconnectivity patterns in chronic schizophrenia.

Methods: Resting-state fMRI images were obtained from 63 individuals diagnosed with chronic schizophrenia (SCZ, average age=33.4yrs, M/F=36/27) and 70 healthy individuals (HC, average age=25.5yrs, M/F=39/31). The thalamic functional connectome method was adapted from Haak⁷ or analysis with the thalamus as the inner region of interest (ROI) and the prefrontal cortex and somatosensory cortex as outer ROIs. The thalamocortical connection matrix was derived from each individual, and then a similarity matrix and manifold learning were constructed. We extracted two thalamic gradient maps that are known to reflect the thalamic structure (gradient 1) and the hierarchy of behavioural characterization ranging from perception to cognition (gradient 2)⁸. The statistical difference between gradient values and the functional network disruptions related to thalamic dysconnectivity in chronic schizophrenia was examined, with age as a covariate, between SCZ and HC.

Results: The left thalamus showed a statistical (MANOVA) difference in SCZ compared to HC. Substantial differences were observed in the statistically significant group difference voxel regions, indicating a decrease in the 1st gradient and an increase in the 2nd gradient. Specifically, the ANOVA analysis revealed the second gradient of the left thalamus exhibited a compression within SCZ in comparison to HC at a trend level. Moreover, the functional network distribution within the 2nd gradient revealed a significant decrease in the visual and default mode networks, while there was an increase in the frontoparietal network. This indicates a segregation of the visual network and frontoparietal network in patients.

Discussion: In alignment with previous studies, the 2nd gradient demonstrated changes which reflect the functional hierarchy of thalamocortical connectivity patterns^{8,9}. Our findings offer insights into the issues related to sensory-to-cognition processing proposed in chronic schizophrenia at the level of neuroimaging-informed functional networks.

S183. THE IMPACT OF CUMULATIVE OBSTETRIC COMPLICATIONS AND CHILDHOOD TRAUMA ON BRAIN VOLUME IN YOUNG PEOPLE WITH PSYCHOTIC EXPERIENCES

Kate Merritt¹, Pedro Luque Laguna², Arjun Sethi³, Mark Drakesmith², Sarah Ashley¹, Michael Bloomfield¹, Leon Fonville⁴, Gavin Perry², Tom Lancaster², Stavros Dimitriadis², Stanley Zammit⁵, C. John Evans², Glyn Lewis¹, Matthew J. Kempton⁶, David E. J. Linden⁷, Abraham Reichenberg⁸, Derek K. Jones², Anthony S. David¹, Anthony David*⁹

¹*Institute of Mental Health, UCL*, ²*CUBRIC, Cardiff*, ³*IOPPN, King's College London*, ⁴*Invicro LLC, London*, ⁵*Cardiff University and University of Bristol*, ⁶*Institute of Psychiatry, Psychology and Neuroscience, King's College London*, ⁷*School for Mental Health and Neuroscience, Maastricht University*, ⁸*Icahn School of Medicine at Mount Sinai*, ⁹*University College London*

Background: Psychotic experiences (PEs) occur in 5-10% of the general population and are associated with exposure to childhood trauma and obstetric complications. However, the neurobiological mechanisms underlying these associations are unclear.

Methods: Using the Avon Longitudinal Study of Parents and Children (ALSPAC), we studied 138 young people aged 20 with PEs (n=49 suspected, n=53 definite, n=36 psychotic disorder) and 275 controls. Voxel-based morphometry assessed whether MRI measures of grey matter volume were associated with i) PEs, ii) cumulative childhood psychological trauma (weighted summary score of 6 trauma types), iii) cumulative pre/peri-natal risk factors for psychosis (weighted summary score of 16 risk factors), and iv) the interaction between PEs and cumulative trauma or pre/peri-natal risk.

Results: PEs were associated with smaller left posterior cingulate (pFWE LESS THAN 0.001, Z=4.19) and thalamus volumes (pFWE=.006, Z=3.91). Cumulative pre/perinatal risk was associated with smaller left subgenual cingulate volume (pFWE LESS THAN 0.001, Z=4.54). A significant interaction between PEs and cumulative pre/perinatal risk found larger striatum (pFWE=0.04, Z=3.89) and smaller right insula volume extending into the supramarginal gyrus and superior temporal gyrus (pFWE=0.002, Z=4.79), specifically in those with definite PEs and psychotic disorder. Cumulative childhood trauma was associated with larger left dorsal striatum (pFWE=0.002, Z=3.65), right prefrontal cortex (pFWE LESS THAN 0.001, Z=4.63) and smaller left insula volume in all participants (pFWE=0.03, Z=3.60), and there was no interaction with PEs group.

Discussion: In summary, pre/peri-natal risk factors and psychological trauma impact similar brain pathways, namely smaller insula and larger striatum volumes. The effect of pre/perinatal risk was greatest in those with more severe PEs, whereas effects of trauma were seen in all participants. In conclusion, environmental risk factors affect brain networks implicated in schizophrenia, namely the salience network, which may increase an individual's propensity to develop later psychotic disorders.

S184. PARSING HETEROGENEITY IN WHITE MATTER INTEGRITY ALONG THE PROGRESSION OF PSYCHOSIS – A MULTI-SITE DIFFUSION TENSOR IMAGING STUDY

Galya Iseli*¹, Sarah Ulrich², Philipp Stämpfli³, Erich Studerus⁴, Anita Riecher-Rössler⁵, Philipp Homan⁶, Stefan Kaiser⁷, Stefan Borgwardt⁸, Matthias Kirschner⁹, André Schmidt¹⁰

¹University Psychiatric Clinics, Translational Neurosciences, ²University Psychiatric Clinics (UPK), ³Psychiatric University Hospital Zurich, ⁴University of Basel, ⁵University of Basel Psychiatric Clinics, ⁶Psychiatric Hospital of the University of Zurich, ⁷Geneva University Hospitals, ⁸University of Lübeck, ⁹University Hospitals of Geneva, ¹⁰University of Basel Psychiatric Hospital Basel

Background: Psychosis develops along a continuum ranging from subclinical psychotic experiences in healthy volunteers from the general population and individuals at clinical high risk to patients with clinically relevant psychosis. Each stage along the continuum demonstrates heterogeneity in clinical profiles and outcome features. While previous research also indicated structural brain heterogeneity at both ends of the continuum, it remains unknown whether it evolves with disease progression and whether divergence from the norm is associated with more adverse clinical features.

Methods: Data of 212 participants collected at three different centers was included in this post-hoc analysis. Samples ranging from five different groups of disease progression were collected at the Department of Psychiatry (UPK) of the University of Basel, the University Hospital of Psychiatry, Bern and the Department of Psychiatry, Psychotherapy and Psychosomatics at the Psychiatric Hospital, University of Zurich: healthy controls (HC, n = 59), schizotypal (SPT, n = 27), at risk mental state (ARMS, n = 35), first episode psychosis (FEP, n = 50), and patients diagnosed with schizophrenia (SZ, n = 41). Structural brain heterogeneity of diffusion tensor imaging (DTI) parameters including fractional anisotropy (FA), mean diffusivity (MD) and fiber density (FD) was computed using the person-based similarity index (PBSI) scores, a novel index that expresses an individual's similarity towards others of the same group. Besides comparing the different DTI PBSIs across groups using the Kruskal-Wallis test, normalized PBSIs were further converted into z-scores (z-nPBSI) indicating deviators to the normative reference. Furthermore, age, sex and diagnostic group adjusted ANCOVAs were performed to determine whether individuals with deviating PBSIs differ in verbal IQ (MWT-B), psychiatric symptoms (BPRS, SANS) and general ability to function (GAF) compared to subjects with non-deviating PBSIs.

Results: Across diagnostic groups significant differences in the PBSI were found for all three diffusion measures FA (H = 51.81, p LESS THAN 0.001). MD (H = 44.49, p LESS THAN 0.001), and FD (H = 55.80, p LESS THAN 0.001). Group differences in FA heterogeneity were found between ARMS-SPT (U = -2.87, p = 0.04), FEP-SZ (U = -4.04, p = LESS THAN 0.001), ARMS-SZ (U = -6.13, p = LESS THAN 0.001), and HC-SZ (U = -6.25, p = LESS THAN 0.001). For MD significant differences were found between HC-SPT (U = -3.39, p = 0.007), FEP-SPT (U = -3.56, p = 0.003), HC-ARMS (U = -4.02, p = LESS THAN 0.001), ARMS-FEP (U = 4.17, p = LESS THAN 0.001), HC-SZ (U = -4.74, p = LESS THAN 0.001), and FEP-SZ (U = -4.87, p = LESS THAN 0.001). For FD, FEP-SZ (U = -2.91, p = 0.03), FEP-SPT (U = -4.31, p = LESS THAN 0.001), ARMS-SZ (U = -4.81, p = LESS THAN 0.001), HC-SZ (U = -4.51, p = LESS THAN 0.001), HC-SPT (U = -5.67, p = LESS THAN 0.001), and ARMS-SPT (U = -5.88, p = LESS THAN 0.001) differed significantly. For FA, SZ showed the greatest percentage of deviators (24.390%) followed by SPT (14.815%), HC (8.475%), FEP (8%) and ARMS (2.857%). For MD 22.5% deviators in SZ, 20% in ARMS, 11.111% in SPT 8% in FEP, and 6.780% in HC. And for FD 25.926% in SPT, 14.634% in SZ, followed by 13.793% in HC, 5.714% in ARMS, and 8.0% in FEP. Across all DTI parameters, the number

of deviators differed significantly across the groups ($\chi^2 = 11.24$, $df = 1$, $p = 0.02$). Post-hoc comparisons revealed significant differences between the groups HC-SPT (OR = 2.94, $p = 0.04$), FEP-SZ (OR = 2.8, $p = 0.04$) and SPT-FEP (OR = 3.64, $p = 0.02$). Furthermore, there were statistical trends for lower GAF scores in SZ patients ($F(1,1) = 3.61$, $p = 0.08$) and individuals with SPT ($F(1,1) = 3.66$, $p = 0.07$) who exhibited deviating nPBSIs compared to those with non-deviating nPBSIs.

Discussion: Our results indicate progressive increases in structural brain heterogeneity. Further large-scale studies are encouraged to examine whether those with marked deviance from normative data reveal more severe clinical features. Such approaches may enable improved prognosis of disease progression and stratified interventions.

S185. EXAMINING RESTING STATE CONNECTIVITY AND ROLE OF ANTIPSYCHOTICS IN SCHIZOPHRENIA: ANALYSIS OF DRUG-NAIVE PATIENTS AT BASELINE AND SIX WEEKS, AND TWO YEARS OF TREATMENT WITH RISPERIDONE

Chithra Uppinkudru^{*1}, Neelabja Roy², Shreshth Shekhar³, Jagadisha Thirthalli⁴, Ganesan Venkatasubramanian⁵, Urvakhsh Mehta⁶

¹Department of Psychiatry, ²National Institute of Mental Health and Neurosciences (NIMHANS), India, ³IISER, Thiruvananthapuram, ⁴National Institute of Mental Health and Neurosciences, ⁵National Institute of Mental Health and Neurosciences, ⁶National Institute of Mental Health and Neuro Sciences (NIMHANS)

Background: The disconnection hypothesis of schizophrenia emphasizes the functional disintegration in the structural connectivity sensorimotor integration, perception, and cognitive processes. Antipsychotics, through their predominant D2 receptor antagonism, are thought to exert their clinical effects, and functional MRI can play a vital role in elucidating these mechanisms. This study aimed to evaluate the changes in the resting state connectivity among drug naïve patients at baseline and two-time points after treatment with risperidone.

Methods: This study enrolled 54 drug-naïve participants (mean age = 33.77 years, SD = 9.2 years, 27 females) who underwent baseline resting-state scans. Follow-up scans were acquired for those initiated on risperidone at six weeks (N=19) and those in symptomatic remission while on treatment after an average of two years (N=21). The paired analysis was conducted in two segments: the first examined participants with good quality baseline and 6-week scans (n=14), while the second part involved participants with good quality baseline and 2-year follow-up scans (n=14). Resting state-fMRI scans for participants across three study phases were obtained on a 3-Tesla MRI scanner (MAGNETOM Skyra, Siemens) over a single run of 10m 6s, with 2s relaxation time to yield 303 volumes. A high-resolution structural MRI (T1 MPRAGE sequence; 5m) of 1-mm section with no inter-slice gap was also acquired. The FMRIB Software Library (FSL version 6.0.5.2) was used for pre-processing and data analysis. Meta ICA-based (Independent Component Analysis) parcellation of 25 networks was applied, and within-network connectivity was analyzed using Generalized Linear Modeling.

Results: The study revealed diminished connectivity in the left sensorimotor network area relative to baseline among individuals following six weeks of Risperidone treatment (P-FWER LESS THAN 0.01). This reduction was also evident at two years of continuous treatment and attainment of symptomatic remission (P-FWER LESS THAN 0.01). Furthermore, the medial

occipital network also exhibited reduced connectivity compared to the baseline ($p=0.02$) at 2-year follow-up.

Discussion: The study findings underscore a potential mechanism of action for risperidone in modulating hyperactivity within the left sensorimotor network, which is instrumental in processing external stimuli, bodily experiences, speech, and motor control. Furthermore, the study sheds light on the conceivable role of the striatal dopaminergic projections to the sensorimotor cortices in possibly mediating symptom response. In conclusion, our study underscores risperidone's potential to reduce hyperactivity in vital sensorimotor and occipital networks. Early reduction in sensorimotor network activity persisted at 2-year follow-up, highlighting its potential as a marker of prospective treatment response.

S186. REVISITING THE KETAMINE ‘MODEL’ FOR SCHIZOPHRENIA THROUGH THE ELECTROPHYSIOLOGY LOOKING GLASS

Larry Ereshefsky^{*1}, Marco Cecchi², Daniel Mathalon³, K.C. Fadem², Elan Cohen⁴, David Walling⁵, Daniel Javitt⁶, Brett English⁷, William Potter⁸

¹*CenExel/Follow the Molecule*, ²*Cognition*, ³*Department of Psychiatry, University of California San Francisco*, ⁴*CenExel Hassman Research Institute*, ⁵*CenExel - CNS*, ⁶*Department of Psychiatry, Columbia University*, ⁷*Cenexel Clinical Sciences*, ⁸*FNIH*

Background: Glutamate dysfunction is thought to play a significant role in the underlying disease course and symptoms in Schizophrenia (SCZ). Recent data suggest that non-D2 modulating mechanisms, i.e., Muscarinic M1 and M4 agonists, demonstrate an efficacy signal. A unifying thread from preclinical studies is that NMDA antagonists impairment i.e., ketamine or MK-801 are reversed by putative antipsychotics across a wide array of pharmacological targets. Following ketamine or phencyclidine exposure in healthy normal volunteers (HNVs) symptoms mimicking some aspects of schizophrenia (SCZ) are observed. In the current investigation, we pooled results from studies sponsored by the ERP Biomarker Qualification Consortium (<https://erpbiomarkers.org>). In the EBS-A trial (NCT04025502; Cecchi et al., 2023), we compared the electrophysiology of stable patients with SCZ against matched HNVs. In EBS-B (NCT04928703; Ereshefsky et al., 2023), we studied HNVs who received ketamine (HNV-K) or placebo. A Consortium member's trial (NCT05049343) data was also included. Data presented elsewhere showed significant differences in ERP/qEEG between HNVs and SCZ, and separately between ketamine vs saline infusions in HNVs. We report the cross-study ERP/EEG findings comparing Ketamine in HNV-K, to no treatment in HNVs to people with stable SCZ.

Methods: EBS-A: 81 HNVs and 80 SCZ were evaluated at 4 sites. Subjects were administered two ERP/EEG testing sessions on separate visits. EBS-B: A three way randomized cross over design in 24 HNVs at one site received 2 ketamine and a single saline infusion. The ketamine protocol used: 0.23 mg/kg bolus over 1 minute, followed by 0.58 mg/kg per hour for 30 minutes, and 0.29 mg/kg per hour for 29 minutes (GunduZ-Bruce et al., 2012). The Consortium member study using similar methodology collected HNV baseline $n=20$ and ketamine infusion $n=19$ data. ERP/EEG data were combined from all these studies using COGNISION® System collecting. Duration-deviant mismatch negativity (MMN); Eyes-closed resting state quantitative (q)EEG; Auditory active deviant oddball (AOB); and 40Hz auditory steady-state response (ASSR). Electrode positions at Fz, Cz, Pz, F3, P3, F4, and P4 matched up to international 10–20 system (Jasper, 1958). qEEG/ERP Group data were

calculated using a One-Way ANOVA comparing HNVs n=124, SCZ n=80, and HNV-K n=43 followed by multiple pair-wise post-hoc ANOVA comparisons with Bonferroni correction. Analyses of SCZ and HNV-K populations will also be reported by re-expressing raw data to z-scores comparing SCZ relative to HNVs against HNV-K relative to HNVs.

Results: Data for selected parameters are reported: Significant Group differences by ANOVA between HNVs, SCZ, and HNV-K as well as Pairwise analyses are reported below the Group stats ($p \leq 0.05$ except where specified, as a trend $p=0.1-0.05$) 1. QEEG Group, Absolute Power $\mu V^2/Hz$ (AP) differences for: Delta, Theta, Alpha1/2, Beta1/2, Gamma ($p=0.051$); Theta/Beta ratio (TBR); Relative Power differences for: Theta, Alpha1, and Beta 1/2/3; and Total Power and Dominant Frequency. QEEG differences across all 3 comparison pairs (pairs) were observed for: Delta AP: HNVs 109 v SCZ 144 v HNV-K 60.1. Theta AP: HNVs 54.2 v SCZ 74.6 v HNV-K 23.6. (RP pair wise data to be presented). Total Power HNVs 381 v SCZ 456 v HNV-K 198. Dominant Frequency HNVs 9.76 v SCZ 9.40 v HNV-K 10.37. Significant differences for 2 of 3 pairs: Alpha1 AP for HNVs 105 v HV-K and HNV-K 40.6 v SCZ 115 but not HNVs v SCZ. Alpha 2 AP for HNV-K 26.4 v SCZ 47.6 and HNVs 105.6 v HNV-K 26.4 but not HNVs v SCZ. Beta1 AP for HNVs 35.1 v HNV-K 17.7 and HNV-K 17.7 v SCZ (38.4), but not HNVs v SCZ. TBR for HNVs 1.20 v SCZ 1.71 and HNV-K 1.25 v SCZ 1.71 but not HNVs v HNV-K. 2. MMN (passive) Group differences: @Fz Amp (μV) and Latency msec (Lat); also @Cz: P50 Amp, P200 Amp and Lat ($p=0.07$), and P3a Amp. MMN differences for all 3 pairs: Lat Fz HNVs 186 v SCZ 203, SCZ 203 v HNV-K 167, and HNVs 186 v HNV-K 167. MMN differences for 2 of 3 pairs: Amp Fz: HNVs -4.08 v SCZ -2.58, SCZ -2.58 v HV-K -4.56, not HNVs v HNV-K; P200 Amp Cz: HNVs 2.86 v SCZ 2.66, HNV-K 1.69 v SCZ 2.66, not HNVs v SCZ; P3a Amp Cz: HNVs 5.21 v SCZ 4.038, HNVs 5.21 v HNV-K 3.78, not HNV-K v SCZ. 3. AOB Group: @Pz P3b Amp and Lat. Button Press Accuracy (BPA) and Mean Reaction Time (MRT). AOB differences for all 3 pairs P3b Pz Amp: HNVs 9.08 v HNV-K 6.00, HNVs 9.08 v SCZ 7.42 and HNV-K 6.00 v SCZ 7.42 ($p=0.051$). AOB differences for 2 of 3 pairs: P3b Lat SCZ 321 v HNV-K 293, HNVs 317 v HNV-K 293, but not HNVs v SCZ; BPA HNVs 95.5 v SCZ 89.8, HNVs 95.5 v HNV-K 89.9, but not SCZ v HNV-K; MRT HNVs 375 v SCZ 457, HNVs 375 v HNV-K 427, but not SCZ v HNV-K. 4. ASSR40 Group: @Fz Intra-Trial Coherence (ITC) 200-500 msec, ITC 500, ITC Evoked Power (EP). ASSR ITC500 Fz differences for 2 pairs: HNVs 0.307 v SCZ 0.256, SCZ 0.256 v HNV-K 0.299 ($p=0.092$), not HNVs v HNV-K. ITC200-500 Fz for 1 pair: HNVs 0.453 v SCZ 0.307, not HNVs v HNV-K and SCZ v HNV-K.

Discussion: The data demonstrate the feasibility of including ERP/qEEG as translational/biomarkers in Early Phase studies. Similarities as well as differences in ERP/qEEG between HNVs and HNV-K and HNVs v SCZ as well as between HNV-K and SCZ suggest utility of the ketamine model for SCZ but with limitations. Variables affecting our results are ketamine dose, sequence of testing, and patient characteristics (age, stable atypical meds).

S187. HERITABILITY OF WHITE MATTER MICROSTRUCTURE AND ASSOCIATIONS WITH SCHIZOPHRENIA LIABILITY AND CHILDHOOD TRAUMA: A DANISH NATION-WIDE TWIN STUDY

Cecilie Lemvig^{*1}, Rachel Brouwer², Jayachandra M. Raghava³, Tina Dam Kristensen⁴, Birte Y. Glenthøj⁵, Bjørn H. Ebdrup⁶

¹Center For Neuropsychiatric Schizophrenia Research, ²Vrije Universiteit Amsterdam, ³Center for Neuropsychiatric Schizophrenia Research and Center for Clinical Intervention and Neuropsychiatric Schizophrenia Research, Mental Health Centre Glostrup, University of Copenhagen, Functional Imaging Unit, Copenhagen University Hospital, ⁴Center for Neuropsychiatric Schizophrenia Research and Center for Clinical Intervention and Neuropsychiatric Schizophrenia Research, ⁵Center for Neuropsychiatric Schizophrenia Research (CNSR) and Center for Clinical Intervention and Neuropsychiatric Schizophrenia Research (CINS), Copenhagen University Hospital, Mental Health Center Glostrup, ⁶Centre for Neuropsychiatric Schizophrenia Research (CNSR), Mental Health Centre

Background: Schizophrenia is a highly heritable disorder associated with altered white matter microstructure. White matter microstructure in itself is also heritable, and some evidence suggest a genetic overlap with schizophrenia. Moreover, childhood trauma is a well-documented risk factor for schizophrenia and has been linked to white matter abnormalities. Dissecting the complex relationship between schizophrenia liability, white matter abnormalities and childhood trauma may increase our understanding of the underlying processes of the disorder.

Methods: Participants were recruited nationwide by linkage of two registers in 2011, The Danish Twin Register and The Danish Psychiatric Central Research Register. We included monozygotic (MZ) and dizygotic (DZ) proband pairs concordant or discordant for a schizophrenia spectrum disorder and healthy controls twin pairs (HC) matched on age and sex. Register diagnoses were confirmed using diagnostic SCAN interviews. Diffusion weighted magnetic resonance imaging scans were conducted on a Philips 3.0 T Achieva whole-body scanner with a 32-channel SENSE head coil. Diffusion tensor model was applied to derive measures of fractional anisotropy, axial diffusivity, radial diffusivity, and mean diffusivity. Childhood trauma was examined using the Childhood Trauma Questionnaire, a self-report questionnaire used to assess five domains of trauma: emotional abuse, physical abuse, sexual abuse, emotional neglect, and physical neglect.

In ongoing analyses, we examine the heritability of white matter microstructure in a cohort enriched for schizophrenia using structural equation modelling to quantify the genetic and environmental contributions to the variability. In addition, we examine genetic or environmental associations between white matter abnormalities, childhood trauma and schizophrenia liability. As an exploratory aim we will examine sex differences in these relationships.

Results: 216 twins participated in the study (mean age: 41.7 (SD 10.3), 49% females), including 32 complete MZ proband pairs, 24 complete DZ proband pairs, 29 complete MZ HC pairs and 20 complete DZ HC pairs. Additionally, six twins from proband pairs participated without their siblings. Most patients were diagnosed with schizophrenia (N=39 (61%)), and the mean age of diagnosis was 27.4 (SD 7.4) years. Proband pairs reported higher levels of childhood trauma compared to HC twin pairs, $t(202) = 7.35$, $p < .001$, and patients reported higher levels compared to their unaffected co-twins $t(43) = 2.68$, $p = .010$.

Discussion: This study aims to provide further evidence that altered white matter microstructure in schizophrenia is heritable and associated with schizophrenia liability, suggesting a partially shared genetic etiology. White matter abnormalities may then constitute an endophenotypes for the disorder and provide a basis to explore genes common to white matter and schizophrenia. Furthermore, we aim to provide a basis to understand the underlying processes involved in the associations between childhood trauma, white matter, and

schizophrenia liability. Results from the structural equation modelling will be presented and discussed at the 2024 SIRS conference.

S188. IDENTIFICATION OF SCHIZOPHRENIA BY APPLYING INTERPRETABLE RADIOMICS MODELING WITH STRUCTURAL MAGNETIC RESONANCE IMAGING OF THE CEREBELLUM

Minji Bang^{*1}, Yaewon Park², Sang-Hyuk Lee¹

¹CHA Bundang Medical Center, ²Yonsei University College of Medicine

Background: The cerebellum is involved in higher-order mental processing as well as sensorimotor functions. Although structural abnormalities in the cerebellum have been demonstrated in patients with schizophrenia, neuroimaging techniques are not yet applicable to identify them given the lack of biomarkers. We aimed to develop a robust diagnostic model for schizophrenia using radiomic features extracted from T1-weighted magnetic resonance imaging (MRI) of the cerebellum.

Methods: A total of 336 participants (174 schizophrenia; 162 healthy controls [HCs]) were allocated to training (122 schizophrenia; 115 HCs) and test (52 schizophrenia; 47 HCs) sets. We obtained 2,568 radiomic features from T1-weighted images of the cerebellar subregions. After feature selection using mutual information, a histogram-based gradient boosting classifier was trained. Discrimination and calibration of the model were evaluated. SHapley Additive exPlanations (SHAP) was applied for determining model interpretability.

Results: We identified 17 radiomic features to differentiate participants with schizophrenia from HCs. In the test set, the radiomics model had an area under the curve, accuracy, sensitivity, and specificity of 0.89 (95% confidence interval: 0.82–0.95), 78.8%, 88.5%, and 75.4%, respectively. The model explanation by SHAP suggested that the second-order size zone non-uniformity feature from the right lobule IX and first-order energy feature from the right lobules V and VI were highly associated with the risk of schizophrenia.

Discussion: The cerebellum-focused radiomics model shows its robustness for the diagnosis of schizophrenia. Our results suggest that microcircuit disruption in the posterior cerebellum is a disease-defining feature of schizophrenia and radiomics modeling has potential for supporting biomarker-based decision-making in clinical practice.

S189. INVESTIGATION OF BRAIN WHITE MATTER IN SCHIZOPHRENIA AND SCHIZOTYPAL PERSONALITY DISORDER USING COMPLEMENTARY DIFFUSION IMAGING MODELS

Philip Szeszko^{*1}, Sean Hollander¹, Mary Kowalchuk¹, Sana Aladin¹, Elen-Sarrah Dolgopolskaia¹, Margaret Zhong¹, Sabrina Ng¹, M. Mercedes Perez-Rodriguez¹, King-Wai Chu¹, Margaret McClure¹, Lazar Fleysher¹, Rene Kahn¹, Mehmet Haznedar¹, Chi Chan¹, Kim Goldstein¹, Erin Hazlett¹

¹Icahn School of Medicine at Mount Sinai

Background: Schizotypal personality disorder (SPD) bears a close resemblance to schizophrenia (SZ), but with fewer and attenuated abnormalities, thus representing a

potentially important and understudied intermediate SZ-spectrum phenotype. There is considerable evidence implicating putative white matter (WM) abnormalities in the pathophysiology of SZ, but such studies are limited in SPD and have relied predominantly on diffusion tensor imaging, which is sensitive, but nonspecific. Deficits in social cognition are considered integral to SZ and SPD, but their neurobiological underpinnings are not well understood. In this study diffusion data were obtained and analyzed using 3 complementary approaches to assess WM and examined in relationship with social cognition in the SZ spectrum from healthy to SPD to SZ to investigate differential impairment and mechanisms of risk and resilience to psychosis.

Methods: This study included 42 (18M/24F) healthy controls (HC; mean age=32.4; SD=5.6), 33 (14M,19F) individuals with SPD (mean age=33.0; SD=7.6) and 42 (26M/16F) individuals with SZ or schizoaffective disorder (mean age=34.0; SD=6.7) assessed using the Structured Clinical Interview for DSM-5 who also received the Positive and Negative Syndrome Scale. In addition, all individuals received the Bell-Lysker Emotion Recognition Test (BLERT) and Mayer-Salovey-Caruso Emotional Intelligence Test to assess social cognition. We computed fractional anisotropy (FA) maps using weighted least squares in FSL's Diffusion Toolbox. We used the free water elimination model implemented in DIPY to deconstruct the diffusion signal into an extracellular free water (FW) map, fractional anisotropy (FA-t), axial (AD-t) and radial (RD-t) diffusivity tissue maps. Accelerated microstructure imaging via convex optimization (AMICO) was used to fit the neurite orientation dispersion and density imaging (NODDI) to derive WM compartments corresponding to the orientation dispersion index (OD) reflecting fiber orientation coherence and neurite density (ND) reflecting packing of axons or dendrites. We created a mean skeleton to represent the center of tracts common to the group, which were then projected onto the overall skeleton followed by voxelwise analyses conducted using tract-based spatial statistics. We compared groups on WM measures using one-way ANCOVA with family-wise error correction (p LESS THAN 0.05) while controlling for age and sex. Independent group t-tests were performed in WM regions for which overall group F-tests showed significant differences while maintaining Type-I error.

Results: Individuals with SZ had widespread lower FA compared to HC whereas individuals with SPD had lower FA compared to HC localized to the splenium of the corpus callosum, which was intermediate to and significantly different from SZ and HC (HC GREATER THAN SPD GREATER THAN SZ). Individuals with SZ had greater FW (but not FA-t) compared to SPD and HC within regions encompassing the splenium of the corpus callosum and extending anteriorly throughout cortico-striatal thalamic cortical circuitry. There was widespread higher OD and lower AD-t in SZ compared to both SPD and HC. Post-hoc analysis of the splenium revealed higher OD in SPD compared to HC that was consistent with the pattern observed in SZ. Greater WM abnormalities were associated with worse performance on the BLERT separately in individuals with SZ and SPD but did not correlate with symptom severity.

Discussion: This is the first study to utilize diffusion tensor imaging, free water imaging and NODDI to investigate putative WM microstructure in the SZ-spectrum. The use of these complementary approaches suggests that findings of lower FA in SZ (and to a lesser extent in SPD) may be related to greater dispersion of fiber orientation (involving cell bodies and glial cells), which could provide potential utility as an intermediate phenotype for SZ. Abnormalities in WM fiber orientation may play a role in social cognitive deficits within the SZ-spectrum.

S190. EVALUATION OF THE GLYMPHATIC SYSTEM IN SCHIZOPHRENIA USING H-MRS AND MRI

Ali Abdolizadeh*¹, Edgardo Torres-Carmona¹, Yasaman Kambari¹, Aron Amaev¹, Jianmeng Song¹, Fumihiko Ueno², Teruki Koizumi³, Shinichiro Nakajima⁴, Philip Gerretsen⁵, Ariel Graff-Guerrero⁵

Background: The glymphatic system (GS), a brain waste clearance pathway, has been reported to be disrupted in various neurodegenerative and vascular diseases. Schizophrenia presents features of accelerated biological brain aging with cognitive decline, premature death, and metabolic anomalies since prodromal stages. These features along with the genetic variations of AQP-4 channels and altered cerebral artery pulsation are also present in neurodegenerative diseases with dysfunctional GS. The cumulative evidence suggests that the GS might be impaired in patients with SCZ. Notably, pathologies have been shown to alter the contribution of macromolecules (MM) to 1H spectrum. Accumulation of brain waste including MM, attributed to impaired GS and/or disruption in the clearance of MM to transfer into the ventricular CSF, have been recently observed in patients with idiopathic normal pressure hydrocephalus. Thus, we hypothesized that patients with schizophrenia would show elevated brain MM levels compared to healthy control (HC) participants. Furthermore, diffusion tensor image analysis along the perivascular space (DTI-ALPS) has been introduced as a non-invasive technique to measure glymphatic activity. The DTI-ALPS method assesses interstitial fluid dynamics by evaluating diffusivity of water molecules in the direction of the perivascular spaces of deep medullary veins. A lower DTI-ALPS index reflecting impaired brain waste clearance has been observed in various neurodegenerative diseases. Thus, we hypothesized that patients with schizophrenia would show lower DTI-ALPS index compared to HC participants. As an external validity for our analyses, we hypothesized that age would be positively correlated with MM and negatively correlated with DTI-ALPS indices due to the age-related decline in the glymphatic function. Additionally, we hypothesized an inverse association between MM and DTI-ALPS indices as construct validity for our methods.

Methods: Forty-seven healthy controls (HCs) and 103 patients with schizophrenia were studied. Data included 135 proton magnetic resonance spectroscopy sets (1H-MRS), 96 DTI sets, with 79 participants contributing both. MM levels were quantified in the dorsal-anterior-cingulate-cortex (dACC), dorsolateral-prefrontal-cortex (DLPFC), and dorsal-caudate (point resolved spectroscopy, echo time=35ms). Diffusivity values in the projection and association fibers near the lateral ventricle body were measured to calculate DTI-ALPS indices. General linear models were performed, adjusting for age, sex, and smoking. Correlation analyses examined relationships with age and clinical variables.

Results: MM levels were not different between the entire patient group and HC group. However, left, right, and bilateral DTI-ALPS indices were lower in the entire patient group compared with HC group (P LESS THAN .001). In the HC group, age was positively correlated with dACC MM and negatively correlated with left, right, and bilateral DTI-ALPS indices (P LESS THAN .001). In the entire patient group, illness duration was positively correlated with dACC MM and negatively correlated with the right DTI-ALPS index (P LESS THAN .05). In the entire population, dACC MM and DTI-ALPS indices showed an inverse correlation (P LESS THAN .01).

Discussion: The results showed a positive correlation between age and MM levels and an inverse correlation between age and DTI-ALPS indices, indicating external validity for our analysis. Furthermore, our finding of an inverse correlation between dACC MM and DTI-ALPS indices provides construct validation for our methods. Our results suggest potential disruptions in the GS of patients with schizophrenia. Improving brain's waste clearance may offer a potential therapeutic approach for patients with schizophrenia.

S191. DECODING THE NEURAL REPRESENTATION OF VALUE IN SCHIZOPHRENIA WITH NEGATIVE SYMPTOMS

Reihaneh Forouhandehpour*¹, Guillermo Horga², Clifford Cassidy¹

¹University of Ottawa, ²Columbia University,

Background: Deficits in pleasure and motivation, a prevalent and debilitating aspect of many neuropsychiatric conditions, remain poorly understood at a mechanistic, neural level. Treatments for these deficits are inefficient at best, so understanding the neural mechanisms underlying these deficits is a necessary first step towards the discovery of urgently needed therapies. Among the most common and disabling of this type of deficits are those comprising a portion of the 'negative symptoms' of schizophrenia (SCZ). The existing theories of negative symptoms, including deficits in motivation and pleasure, cast these deficits as arising from abnormalities in the neural representation of value or cost/benefit computations in the presence of spared pleasure responses. Prior work has not clarified these mechanisms likely due to limitations of existing paradigms which could be improved by disentangling multiple aspects of value-based decision making and using multivariate pattern analyses (MVPA), a commonly used means of quantifying value representation. In this fMRI study we used a novel decision-making task (the Movie Shopping Task) in which brain activity is monitored while participants experience pleasurable stimuli (movie trailers) and make value-based decisions (willingness to pay/work to win the movies advertised).

Methods: Participants: We recruited 37 participants, 17 people with schizophrenia (female=4, aged 39±9) with at least moderate levels of negative symptoms and 20 healthy participants (female=4, aged 30±9).

Data collection: Participants underwent MRI scanning using the Siemens Biograph MR PET scanner (3-Tesla) located at The Royal Ottawa Mental Health Centre. For each participant, we collected 10 BOLD fMRI, structural T1 and spin-echo susceptibility images.

fMRI task: Participants performed the Movie Shopping Task. On each trial participants watched a movie trailer and received a \$5 endowment to bid on the movie advertised. High bids increased the odds of winning a copy of the movie (willingness-to-pay (WTP), following the Becker-DeGroot-Marschak (BDM) procedure). Participants then have had another chance to win the movie by making repeated key presses (willingness-to-work (WTW)). There were

90 trials divided into two 70-minute scan sessions. Following each session, two trials were randomly selected for prize payout (1 for auction, 1 for effort).

fMRI data analysis: Standard fMRI preprocessing was performed using Fmrip:20.0.2. For each participant a support vector regression was performed using Nilearn and Scikit-learn relating brain activity to participant responses. For this, the brain activity patterns during the trailer viewing were decoded to predict participant willingness-to-pay. This primary analysis was performed within a value-encoding regions of ventromedial prefrontal cortex (vmPFC) and Ventral Striatum (VSt).

Results: Using MVPA, patterns of brain activity were identified in two groups (healthy controls and schizophrenia patients) and related to willingness-to-pay. Preliminary results showed patterns of brain activity in the ventromedial prefrontal cortex during movie trailer viewing ($t_{19}=4.40$, $p=0.0002$, 1-sample t-tests) significantly predicted financial decisions in the control group. Compared to controls, these patterns of brain activity were significantly less predictive of willingness-to-pay in the schizophrenia group ($t_{35}=2.73$, $p=0.009$, 2-sample t-test)

Discussion: Our preliminary data suggest that value regions in the prefrontal cortex and striatum are not effectively representing value to support decision making in individuals with schizophrenia, consistent with a leading theory of negative symptoms in schizophrenia.

S192. USING EDGE TIME SERIES TO ANALYSE TIME-VARYING FUNCTIONAL CONNECTIVITY IN PSYCHOSIS

Abigail Gee^{*1}, Edward Bullmore², Morgan Sarah²

¹*Kings College London*, ²*University of Cambridge*

Background: Several authors have identified differences in dynamic resting-state functional connectivity in patients with psychotic disorders compared to healthy control subjects (Cattarinussi et al., 2023; Du et al., 2017). However, to date most studies have used methods such as the sliding-window technique, which is sensitive to choice of parameters such as the length of the window and how far the window should move at each step (Savva et al., 2019). In this study edge-centric analysis (Faskowitz et al., 2020) was used to examine differences in time-varying connectivity in patients with psychotic disorders compared to healthy control subjects, which has higher temporal resolution than other methods and unwraps the data without applying additional modelling.

Methods: We analysed resting-state fMRI data from 67 patients with schizophrenia and 81 healthy control subjects using the Center for Biomedical Research Excellence (COBRE) dataset. We then replicated these results in the larger, transdiagnostic Bipolar and Schizophrenia Network for Intermediate Phenotypes (BSNIP) dataset which included 176 healthy controls, 91 patients with bipolar disorder with psychotic symptoms, 96 patients with schizoaffective disorder and 148 patients with schizophrenia (total N=337 patients).

The edge-time series (ETS) for these subjects was calculated by first standardising the regional time series and then calculating the element-wise product between every pair of regions (nodes) in the brain. This unwrapped the functional connectivity correlations and produced a measure of co-fluctuation between each pair of nodes, at each timeframe. The ETS can be aggregated into a single measure of whole brain co-fluctuation by calculating the root sum square (RSS). The “peaks”, or high amplitude frames, were identified by comparing the RSS time series to

an ensemble RSS generated using a null model. A linear regression model was used to compare the peak frequency and amplitude, while controlling for age and sex. Network Based Statistics (NBS) was used to compare the mean co-fluctuation patterns at these timepoints.

Results: In the COBRE dataset, patients with schizophrenia had less frequent peaks ($t = -2.80$, $p = 0.0058$) and lower amplitude peaks ($t = -3.13$, $p = 0.0021$) compared to control subjects. Using NBS, we identified a network that was significantly less activated in patients than in controls during the peak time points, which included connections between the fusiform, lateral occipital, orbitofrontal, post-central, insula, superior temporal and superior parietal regions bilaterally, and the right cingulate and inferior parietal regions. The strongest connections were between the Yeo (Yeo et al., 2011) visual and default mode networks. In the replication BSNIP dataset, collectively the patients with psychotic disorders had significantly less frequent peaks ($t = -4.56$, $p = \text{LESS THAN } 0.001$), but peak amplitude was not significantly different ($t = -1.07$, $p = 0.28$). The peak frequency was also lower in patients with bipolar disorder ($t = -3.34$, $p = \text{LESS THAN } 0.001$) and schizoaffective disorder ($t = -3.71$, $p = \text{LESS THAN } 0.001$) when compared to control subjects. The mean functional connectivity in the previously identified NBS network was significantly lower in BSNIP patients compared to control subjects during peak time points ($t = -4.93$, $p = \text{LESS THAN } 0.001$).

Discussion: These results suggest that whole brain co-fluctuations are less frequent in patients with schizophrenia. Our results replicated in a larger transdiagnostic dataset and were also observed in patients with bipolar disorder and schizoaffective disorder. This is consistent with previous studies which identified that patients with schizophrenia spend significantly less time than controls in states of large-scale connectivity (Miller et al., 2016). We identified specific networks which were less activated in patients compared to controls during the peak timepoints. Further studies looking at early psychosis and antipsychotic naïve patients will be important to build on these results.

S193. CEREBELLAR DYSCONNECTIVITY IN SCHIZOPHRENIA AND BIPOLAR DISORDER IS ASSOCIATED WITH COGNITIVE FUNCTIONING AND PSYCHOTIC SYMPTOMS

Giulia Cattarinussi^{*1}, Annabella Di Giorgio², Fabio Sambataro¹

¹*Department of Neuroscience, University of Padova,* ²*Department of Mental Health and Addictions, ASST Papa Giovanni XXIII,*

Background: Abnormal cerebellar functional connectivity (FC) has been independently implicated in the pathophysiology of schizophrenia (SCZ) and bipolar disorder (BD). However, cerebellar dysconnectivity patterns in these two disorders and their association with cognitive functioning and clinical symptoms have not been fully clarified. In this study, we examined cerebellar FC alterations in SCZ and BD-I and their association with cognitive and psychotic symptoms.

Methods: Resting-state functional magnetic resonance imaging (rs-fMRI) data of 39 patients with SCZ, 43 BD-I, and 61 healthy controls from the Consortium for Neuropsychiatric Phenomics dataset were examined. The cerebellum was parcellated into ten functional systems, and seed-based FC was calculated for each cerebellar system. Principal component analyses were used to reduce the dimensionality of the diagnosis-related FC and cognitive variables. Multiple regression analyses were used to assess the relationship between FC and cognitive and clinical data.

Results: We observed decreased cerebellar FC with the frontal, temporal, occipital, and thalamic areas in patients with SCZ, and a more widespread decrease in cerebellar FC in patients with BD-I, involving the frontal, cingulate, parietal, temporal, occipital, and thalamic regions. SCZ patients presented increased within-cerebellum and cerebellar-frontal FC compared to BD-I patients. In BD-I, memory and verbal learning performances, that were higher compared to SCZ, showed a greater interaction effect of cerebellar FC patterns. Additionally, patterns of increased cortico-cerebellar FC were marginally associated with positive symptoms in patients.

Discussion: Our findings suggest shared and distinct patterns of cortico-cerebellar dysconnectivity in SCZ and BD-I, that are associated with cognitive impairments and psychotic symptoms.

S194. NEURODEVELOPMENTALLY-ROOTED BRAIN EPICENTERS OF EARLY-ONSET SCHIZOPHRENIA

Yun-Shuang Fan^{*1}, Yong Xu², Meike Dorothee Hettwer³, Pengfei Yang¹, Wei Sheng¹, Chong Wang¹, Matthias Kirschner⁴, Sofie Louise Valk³, Huaifu Chen¹

¹University of Electronic Science and Technology of China, ²First Hospital/First Clinical Medical College of Shanxi Medical University, ³Max Planck Institute for Human Cognitive and Brain Sciences, ⁴McGill University

Background: Schizophrenia (SZ) is increasingly conceptualized as a neurodevelopmental disorder with a polygenic architecture, whose pathological process originates early in brain development. However, why, when, and where these alterations take place in the brain is incompletely understood.

Numerous neuroimaging studies have indicated that SZ has pronounced brain structural alterations, typically showing cortical thinning in widespread brain regions. Moreover, SZ-related brain alterations are not randomly distributed but follow the intrinsic network organization of the human connectome. During neurodevelopment, the human brain exhibits systematic patterns of maturation along anatomically and functionally connected regions, referred to as the “connectome”. Despite the many biological and functional benefits for resource sharing facilitated by a refined connectome, pathological perturbations are also suggested to propagate via connections among regions.

To investigate the putative early pathological origins that propagate through the connectome, here called “disease epicenters”, we used early-onset SZ (EOS) patients aged 7-17 as a neurodevelopmental disease model. Based on the assumption that regions with large (or less) deformation are more likely to be interconnected, we identified early disease epicenters of EOS by evaluating the influence of normative functional and structural connectivity profiles on the spatial distribution of cortical thickness alterations in patients.

Methods: Multimodal MRI data of 95 antipsychotic-naïve first-episode EOS patients and demographically-matched 99 typically developing (TD) controls were collected from the First Hospital of Shanxi Medical University. Cortical thickness was extracted from T1-weighted structural data and compared between patients and controls. Following, disease epicenters were determined by correlating cortical thickness abnormalities in patients with normative patterns of structural and functional connectivity separately derived from diffusion tensor imaging and resting-state fMRI data. Next, we tested whether epicenters showed patterns of disease

progression as a function of age of onset by conducting group-specific epicenter mappings. To contextualize these observations within microscale transcriptomic architecture, we applied partial least squares (PLS) analysis to disease epicenters and ex vivo microarray gene expression maps. We further linked gene PLS weights with the differential gene expressions of six major psychiatric disorders including SZ, autism spectrum disorder (ASD), bipolar disorder (BD), major depressive disorder, alcoholism, and inflammatory bowel disease. Finally, we explored the overlap between epicenter-related genes and evolution-related genes located in human accelerated regions (HARs) of the genome, given previous hypothesis on the relationship between brain expansion and SZ.

Results: Disease epicenters of cortical thickness increases in EOS were located in sensorimotor regions subserving visual, somatosensory and motor functions, while the epicenter end of cortical thickness decreases was situated in association regions linked to language, affective and cognitive functions. When comparing epicenter maps from childhood to adolescence, we observed that disease epicenters of EOS shifted and gradually faded out with increased age. Using transcriptomic decoding we observed that disease epicenters of cortical thickening were associated with axon-related genes predominantly expressed in oligodendrocytes; while disease epicenters of cortical thinning were associated with synapse-related genes mainly expressed in excited/inhibitory neurons. These epicenter-related genes were correlated with dysregulated gene expression observed in SZ, ASD and BD. Moreover, the epicenter axis was associated with brain expression maps of evolution-related HARs genes.

Discussion: In this study, we used the epicenter model to identify probable pathological origins in SZ and found a sensorimotor (thickening) to association (thinning) (S-A) pattern of cortical thickness alterations in EOS. The S-A epicenter map aligns with the human neurodevelopmental axis from childhood to adolescence, subserving a cognitive continuum from visual, motor, memory, affective to language. The developmental delay of the sensorimotor pole in SZ might be attributed to excessive expressions of oligodendrocytes-related genes during childhood, while the overgrowth of association regions in SZ could result from excessive expressions of neurons themselves.

The associations between epicenter-related genes and dysregulated genes specific to SZ, ASD and BD suggest that the S-A epicenter axis might serve as a converging pathophysiological framework across multiple complex psychiatric disorders. Moreover, the overlap between epicenter-related genes and HARs genes indirectly supports the “evolution hypothesis”, pointing that these mental illnesses emerge as costly by-products of human evolution.

Our findings suggest developmentally-rooted pathological origins of SZ during brain maturation and may contribute to a better understanding of the etiology of these neurodevelopmental disorders.

S195. CORTICO-STRIATAL WHITE MATTER DYSCONNECTIVITY IN SCHIZOPHRENIA SPECTRUM DISORDER: A MULTISITE HARMONIZED TRACTOGRAPHY STUDY

Hyungyou Park^{*1}, Minah Kim², Kang-Ik Kevin Cho³, Minji Ha⁴, Moonyoung Jang², Sunghyun Park², Jun Soo Kwon⁴

¹Seoul National University College of Natural Sciences, ²Department of Neuropsychiatry, Seoul National University Hospital, ³Brigham and Women's Hospital, Harvard Medical School, ⁴Department of Brain and Cognitive Sciences, Seoul National University College of Natural Sciences

Background: Dysfunction of the striatum and its upstream cortex is central to the pathophysiology of psychosis in its clinical stages. Cortical projections, either segregated or integrated, regulate striatal functions; however, the anatomical disruptions of cortico-striatal connections in psychosis remain poorly understood. The aim of this study was to elucidate alterations in white matter (WM) connectivity between the cerebral cortices and the striatum and their association with symptomatology in different phases of psychosis.

Methods: Datasets were collected from 277 healthy controls (HCs), 162 participants at clinical high risk for psychosis (CHR), 132 patients with first-episode psychosis (FEP), and 173 patients with chronic schizophrenia (CSZ). All participants underwent T1 and diffusion-weighted imaging (DWI) scans at four sites using five different acquisition parameter sets. Retrospective harmonization was performed on all DWI data to minimize site-specific variation, and probabilistic tractography was then used to examine cortico-striatal WM connectivity. Connectivity values showing significant group differences were subjected to regression analysis to demonstrate their associations with symptom severity.

Results: Reduced striatal WM connectivity with the temporal cortex was significantly presented in FEP patients compared to other groups. In CSZ patients, connectivity of executive (dorsal frontal) and occipital cortices was significantly diminished relative to HCs and CHR individuals. Furthermore, decreased executive connectivity was negatively associated with the severity of both positive and negative symptoms in CSZ patients.

Discussion: This study highlights the disrupted striatal WM connectivity in the executive (dorsal) circuit as a significant pathological and symptomatic underpinning in CSZ, along with the involvement of temporal (ventral) connectivity in the early stage of psychosis. Demonstrating specific WM dysconnectivity across phases of psychosis, these findings provide the anatomical basis of cortico-striatal dysfunctions, particularly integration of executive and sensory inputs, throughout the disease progression.

S196. LARGE-SCALE CROSS-DISORDER ANALYSIS OF CEREBRAL CORTICAL PATTERNS IN THE FOUR MAJOR PSYCHIATRIC DISORDERS: A MULTI-INSTITUTIONAL STRUCTURAL MRI IMAGING STUDY

Junya Matsumoto*¹, Masaki Fukunaga², Kenichiro Miura¹, Kiyotaka Nemoto³, Naohiro Okada⁴, Naoki Hashimoto⁵, Kazutaka Ohi⁶, Tsutomu Takahashi⁷, Michihiko Koeda⁸, Hidenaga Yamamori⁹, Michiko Fujimoto¹⁰, Yuka Yasuda¹¹, Satsuki Ito¹, Naomi Hasegawa¹, Shinsuke Koike⁴, Motoaki Nakamura¹², Go Okada¹³, Theo G.M. van Erp¹⁴, Jessica Turner¹⁵, Paul M. Thompson¹⁶, Jun Miyata¹⁷, Shusuke Numata¹⁸, Toshiaki Onitsuka¹⁹, Reiji Yoshimura²⁰, Shin Nakagawa²¹, Yoshiyuki Watanabe²², Norio Ozaki²³, Ryota Hashimoto¹

¹National Institute of Mental Health, National Center of Neurology and Psychiatry, ²National Institute for Physiological Sciences, ³University of Tsukuba, ⁴The University of Tokyo, ⁵Hokkaido University Graduate School of Medicine, ⁶Gifu University Graduate School of Medicine, ⁷University of Toyama Graduate School of Medicine and Pharmaceutical Sciences, ⁸Nippon Medical School, ⁹Japan Community Health Care Organization Osaka Hospital, ¹⁰Osaka University Graduate School of Medicine, ¹¹Life Grow Brilliant Mental Clinic, ¹²Showa University, ¹³Hiroshima University, ¹⁴University of California Irvine, ¹⁵The Ohio State University, ¹⁶University of Southern California, ¹⁷Kyoto University, ¹⁸Tokushima University Hospital, ¹⁹National Hospital Organization Sakakibara Hospital, ²⁰University of Occupational

Background: Psychiatric disorders such as schizophrenia (SZ), bipolar disorder (BD), major depressive disorder (MDD), and autism spectrum disorder (ASD) are operationally classified based on symptoms. While different symptoms separate diagnoses, some symptoms are common to other diagnoses. We hypothesize that some cortical structural alterations detected by neuroimaging also have some commonality between four major psychiatric disorders.

Methods: From 14 institutes, 3,068 healthy subjects, 1,426 patients with schizophrenia, 237 with bipolar disorder, 612 with major depressive disorder, and 206 with autism spectrum disorder participated in the study. A total of 5,549 T1-weighted MRI data were used. Cortical structural analysis was performed with FreeSurfer. For each scanner, the effect sizes of the difference between the healthy comparison subjects and patients with each disorder were calculated using a linear regression model, and after that, they were meta-analyzed. The effect sizes for 68 regions of interest (ROIs) of the DK atlas regions were made into a 68-dimensional vector for each disorder, and the cosine similarity was calculated from the inner product of the vectors between the disorder groups to examine whether the patterns were similar.

Results: The results showed that cortical thickness was generally thinner in individuals with schizophrenia, bipolar disorder, and major depressive disorder, but not in autism spectrum disorder. On the other hand, the cortical surface area of the cortex was found to be smaller in individuals with schizophrenia and major depressive disorder, but not in bipolar disorder. The cortical thickness pattern between each disorder group and healthy comparison subjects was similar in the pair of SZ and BD (0.943), SZ and MDD (0.959), and BD and MDD (0.934). The cortical surface area pattern between each disorder group and healthy comparison subjects was similar in the pair of SZ and MDD (0.945), SZ and ASD (0.867), and MDD and ASD (0.811).

Discussion: The difference in similarity of cortical thickness and surface area patterns in each of the four major psychiatric disorders was revealed. Genetic correlation studies report that schizophrenia, bipolar disorder, and major depressive disorder correlate with each other, while autism spectrum disorder does not so correlate with major depressive disorder and bipolar disorder, which is consistent with the similarity patterns of cortical thickness. Cortical thickness and surface area have also been found to show a negative genetic correlation, and neurobiological mechanisms of cortical thickness and surface area are different. Cortical thickness is affected by myelination, branching, and pruning, while cortical surface area is expanded by the proliferation of neural progenitor cells. Therefore, differences in cortical thickness and surface area patterns may reflect differences in genetic and neurobiological brain pathology.

S197. THE ASSOCIATION BETWEEN CHRONIC TOBACCO SMOKING AND BRAIN ALTERATIONS IN SCHIZOPHRENIA: A SYSTEMATIC REVIEW OF MAGNETIC RESONANCE IMAGING STUDIES

Merel Koster^{*1}, Lilli Mannsdörfer¹, Marieke van der Pluijm¹, Lieuwe de Haan¹, Tim Ziermans², Guido van Wingen¹, Jentien Vermeulen¹

¹Amsterdam UMC, ²University of Amsterdam

Background: The high comorbidity of tobacco smoking in patients with schizophrenia spectrum disorders (SSD) poses a serious health concern, linked to increased mortality and adverse clinical outcomes in SSD patients. The neurobiological mechanisms underlying this comorbidity are complex and not fully understood. Addressing the need for a comprehensive overview of the impact of tobacco use on the neurobiology of SSD, we conducted a systematic review on the association of chronic tobacco smoking in patients with SSD across all magnetic resonance imaging (MRI) modalities.

Methods: PsycINFO, Web of Science, PubMed, and Biosis were searched from inception to the 7th of June 2023. We included all MRI studies in patients diagnosed with a schizophrenia spectrum disorder (SSD) who investigated the effects of current habitual cigarette smoking. Twenty-two studies were included, comprising eight structural and fourteen functional MRI studies.

Results: Structural studies showed widespread independent and additive reductions in grey matter in relation to smoking and SSD. Results of functional studies were mixed, but mainly suggested that smoking might reverse or preserve functional deficits associated SSD. However, it is important to consider that results of five of these studies (83%) stem from the same sample, and studies in other samples do not support this. Interestingly, although results are mixed, smoking appears to have distinct effects on neural dynamics in patients versus controls, advocating for a different neural foundation of tobacco addiction in patients compared to controls. Task-based studies also point towards this, as results mostly imply a unique neural activation pattern in smokers with schizophrenia involving the brain reward system. Thus, functional results indicate a distinct neurobiological mechanism for tobacco addiction in patients with SSD.

Discussion: The nicotinic acetylcholine receptor (nAChR) may play a key role in explaining functional differences observed in smoking between SSD patients and controls. Genetic variations and expression changes of the nAChR associated with SSD could affect neurotransmitter release and thus the brain's response to nicotine, compared to controls. Hence, SSD-related neurobiological alterations at the nAChR level might explain the differential effects of nicotine on the psychotic versus non-psychotic brain. However, the limited number of studies and high sample overlap between these studies make it challenging to conclusively ascertain the nature and extent of smoking's impact on the brain function of patients with SSD. Our findings highlight the need for longitudinal and exposure-dependent studies to differentiate between inherent anatomical and physiological differences and the (long-term) effects of smoking on SSD, and to unravel the complex interaction between smoking and SSD at various disease stages. This could lead to more effective strategies for addressing smoking susceptibility in patients with SSD, potentially improving clinical outcomes.

S198. ALTERED HIPPOCAMPAL SHAPE MORPHOLOGY IN SCHIZOPHRENIA AND AT-RISK MENTAL STATE

Yoichiro Takayanagi^{*1}, Dominic Padova², Can Ceritoglu², Daiki Sasabayashi³, Tsutomu Takahashi³, Shimako Nishiyama⁴, Haruko Kobayashi³, Kazumi Sakamoto³, Misako Torigoe³, Mizuho Takayanagi³, Kyo Noguchi⁵, Noa Tsujii⁶, Michio Suzuki³

¹University of Toyama Graduate School of Medicine and Pharmaceutical Sciences, ²Center for Imaging Science and Institute for Computational Medicine, Department of Biomedical Engineering, ³Department of Neuropsychiatry, University of Toyama Graduate School of

Medicine and Pharmaceutical Sciences, ⁴Centre for Health Care and Human Sciences, University of Toyama, ⁵Department of Radiology, University of Toyama Graduate School of Medicine and Pharmaceutical Sciences, ⁶Department of Child Mental Health and Development, Toyama University Hospital

Background: Hippocampus are involved in a variety of important roles such as memory, learning and emotional regulation. Past studies indicate that in individuals with psychotic disorders such as schizophrenia (SZ) and those with clinical/genetical high risk for psychosis, structural alterations (e.g., volume reduction) of hippocampus as a whole, or those of hippocampal subregions are related to their pathophysiology. In this study, we evaluated the morphological alterations of substructures of hippocampus in subjects with SZ and at-risk mental state (ARMS) by the large deformation diffeomorphic metric mapping (LDDMM), which can analyze shape datasets, and define statistically significant shape variations in the considered structure.

Methods: Eighty-one SZ patients, 56 individuals with ARMS, and 90 healthy controls were recruited at the Toyama University hospital. Subjects underwent a 3-D T1-weighted magnetic resonance imaging (MRI) scanning using a 3-T scanner. Bilateral hippocampi were extracted by FreeSurfer (version 7.2). Using LDDMM, all vertices of each subject's hippocampus were mapped on to the population template. Hippocampus were subdivided into 20 clusters. We measured the logarithm of the surface Jacobian determinant (surface area change), and the logarithm of the ratio of the full Jacobian determinant to the surface Jacobian determinant (normal surface change) for each cluster. A significant negative (positive) log-Jacobian ratio paired with an insignificant or significant negative (positive) log-surface Jacobian in a cluster is interpreted as surface compression (expansion).

The association between the response variable (surface area or normal surface change) and diagnostic group, covarying for age, sex, antipsychotic (AP) medication dosage and log-intracranial volume, was assessed using multiple linear regression. The p-values from 10,000 permutation testing simulations across clusters are corrected for family-wise error rate (FWER) at the 0.05 significance level.

Results: The SZ and ARMS groups exhibited no significant surface area changes. The SZ group displayed expansion normal to the surface in the subiculum (3.7-6.8%) and CA1 (3.7-5.9%) on the right side compared to healthy controls. The ARMS group exhibited a 3.9% normal surface expansion of the subiculum on the right side. Higher doses of AP medication were associated with a compression normal to the surface in the CA1 clusters on the right side. A higher dose of AP was linked to normal surface compression in the left side CA1 region on the dorsal lateral tail of the right hippocampus.

Discussion: A common surface expansion in SZ and ARMS groups found in the right subiculum may be related to the vulnerability to psychosis. Further surface expansion in the right CA1 and subiculum might underlie the manifestation of overt psychotic symptoms. Our data also suggests that human hippocampal tissue could dynamically change, and such changes may be associated with prodromal conditions of psychosis, psychotic symptoms, or antipsychotic medications.

S199. TRANSDIAGNOSTIC TYPES OF FORMAL THOUGHT DISORDER AND THEIR ASSOCIATION WITH GRAY MATTER BRAIN STRUCTURE: A MODEL-BASED CLUSTER ANALYTIC APPROACH

Frederike Stein*¹, Anna Merle Gudjons², Katharina Brosch², Lea Teutenber², Dominik Grotegerd³, Susanne Meinert³, Nina Alexander², Benjamin Straube², Udo Dannlowski³, Tilo Kircher²

¹University of Marburg, ²Department of Psychiatry and Psychotherapy, University of Marburg, Germany, ³Institute for Translational Psychiatry, University of Münster

Background: Formal thought disorder (FTD) is a complex syndrome referring to impaired language and thought processes prevalent in psychotic and affective disorders. Clustering (i.e., identification of new data-driven clinical subtypes) approaches have established latent structures in several syndromes. But there is no data yet on FTD clustering across different disorders and particularly not on their brain structural correlates. Therefore, this study aims to identify transdiagnostic subtypes of FTD using a data-driven approach.

Methods: In N=1,032 patients meeting DSM-IV-TR criteria for Schizophrenia (SZ), Schizoaffective Disorder (SZA), Major Depressive Disorder (MDD), and Bipolar Disorder (BD), a latent profile analysis (LPA) of FTD was performed using ratings of 15 speech and language symptoms from rater-based scales (SANS, SAPS, YMRS, HAM-D). Identified clusters were compared with regard to FTD symptoms and neurocognitive functioning. We explored associations of FTD clusters with gray matter volume (GMV) and cortical surface using T1-weighted magnet-resonance-imaging data and full factorial models in SPM.

Results: LPA revealed four FTD symptom clusters: minimal, poverty, inhibition, and severe. Post-hoc tests showed that clusters differed in neurocognitive functioning. Patients exhibiting severe FTD compared to minimal FTD showed GMV reductions in the right superior and middle frontal gyri. The inhibition cluster showed a GMV reduction in the right inferior and middle temporal gyri, and fusiform gyrus compared with minimal and severe FTD. Sulcal depth was reduced around the left insula, superior temporal sulcus and temporal pole in the poverty cluster, and in the bilateral insula in the severe FTD cluster, both compared to the inhibition cluster. None of the results was related to DSM-IV diagnosis.

Discussion: Our results unravel the clinical heterogeneity of FTD across affective and psychotic disorders. Associations of FTD clusters with neuroanatomical substrates imply language-related GMV and surface structures being involved in thought and language impairment across disorders.

S200. NEURAL CIRCUITRY AND THERAPEUTIC TARGETING OF DEPRESSIVE SYMPTOMS IN SCHIZOPHRENIA SPECTRUM DISORDERS

Julia Gallucci*¹, Ju-Chi Yu², Lindsay D. Oliver², Hajer Nakua¹, Peter Zhukovsky², Erin W. Dickie², Zafiris J Daskalakis³, George Foussias², Daniel M. Blumberger¹, Colin Hawco¹, Aristotle N. Voineskos¹

¹Centre for Addiction and Mental Health, University of Toronto, ²Centre for Addiction and Mental Health, ³University of California San Diego

Background: Conceptual similarities between depressive and negative symptoms complicate biomarker and intervention development. This study employed a data-driven approach to delineate the neural circuitry underlying depressive and negative symptoms in schizophrenia spectrum disorders (SSDs).

Methods: Data from three studies: two neuroimaging studies and a randomized repetitive transcranial magnetic stimulation (rTMS) trial were analyzed (n=157 SSDs) to assess brain-behavior relationships. Partial Least Squares Correlation (PLSC) investigated associations between resting-state functional connectivity and depressive and negative symptoms. Secondary analysis of rTMS trial data (active n=37, sham n=33) were used to assess relationships between

PLSC-derived symptom profiles and treatment outcomes.

Results: PLSC identified three latent variables (LVs) relating functional brain circuitry with symptom profiles. LV1 related a general depressive symptom factor with positive associations between and within Default Mode Network (DMN), Frontoparietal Network (FPN), and Cingulo-Opercular Network (CON). LV2 related negative symptoms (no depressive symptoms) via negative associations, especially between FPN and CON, but also between DMN with FPN

and CON. LV3 related a guilt and early wakening depression factor via negative rather than positive associations to the DMN, FPN, and CON. The secondary visual network had a positive association with general depressive symptoms and negative associations with guilt and negative symptoms. Active (but not sham) rTMS to the bilateral dorsolateral prefrontal cortex (DLPFC)

reduced general depressive but not guilt-related or negative symptoms.

Discussion: Our findings clearly differentiate the neural circuitry underlying depressive and negative symptoms, and even segregated across the two-factor structure of depression in SSDs. These findings support divergent neurobiological pathways of depressive symptoms and negative symptoms in people with SSDs. As treatment options are currently limited, rTMS to the bilateral DLPFC is worth exploring further for general depressive symptoms in people with SSDs.

S201. TEMPORO-FRONTAL MMN IN SCHIZOPHRENIA AND ITS ASSOCIATION WITH COGNITION, CLINICAL SYMPTOMS, AND FUNCTIONAL OUTCOME: AN ESTIMATED SOURCE-LEVEL EEG STUDY

Daisuke Koshiyama^{*1}, Makoto Miyakoshi², Kumiko Tanaka-Koshiyama³, Gregory Light⁴

¹*Department of Neuropsychiatry, The University of Tokyo,* ²*Swartz Center for Neural Computation, University of California San Diego,* ³*Department of Psychiatry, Tokyo Metropolitan Matsuzawa Hospital,* ⁴*Department of Psychiatry, University of California San Diego*

Background: Mismatch negativity (MMN) is a sensitive translational biomarker of schizophrenia. MMN amplitude is reduced in schizophrenia patients and associated with clinical symptoms and impairments in cognitive and psychosocial functioning. While MMN is generated by temporo-frontal neural networks, the contribution of these sources to clinical implications has not been previously fully described. This study aimed to explore the impaired temporo-frontal MMN source relationships to cognition, clinical symptoms and functional outcome in schizophrenia patients.

Methods: We measured MMN using electroencephalography in 449 healthy subjects and 589 schizophrenia patients and evaluated cognition both in the groups and clinical symptoms and functional outcome in patients. We performed source level analyses using EEGLAB.

Results: We demonstrated that estimated temporo-frontal cortical MMN amplitude that was reduced in schizophrenia compared to healthy subjects contributed to wide range of cognition, clinical symptoms and functional outcome in patients. Cognitive function was mainly correlated with MMN in the prefrontal cortex in patients ($r = -0.13$, $p = 0.0087$); MMN in the temporal cortex was correlated with negative symptoms ($r = -0.15$, $p = 0.0050$) and functional outcomes ($r = 0.16$, $p = 0.0035$) in patients. Secondary analyses showed a correlation between hallucination and MMN in the left middle temporal cortex in patients ($r = -0.14$, $p = 0.0092$).

Discussion: It is an interesting and important phenomenon that MMN reflects different clinical symptoms in various regions in the brain. Clarification of the neural mechanisms underlying the MMN source locations detected in this study, in both future clinical and animal studies, will strengthen the utility of MMN as a translational brain marker; this should further pave the way for clarifying the pathophysiology of schizophrenia and the development of novel drugs.

S202. GRAY MATTER COVARIANCE NETWORKS ASSOCIATED WITH SEVERITY OF CLINICAL SYMPTOMS BEFORE AND AFTER SWITCHING TO CLOZAPINE IN PATIENTS WITH TREATMENT-RESISTANT SCHIZOPHRENIA

Wi Hoon Jung^{*1}, Euitae Kim²

¹Gachon University, ²Seoul National University Bundang Hospital

Background: Investigations have demonstrated that patients' use of antipsychotic medications is associated with loss of gray matter volume (GMV) (Lawrie, 2018). In patients with treatment-resistant schizophrenia taking clozapine, reductions in GMV have been observed, especially in cortico-striatal regions such as the caudate and putamen (Mouchlianitis et al., 2016). However, to date, the effects of clozapine on brain alteration, particularly GMV, and its association with clinical symptoms have been primarily investigated using univariate approaches [i.e., voxel or cluster level of inference on GMV maps generated from voxel-based morphometry (VBM)]. Adoption of a multivariate approach – source-based morphometry (SBM), a multivariate extension of VBM utilizing spatially independent component analysis (ICA) to obtain patterns of common GMV variation among participants (hereinafter referred to as “gray matter covariance network”) – may be more powerful in ascertaining the effects of clozapine on brain structures and their association with clinical symptoms (Xu et al., 2009; Kašpárek et al., 2010). Therefore, here we apply SBM to investigate differences between pre- and post-switching to clozapine in gray matter covariance networks and the association between clinical symptom severity (i.e., total PANSS scores) and the networks.

Methods: We recruited patients with schizophrenia ($n = 38$) planning to start clozapine and prospectively investigated changes in symptom severity (total Positive and Negative Syndrome Scale [PANSS] scores) and structural brain, particularly GMV. Of these, data from 29 patients (18 females; age [mean±S.D.], 35.66 ± 10.75 years old; duration of illness, 102.97 ± 100.72 months) were used in the final analysis due to several reasons (e.g., poor image quality or dropout). T1-weighted brain magnetic images were obtained before and 18 weeks after the initiation of clozapine treatment. The VBM method with the Computational Anatomy Toolbox (CAT) was performed to extract GMV images. Next, the SBM method with the GIFT toolbox was applied to the GMV images of all participants to extract 41 gray matter covariance networks. The number of independent components (ICs; i.e., gray matter covariance networks)

was determined by the minimum description length (MDL) algorithm. Based on the stability index (GREATER THAN 0.95) for ICA estimate-clusters, 15 ICs were selected and used for the subsequent statistical analyses. For the fifteen ICs, paired t-tests were performed to investigate which networks' loading coefficients changed significantly after switching to clozapine. We then performed correlation analyses between each network's loading coefficient and total PANSS score over time to determine which networks' loading coefficient was associated with clinical symptom severity (i.e., total PANSS score). Significant threshold was set at p LESS THAN 0.05 and corrected for multiple comparisons using Bonferroni correction (i.e., p LESS THAN 0.0033 = 0.05/15).

Results: We observed a significant improvement in patients' symptoms after treatment with clozapine (total PANSS score before and after treatment [mean±S.D.], 71.45±13.35 and 60.41±7.56; total PANSS score reduction after treatment, 14.18±10.49%, t-value = 3.87; p LESS THAN 0.001). We then observed a significant decrease in the loading coefficients of IC 10, composed of striatum, after switching to clozapine (t = 11.61, p LESS THAN 0.001). We also found that the total PANSS score was positively associated with the loading coefficients of IC 9, composed of thalamus and cerebellum, over time (r = 0.45, p LESS THAN 0.001).

Discussion: Consistent with previous studies, this study confirmed structural brain changes in the striatum after switching to clozapine, showing a reduced loading coefficient of IC 10. This study also showed that patients' clinical symptom severity was related to specific gray matter covariance networks (IC 9), composed with the thalamus and cerebellum. These results provide evidence that the use of clozapine can lead to improvement in clinical symptoms and changes in brain structure in the patients with treatment-resistant schizophrenia. These results also suggest that the severity of clinical symptoms may be related to specific brain structures.

S203. ANTIPSYCHOTIC UTILIZATION PATTERNS IN SCHIZOPHRENIA-SPECTRUM DISORDER PATIENTS BETWEEN 2006 AND 2016 IN HONG KONG: A POPULATION-BASED COHORT STUDY

Catherine Zhiqian Fan¹, Nicole Lau¹, Joe Kwun Nam Chan¹, Corine Sau Man Wong¹, Wing Chung Chang^{*1}

¹The University of Hong Kong,

Background: There are limited studies examining real-world antipsychotic use in patients with schizophrenia-spectrum disorders (SSD). Previous studies found an increasing trend in the antipsychotic prescription rates in SSD in some Western countries, while some studies identified an opposite trend in Asian regions. We aimed to examine antipsychotic utilization patterns and the temporal trends in SSD patients in Hong Kong between 2006 and 2016.

Methods: This population-based cohort study comprised 32,128 patients aged 18 years or above diagnosed with SSD between January 2006 and December 2016. The cohort was extracted from a territory-wide medical record database of public healthcare services in Hong Kong. The annual prevalence was calculated for any antipsychotic, first-generation antipsychotic (FGA) only, second-generation antipsychotic (SGA) only, FGA+SGA (i.e., use of both FGA and SGA in a year), and individual antipsychotic agents. Joinpoint regression analysis was performed to examine temporal changes in antipsychotic prescription. We calculated average annual percent change (AAPC) and annual percent change (APC) to examine the trends during the study period.

Results: Annual prevalence of overall antipsychotic use decreased over the study period with an AAPC of -1.76 ([-1.84–1.68]; p LESS THAN 0.001). There was a steeper decrease in antipsychotic prevalence (APC: -2.40; [-2.83–1.96]; p LESS THAN 0.001) from 2006 to 2008, followed by a lesser degree of decrease (APC: -1.60; [-1.65–1.957]; p LESS THAN 0.001) during 2008-2016. Over 11 years, the use of SGA increased with an AAPC of 8.00 ([7.84–8.17]; p LESS THAN 0.001), while FGA decreased steadily with an AAPC of -7.99 ([-8.63–7.35]; p LESS THAN 0.001). For FGA only and SGA only, the two-joinpoint model is selected as the optimal solution (FGA: wBIC = 1.08; SGA: wBIC = 0.79). A one-joinpoint model is selected for FGA+SGA (wBIC = 1.52). The FGA and SGA prevalence trends intersected at 2010. The FGA+SGA use over the 11 years was relatively stable with an AAPC of 0.85 ([-0.06–1.77]; p=0.07). Risperidone, olanzapine, and haloperidol represented the three most frequently-prescribed individual antipsychotic agents over 11 years. In particular, risperidone (AAPC: 10.11 [9.38–10.86]; p LESS THAN 0.001) and olanzapine (AAPC: 11.97 [9.67–14.32]; p LESS THAN 0.001) showed the sharpest increase in prevalence over the study period.

Discussion: Our results show decreasing antipsychotic prevalence among SSD patients in Hong Kong from 2006 to 2016, which adds supporting evidence to previous findings in other Asian countries. The heterogeneity in antipsychotic prevalence between Asian and Western countries may be explained by differences in cultural context, healthcare system and prescribing practices. Also, we affirm the rising SGA use and declining FGA use across years. Future research should clarify if utilisation patterns regarding the antipsychotic polypharmacy and the usage of long-acting injectable formulation and clozapine for treatment-resistance SSD.

S204. PATTERN OF USE OF CLOZAPINE IN ARGENTINA

Alejo Corrales^{*1}, Federrico Rebok², Manuel Villapriño³, Pedro Damian Gargoloff⁴

¹Argentine National University UNT, ²Hospital "Dr. Braulio A. Moyano", Servicio de Emergencia, ³Departamento de Neurociencias., Facultad de Ciencias Medicas. Universidad de Cuyo, ⁴Hospital "Dr. Alejandro Korn", Servicio de Subagudos Hombres.,

Background: Clozapine is a complex antipsychotic with binding affinities for a wide variety of receptors and pharmacologically active metabolites. Clozapine is currently the most effective antipsychotic in the therapy of Treatment Resistant Schizophrenia (TRS), however clozapine is not effective in 40-70 % of patients with adequate dosage and duration [2]. The term treatment resistance is widely used in the context of psychiatric disorders, but defining it, both conceptually and in practice, has proven to be complex. The concept of TRS remain inconsistent and vary considerably between countries. A number of pharmacological and non-pharmacological approaches for TRS have been evaluated in clinical trials. Despite the efficacy of clozapine in the treatment of TRS, there is some evidence that it is underutilized in patients with this condition. There are a variety of potential reasons for this underutilization, including concerns regarding side-effects and differences in local practice patterns. To date there is no data about pattern of use of clozapine in Argentina.

Objectives: 1-To describe clozapine treatment patterns among psychiatrists in Argentina. 2-To compare if the use is in accordance to international standard. 3-To assess the management patterns of those patients with schizophrenia resistant to clozapine.

Methods: This was an Argentinean study, utilizing an online survey that was conducted between May to August 2020. The questionnaire was administrated through google drive

platform. A cross-sectional questionnaire including 24 common issues related to clozapine therapy divided into three sections, was distributed to psychiatrists treating schizophrenic patients and answered anonymously. The first section includes items detailing professional practices characteristics; the second section includes items asking about the use of clozapine for the treatment schizophrenia, the third section includes items about management of clozapine resistant treatment patients. Statistical analysis was performed using Chi-Square test.

Results: Key findings of the clozapine patten use survey of Argentina show that 57.4% of psychiatric clozapine prescribers work in both public and private practice. The majority of the surveyed psychiatrists manage psychotic disorders (98.2%) as well as mood disorders (94.1%), anxiety disorders (89.9%) and personality disorders (74.2%), and 62.3 % manage 10 or less patients under clozapine treatment. TRS was the main indication of clozapine treatment, however lack of antipsychotic response without full criteria of TRS was also considered an indication. Although, increasing the clozapine plasma levels was considered the first strategy utilized in persistent positive negative and mixed symptoms, clozapine combined with other antipsychotic drugs has also been considered. Augmentation of clozapine with a mood stabilizer was a frequently selected strategy for treating patients with suicidal and aggressive behavior. There is not a statistically significant differences regarding the relationship between the two variables. (Chi Square=1.2, df=1, p GREATER THAN .05).

Discussion: We observe that, like other countries, clozapine is underutilized in patients with TRS. Perhaps the reason of this underutilization is the fact of that there is not a local TRS treatment guideline. The doses and clozapine indication were consistent with international standards. Regarding the management of clozapine fails in TRS, similar strategies were observed in our sample compared to international recommendations.

S205. ROLE OF THE GUT MICROBIOME IN ABSORPTION OF ARIPIPRAZOLE AND QUETIAPINE IN SCHIZOPHRENIA SPECTRUM AND BIPOLAR DISORDER PATIENTS

Anton Scheurink*¹, Jenny Borkent¹, Magda Iouannou¹, Bartholomeus C. M. Haarman², Iris Sommer³

¹University Medical Center Groningen, ²Department of Psychiatry, University Medical Center Groningen, Groningen, The Netherlands, ³UMC Groningen

Background: The human gut microbiome has been recognized as a key factor in absorbing and digesting medicine. Especially the absorption of medicines with low solubility, such as antipsychotic medications (APM), may be influenced by composition of the gut microbiome. It is unclear which features of the microbiome are beneficial or detrimental to APM absorption and transformation. More insight on this topic may optimize current treatments and improve response rates to APM. To this end, we analyzed early data of the gut microbiome and uptake of APM of patients with a schizophrenia spectrum or bipolar disorder.

Methods: We collected stool samples, blood plasma samples and self-reports on oral APM use from patients with a schizophrenia spectrum or bipolar disorder. Stool samples were frozen and stored at -80 degrees Celcius. Microbial DNA was isolated from the stool samples using the QIAamp Fast DNA Stool kit and were shotgun-sequenced using the Illumina Novaseq 6000, by Novogene, UK. Absorption of APM was determined by dividing plasma APM levels by reported APM dose. Analysis was performed in R using Mia within the Bioconductor environment.

Results: 23 patients (4 SSD, 19 BD; 20 female, 3 male) used quetiapine and 11 (10 SSD, 1 BD; 5 female, 3 male) used aripiprazole. Whether participants used aripiprazole or quetiapine did not significantly explain variance between microbiome samples (explained variance = 0.03, $p = 0.28$). BMI near-significantly explained 3 percent of variance between samples ($p = 0.051$). Reported medication intake and plasma concentrations of APM correlated well for both quetiapine (adjusted $R^2 = 0.28$, $p = 0.006$) and aripiprazole (adjusted $R^2 = 0.60$, $p = 0.003$). When corrected for age, we found a negative significant relation between alpha diversity and uptake of aripiprazole (standardized $b = -0.6 \pm 0.2$, $p = 0.04$, model $p = 0.04$, adjusted $R^2 = 0.43$), but not for quetiapine (standardized $b = -0.1 \pm 0.2$, $p = 0.54$, model $p = 0.75$, adjusted $R^2 = -0.07$). However, this relationship between alpha diversity and aripiprazole uptake disappears when also including BMI as a covariate (standardized $b = -0.6 \pm 0.5$, $p = 0.26$, model $p = 0.07$, adjusted $R^2 = -0.46$), which may be due to our small sample size.

Discussion: This pilot projects hints that there may be a link between low gut microbiome diversity and the increased absorption of APM. This is somewhat in line with animal studies reporting that antibiotic depletion of the microbiome leads to increased bioavailability of olanzapine. Interestingly, decreased species diversity is also associated with metabolic problems such as obesity and cardiovascular problems. For now, our study does not include enough data to identify individual responsible bacterial species. Our future analysis of new stool samples may help elucidate these issues and reduce the response rates to current APM.

S206. RISK OF CONGENITAL MALFORMATIONS ASSOCIATED WITH FIRST-TRIMESTER EXPOSURE TO ANTIPSYCHOTICS: A POPULATION-BASED COHORT STUDY

Kwun Nam Chan^{*1}, Krystal Chi Kei Lee², Corine Sau Man Wong³, Wing Chung Chang⁴

¹*Li Ka Shing Faculty of Medicine, University of Hong Kong*, ²*Department of Psychiatry, School of Clinical medicine, LKS Faculty of Medicine, the University of Hong Kong, Hong Kong*, ³*School of Public Health, LKS Faculty of Medicine, The University of Hong Kong*, ⁴*Department of Psychiatry, School of Clinical medicine, LKS Faculty of Medicine, The University of Hong Kong*

Background: A growing number of studies has evaluated the teratogenic effects of antipsychotics. A recent meta-analysis revealed that first-trimester exposure to second-generation antipsychotics (SGA) was associated with increased risk of major congenital malformations. Yet, prior studies were generally based on small sample size and did not take into consideration important confounding effect of maternal physical and psychiatric morbidities. This study aimed to examine the risk of major and organ-specific congenital malformations among infants exposed to SGA, first-generation antipsychotics (FGA) and commonly-prescribed antipsychotic agents.

Methods: This population-based cohort study comprised 465,069 pregnant women (of which 419 and 420 redeemed ≥ 1 prescription of SGA and FGA during first-trimester, respectively) aged 15–50 years who gave a singleton livebirth or stillbirth between January 2003 and December 2018, using a territory-wide medical-record database of public healthcare services in Hong Kong. Propensity-score (PS)-adjusted logistic regression analyses were conducted to examine the risk of congenital malformations following first-trimester exposure to antipsychotic classes (SGA and FGA), and six most frequently-prescribed individual antipsychotics. Exploratory analyses were also performed to evaluate dose-response

relationship by assessing associations of dose levels (i.e., high, low and unexposed) of individual antipsychotics with the risk of major congenital malformations.

Results: Prevalence of any major malformations was 4.9% (95% CI: 4.9%-5.0%) in unexposed infants, 9.1% (6.7%-12.3%) in SGA-exposed infants, and 6.2% (4.3%-9.0%) in FGA-exposed infants. Exposure to SGA (adjusted odds ratio: 1.59 [95% CI: 1.03–2.38]), but not FGA (1.29 [0.79-2.02]), was associated with an increased risk of major malformations. Among individual antipsychotics, quetiapine (1.99 [1.15–3.29]) and risperidone (in sensitivity analysis on women with psychiatric-diagnosis; 3.81 [1.49–9.77]) were associated with elevated rates of major malformations. Analyses stratified by dose levels revealed that only high-dose quetiapine exposure was related to increased risk of major malformations (2.51 [1.14–4.95]). A significant association between SGA and an increased risk of respiratory-system anomalies was noted (5.00 [1.05–15.46]). Generally, the significant results were inconsistent across sensitivity analyses, precluding firm conclusions.

Discussion: Our study observed a small increased risk of major malformations associated with SGA and quetiapine in a predominantly Chinese population, which was not robustly affirmed in sensitivity analyses. On the whole, our findings did not provide strong evidence of the association of prenatal antipsychotic exposure and increased risk for congenital malformations. Research with large sample size clarifying comparative safety of individual antipsychotics on specific malformations is warranted to provide clinically-useful data on the risk of teratogenicity that can better inform the complex decision-making in the maintenance or discontinuation of antipsychotic treatment during early pregnancy.

S207. A META-ANALYSIS OF AUGMENTATION THERAPY WITH SEROTONIN1A RECEPTOR PARTIAL AGONISTS ON COGNITIVE FUNCTION IN SCHIZOPHRENIA

Tomiki Sumiyoshi*¹, Ayumu Wada², Andrew Stickley², Yuma Yokoi², Risa Yamada²

¹*Department of Preventive Intervention for Psychiatric Disorders, National Institute of Mental Health, National Center of Neurology and Psychiatry*, ²*National Center of Neurology and Psychiatry*

Background: The use of serotonin (5-HT)_{1A} receptor partial agonists (5-HT_{1A}- PAs) of the azapirone class (e.g., buspirone and tandospirone) as an add-on therapy was associated with beneficial effects on psychotic symptoms, especially positive symptoms, in patients with schizophrenia (Yamada et al. IJNP 2023). By conducting a systematic review and meta-analysis, we evaluated whether augmentation with 5-HT_{1A}-PAs would improve specific domains of neurocognitive function in schizophrenia patients.

Methods: A literature search was performed from 1987 to May 2023 to identify randomized controlled trials. The standardized mean difference (SMD) with 95% confidence intervals (CI) was calculated when there were 2 or more studies (Yamada et al. Schizophr Res Cogn 2023).

Results: Random-effects model meta-analyses revealed that add-on therapy with buspirone or tandospirone had a significant beneficial effect on attention/processing speed (SMD = 0.37, 95% CI = 0.12 to 0.61). By contrast, these 5-HT_{1A}-PAs did not have a significant effect on verbal learning (SMD = 0.08, 95 % CI = 0.31 to 0.47) or working memory (SMD = 0.15, 95 % CI = 0.09 to 0.39). Regarding executive functions (Wisconsin Card Sorting Test), positive but non-significant results were seen with the category number (SMD = 0.26, 95 % CI = 0.81

to 1.32), while non-significant effects were noted for percent preservation errors (SMD = 0.10, 95 % CI = 0.53 to 0.33).

Discussion: These findings support the idea that some compounds that stimulate 5-HT1A receptors provide an effective pharmacologic enhancer for a key domain of cognition in patients with schizophrenia. Further studies with various types of 5-HT1A agonists, e.g., brexpiprazole and ulotaront, are warranted to examine the potential cognitive efficacy of optimally stimulating these receptors.

S208. EFFECTS OF CANNABIDIOL ON GLUTAMATE, PERFUSION AND EMOTION PROCESSING FMRI IN PSYCHOSIS RISK

Cathy Davies^{*1}, Matthijs Bosson², Daniel Martins¹, Robin Wilson¹, Elizabeth Appiah-Kusi¹, Grace Blest-Hopley¹, Paul Allen¹, Fernando Zelaya¹, David Lythgoe¹, Michael Brammer¹, Jesus Perez³, Philip McGuire⁴, Sagnik Bhattacharyya¹

¹*Institute of Psychiatry, Psychology and Neuroscience, King's College London*, ²*Brain Center Rudolf Magnus, University Medical Center Utrecht*, ³*CAMEO Early Intervention Service, Cambridgeshire and Peterborough NHS Foundation Trust*, ⁴*University of Oxford*

Background: The pathophysiology driving psychosis onset is thought to involve dysfunction in a hippocampal-midbrain-striatal circuit. Evidence suggests that patients at Clinical High Risk (CHR) for psychosis show altered levels of hippocampal glutamate, elevated hippocampal/striatal perfusion, and emotion-processing deficits associated with aberrant neural responses (particularly to fear-related stimuli) in these regions. Cannabidiol (CBD) is a non-intoxicating constituent of the cannabis plant with antipsychotic and anxiolytic properties. Previous work suggests that CBD modulates hippocampal glutamate, cerebral perfusion and activation within the mediotemporal cortex and striatum during various emotional/cognitive paradigms. However, whether CBD has ameliorative effects on these parameters in CHR individuals remains unclear.

Methods: Using a randomised, double-blind, parallel-group design, 33 CHR patients were randomised to a single oral dose of CBD (600 mg) or placebo. Healthy controls (n=19) were studied under identical conditions but did not receive any drug. Participants underwent 3T MRI during a fearful face-processing paradigm (fMRI) to measure mediotemporal and striatal activation, arterial spin labelling (ASL) to examine hippocampal perfusion, and 1H-MRS to measure hippocampal glutamate. Differences related to the CHR state (CHR-placebo vs controls), effects of CBD (CHR-placebo vs CHR-CBD), and linear relationship analyses (i.e. for CHR-placebo GREATER THAN CHR-CBD GREATER THAN controls, or vice versa) were examined for all three imaging modalities.

Results: During fear processing, relative to controls the CHR-placebo group showed significantly greater activation in the parahippocampal gyrus but lower striatal activation (all pcorr LESS THAN .01). Within these regions, activation in the CHR-CBD group was significantly intermediate between that of CHR-placebo and healthy controls (all pcorr LESS THAN .01). The CHR-placebo group also had significantly greater hippocampal perfusion bilaterally vs controls (both pFWE LESS THAN .01), and a significant linear relationship was identified in a small right hippocampal cluster (pFWE=.035), such that CHR-placebo GREATER THAN CHR-CBD GREATER THAN controls. Finally, CHR-placebo patients had significantly lower hippocampal glutamate relative to controls (p=.015), and a significant linear relationship was observed across groups, such that controls GREATER THAN CHR-CBD

GREATER THAN CHR-placebo ($p=.031$). However, direct CBD vs placebo effects were only observed for the fMRI results.

Discussion: Our findings suggest that CBD may partially modulate function of the neural circuitry implicated in aberrant emotion processing and psychosis onset, and in a direction indicative of normalisation. These results add to evidence that CBD may be a promising novel therapeutic for CHR patients. Further (within-subject) research is required to replicate these findings and examine whether acute neurofunctional/physiological effects translate into clinical efficacy after a period of treatment.

S209. ANTIPSYCHOTICS AND BRAIN INSULIN ACTION: A DOUBLE-EDGED SWORD

Sally Wu^{*1}, Laurie Hamel², Sandra Pereira², Roger Raymond², Raghunath Singh², Emily Au¹, Dan Li³, Jose Nobrega², Adria Giacca⁴, Ariel Graff², Gary Remington², Margaret Hahn², Sri Mahavir Agarwal²

¹*Institute of Medical Science, University of Toronto*, ²*Centre for Addiction and Mental Health (CAMH)*, ³*University of Toronto*, ⁴*Department of Psychiatry, University of Toronto*

Background: Antipsychotics (APs) are the cornerstone of treatment in schizophrenia but are associated with an increased risk of type 2 diabetes. While the field has primarily focused on metabolic effects induced by high liability agents such as clozapine and olanzapine, all APs have similar risk propensity for diabetes. APs have a highly heterogeneous receptor affinity, and all of them are, without exception, dopamine 2 receptor (D2R) antagonists. An interesting body of work suggest that the cross talk between central insulin and dopamine facilitates the antipsychotic effects of APs. However, this effect may be diminished with chronic treatment of APs as these agents induce central and peripheral insulin resistance, resulting in impairments in both metabolic health and cognition. Previous studies examining the effects of APs on insulin and glucose regulation has primarily focused on peripheral pathways. However, insulin receptors and insulin-responsive glucose transporters are widely distributed throughout the brain. Aberrant brain insulin signaling is posited to lie at the crossroads of metabolic and cognitive disorders, and evidence suggests that the central nervous system (CNS) is involved in AP-induced metabolic dysregulation. Our pilot data using [1-14C]2-deoxy-D-glucose (2DG) autoradiography suggests that olanzapine attenuates insulin-mediated glucose uptake across multiple regions in the brain. However, it is not known whether this effect is limited to olanzapine, or if other APs induce similar changes in brain insulin action. Thus, we want to further explore whether this is a class or D2R antagonism driven effect by using other APs such as haloperidol (HAL) (a D2R only antagonist) and raclopride (RAC) (a selective D2R antagonist).

Methods: 2DG autoradiography procedures were used to measure cerebral glucose uptake alongside a central infusion of insulin or vehicle into the third ventricle. Male rats were pretreated with HAL (0.25 mg/kg) or RAC (0.3 mg/kg) or vehicle. Each dose was chosen to reflect clinically relevant D2R occupancy (GREATER THAN 70%). Groups included (central-peripheral) vehicle-vehicle ($n = 6$), insulin-vehicle ($n = 6$), vehicle-HAL ($n = 6$), insulin-HAL ($n = 6$), vehicle-RAC ($n = 5$), and insulin-RAC ($n = 5$). Regions of interests for analysis included the frontal cortex, nucleus accumbens, hypothalamus, hippocampus, amygdala, cerebellum, and dorsal vagal complex, based on their role in metabolism, energy homeostasis,

and cognition. Regional tissue radioactivity was quantified on coded films using the MCID Elite system as an index of glucose uptake.

Results: Intracerebroventricular (ICV) insulin significantly increased cerebral glucose uptake in all regions of interests compared to ICV vehicle. This effect was attenuated by HAL and RAC, such that the levels of cerebral glucose uptake in the insulin-HAL and insulin-RAC groups were comparable to the control groups. Interestingly, the effect of HAL and RAC were not as potent compared to olanzapine, where in the insulin-olanzapine the level of cerebral glucose uptake was completely abolished.

Discussion: Acute dosing of HAL and RAC can induce central insulin resistance in the brain beyond areas responsible for metabolism and energy homeostasis, including areas involved in cognition. Our findings provide corroborating evidence that strengthen the role of the CNS in modulating peripheral AP-induced metabolic effects. Notably, our results demonstrate that all classes of APs may induce cerebral insulin resistance, and the culprit may be the effect of D2R antagonism. This knowledge may aid in translation to humans by suggesting treatment interventions targeting these mechanisms.

S210. BRAIN STRUCTURAL CHANGES AFTER ONE-WEEK EXPOSURE TO ANTIPSYCHOTICS IN HEALTHY VOLUNTEERS

Pierluigi Selvaggi^{*1}, Martin Osugo¹, Uzma Zahid¹, Thomas Whitehurst², Ellis Chika Onwordi², Ben Statton², Tobias Wood¹, Valeria Finelli¹, George Chapman², Robin Murray¹, Tiago Reis Marques¹, Mitul A Mehta¹, Oliver Howes¹

¹*Institute of Psychiatry, Psychology and Neuroscience, King's College London*, ²*Psychiatric Imaging Group, MRC London Institute of Medical Sciences, Hammersmith Hospital*

Background: The effect of antipsychotics on brain structure is still hotly debated. Studies in patients reported mixed results with difficulties in separating disease and treatment effects. Single-dose studies in healthy volunteers (HV) have shown no change or reduction in striatal volumes. Pre-clinical studies in rodents reported reduced cortical and increased striatal volumes. In addition, some authors have questioned whether changes or differences in brain volumes assessed with MRI might represent epiphenomena of different biochemical or physical effects not necessarily linked with the pathophysiological process. Nonetheless, determining the effects of antipsychotics on brain physiology is critical to the understanding of biological mechanisms driving their clinical efficacy side effects.

Methods: A total of 50 HV (28 females, mean age 26.7 years) completed a double-blinded, randomized, crossover, placebo-controlled study composed of two arms. In Arm 1 participants (N= 25, 14 females) received either amisulpride 400mg or placebo daily for seven days. In Arm 2 (N= 25, 14 females) participants received either aripiprazole 10mg or placebo daily for seven days. MRI was performed at the end of each treatment period. The MP2RAGE sequence was used to derive T1-weighted (T1w) images and T1 maps. T1 mapping is more informative on brain microstructure as compared with standard T1w images as it can measure the magnetic resonance properties of the tissue (e.g., T1 relaxation time) quantitatively. T1w-images were processed using FreeSurfer to extract brain volume, cortical thickness, and cortical surface. We focused on striatal changes in light of earlier results. Eight striatal ROIs were selected from the subcortical parcellation available in FreeSurfer to extract volume and T1 signal. In each ROI, the main effects of the condition (i.e., drug or placebo) within each arm and the condition-by-arm interaction were tested by applying FDR correction. The same analysis was also performed

on cortical thickness and surface. Also, both T1w images and T1-maps entered a whole-brain voxel-wise analysis in FSL randomise. In all analyses order (i.e., drug first or placebo first) was used as a covariate of no interest.

Results: The ROI analysis in the striatum revealed an increased volume in the left putamen after amisulpride (pFDR= 0.042) and in the right putamen after aripiprazole (pFDR= 0.016). No other main effects or condition-by-arms interaction were found in the ROI analysis (all pFDR GREATER THAN 0.291). No main effects of condition or condition-by-arms interaction were found in ROI analysis on T1 maps (all pFDR GREATER THAN 0.253). We did not find differences between amisulpride/aripiprazole and placebo or condition-by-arm interactions in the whole-brain voxel-wise analyses. No main effects or interactions were found on cortical thickness and surface metrics.

Discussion: These results are in line with pre-clinical and longitudinal studies in patients reporting increased striatal volume after exposure to antipsychotics. The lack of an effect on quantitative T1 maps may suggest that the volumetric changes observed here and in previous studies do not reflect actual changes in brain tissue. It might be possible that other factors (e.g., peripheral effects or changes in water content) could explain changes in brain volume. Another possible interpretation is that short-term exposure produces small-to-negligible effects, and that long-term exposure is needed to produce tissue remodelling. Taken together these results encourage further investigations aimed at clarifying whether changes detected with MRI after short- and long-term antipsychotic exposure are associated with brain tissue microstructural changes or are rather only "apparent" morphometric changes.

S211. THE EVER-GROWING CASE FOR CLOZAPINE IN THE TREATMENT OF SCHIZOPHRENIA: AN OBLIGATION FOR PSYCHIATRISTS AND PSYCHIATRY

Robert Bittner*¹, Mishal Qubad²

¹*University Hospital Frankfurt, Goethe University,* ²*Goethe University*

Background: Like no other medication, clozapine epitomizes two fundamental challenges in the pharmacotherapy of schizophrenia: a dearth of innovation, and insufficient implementation of established treatments. Clozapine remains the most effective antipsychotic and the only drug approved for treatment-resistant schizophrenia (TRS) – not least, because the neurobiological underpinnings of its unique efficacy continue to elude researchers. Consequently, clozapine should be widely used for TRS but also for certain non-TRS patients. Yet, only a fraction of suitable patients actually receives clozapine – often years after treatment resistance becomes evident. Analyzing the causes and consequences of this problem is crucial for substantially improving the quality of care for TRS patients.

Methods: In this review, we contrast the literature advocating its safe and effective use with current evidence regarding the causes and consequences of clozapine underutilization. We based our review on a Medline and Google Scholar search for all relevant topics, selecting both relevant individual clinical studies as well as meta-analyses and reviews. We included all articles that were published until January 2023. We searched for publications containing the following MeSH terms: treatment-resistant schizophrenia [AND] criteria, treatment-resistant schizophrenia [AND] treatment, treatment-resistant schizophrenia [AND] neurobiology, clozapine [AND] xx, with xx reflecting the topic we aimed to focus at that timepoint (e.g. side effects, neutropenia, agranulocytosis, hypersalivation, pneumonia, myocarditis, withdrawal, discontinuation, metabolic syndrome, gastrointestinal side effects, sedation, mortality,

pharmacokinetics, pharmacodynamics, clinical effects, clozapine-resistant schizophrenia, shared decision-making, patient satisfaction).

Results: Clozapine has a singular impact on key mediators of poor illness outcome. It is the most effective drug for improving positive symptoms and global psychopathology both in the most severely ill and in the full spectrum of patients. Its effects on negative and depressive symptoms rank among the best of all antipsychotics. Clozapine shows superior anti-suicidal efficacy and the largest reduction of aggression. It also decreases the risk for new and persisting co-morbid substance use disorders (SUDs). Additional long-term benefits include improved treatment adherence and reduced rehospitalization rates. Furthermore, clozapine is the most effective antipsychotic for reducing all-cause mortality in TRS. Delaying clozapine treatment has a negative impact on long-term outcome. Patients' experience with clozapine treatment is largely positive despite a comparatively high rate of side effects. Patients prefer clozapine, while psychiatrists regard it as a burden due to concerns regarding safety and side effect management. Shared decision-making, which increases the likelihood of a clozapine recommendation, is not routinely used, possibly due to stigmatization of TRS patients.

Discussion: Compared to all other available pharmacological treatment options the broad beneficial impact of clozapine on patients' life remains second to none. The mortality-reducing effects of clozapine alone warrant its regular use. Therefore, psychiatrists must not exclude patients from the decision regarding a clozapine trial by not even offering it. Rather, they have a clear obligation to align their actions more closely with the existing evidence and patients' needs and to facilitate the timely initiation of clozapine.

S212. EFFECTS OF ANTICHOLINERGIC BURDEN ON FUNCTIONING IN FIRST-EPISODE PSYCHOSIS

Agnes Belkacem^{*1}, Katie Lavigne², Ridha Joober³, Ashok Malla³, Jai Shah⁴, Martin Lepage³

¹McGill University, ²McGill University; Douglas Mental Health University Institute; Montreal Neurological Institute-Hospital, ³Douglas Mental Health Research Institute, ⁴Douglas Mental Health University Institute

Background: Treatment for a first-episode of psychosis (FEP) typically begins with antipsychotics. However, these medications and others (e.g., antidepressants) may have an anticholinergic burden, i.e., an accumulation of medications that block the cholinergic system. Recent evidence suggests that anticholinergic burden is associated with cognitive deficits and some studies have reported an association between the two. However, very few have examined a link between the two in the early stages of the disease, whether cross-sectionally or longitudinally. We hypothesized that FEP patients with the highest anticholinergic burden would show the poorest levels of functioning compared to those in the low anticholinergic burden group at program entry (three months after admission). Longitudinally, we expected all groups to improve at month 12, but the high anticholinergic burden group would still have the lowest level of functioning.

Methods: Patients (n=444) completed the Social and Occupational Functioning Assessment Scale (SOFAS) at both timepoints. They were divided into two groups; low anticholinergic burden (n=349) and high anticholinergic burden (n=95), based on a Drug Burden Index (DBI) cutoff of 1.

Results: Our results suggest that patients exposed to a high anticholinergic burden have reduced functioning compared with those with a low anticholinergic burden ($F(1,439)=4.40$, P

LESS THAN 0.05). Our longitudinal results indicate that although functioning may improve over time, patients exposed to a high anticholinergic burden have reduced functioning compared to those in the other group ($\chi^2=5.52$, $df=1$, P LESS THAN 0.05).

Discussion: Our study highlights the need to properly assess exposure to anticholinergic burden when prescribing medication for psychosis.

S213. EXPOSURE TO CHRONIC STRESS PRODUCES MOTIVATIONAL ANHEDONIA AND SOCIABILITY DEFICITS IN RATS: RESTORATIVE PROPERTIES OF CHRONIC LURASIDONE TREATMENT

Marco Andrea Riva^{*1}, Veronica Begni¹, Alessia Marchesin¹, Eleonora Corridori², Sara Salviati², Simona Scheggi²

¹University of Milan, ²University of Siena

Background:

Exposure to stress is one of the most important factors for the development of mental disorders. Indeed, exposure to stress may interfere with an array of neurobiological mechanisms leading to the manifestation of selected psychopathologic domains that represent an important target for pharmacological interventions. With this respect, stress-based animal models are instrumental in investigating the occurrence of specific behavioral deficits, their molecular underpinnings as well as the potential impact for drug treatment. As an example, we have previously demonstrated that chronic treatment with lurasidone, a multi-receptor antipsychotic drug, is able to normalize consummatory anhedonia in the chronic mild stress model [1] [2]. In the present study, we used two different stress paradigms to investigate the ability of lurasidone to ameliorate motivational anhedonia as well as reduced sociability, which represent key psychopathologic domains that are shared between different disorders and that have a strong impact on patient functioning.

Methods: In the first experimental paradigm, Sprague-Dawley male rats were exposed to an unavoidable chronic stress (UCS) protocol for 3 weeks in order to disrupt the motivation to acquire a reward-directed behavior [3]. Motivational anhedonia was assessed using sucrose self-administration in operant chambers provided with one active lever delivering a sucrose pellet. Rats were tested in fixed-ratio (FR) sessions (FR-1 and FR-5) as well as in the progressive ratio (PR) task. After having established the behavioral deficit, the animals ($n=10$ /experimental group) were then divided into two subgroups that continued (or did not) stress exposure and received vehicle or lurasidone (3 mg/kg) once daily. Next, to verify their reactivity to avoidable aversive stimuli, stressed animals were exposed to the escape test. In the second paradigm, we used the social defeat stress model to investigate motivational deficits as well as to study sociability impairment as a consequence of stress exposure and the modulation by chronic lurasidone treatment.

Results: We confirmed that exposure of rats to UCS was able to produce a significant reduction in the competence to acquire self-administration, at FR1 and FR5 schedules. Moreover, UCS rats show impaired motivation in the progressive ratio protocol (-50% in breaking point, p LESS THAN 0.001 vs. control/vehicle). After two weeks of drug administration, lurasidone treatment at the lowest dose (3 mg/kg) was able to rescue the motivation in stressed rats, an effect that was not observed using the highest dose (10 mg/kg) of the antipsychotic drug. Conversely, when we investigated the emotional reactivity to negative stimuli, we found that

animals exposed to UCS and treated with vehicle showed a significant impairment of the escape competence and that such changes were restored by chronic treatment with lurasidone at both doses. The social defeat model was also associated with motivational deficits that were improved by lurasidone (3 mg/kg), a treatment that was fully effective in restoring sociability deficits in rats exposed to stress.

Discussion: Conclusions

In summary, these novel data provide support for the ability of lurasidone treatment to ameliorate different psychopathologic domains, including impaired motivation and reduced sociability, which represent core elements for the disability associated with mental disorders.

S214. EFFECTS OF ALSTONINE ON MK-801-INDUCED BEHAVIORS IN ZEBRAFISH

Leonardo Bastos^{*1}, Matheus Gallas-Lopes¹, Thailana Stahlhofer-Buss¹, Stefani M. Portela¹, Rafael Chitolina¹, Carlos G. Reis¹, Sofia Z. Becker¹, Maurice M. Iwu², Angelo Piato¹, Elaine Elisabetsky¹, Ana P. Herrmann¹

¹*Universidade Federal do Rio Grande do Sul*, ²*Bioresources Institute of Nigeria*

Background: Alstonine (ALS) is an indole alkaloid identified as the major compound of a plant-based remedy traditionally used in Nigeria to treat mentally ill patients. Studies using mice showed that ALS behaves as an antipsychotic, counteracting behavioral phenotypes associated with positive (MK-801-induced hyperlocomotion and apomorphine-induced stereotypy), negative (MK-801-induced social withdrawal) and cognitive (MK-801-induced induced memory deficits) symptoms of schizophrenia. However, the external validity of these findings is limited by the use of a single model organism, justifying the need to further explore the therapeutic potential of ALS. This study aimed to evaluate the effects of acute administration of ALS on MK-801-induced behavioral phenotypes in zebrafish (*Danio rerio*).

Methods: 120 male and female adult short-fin wild-type zebrafish (4 months old, 300-500 mg) were used. Fish were allocated to the treatment groups (n=15) using block randomization to counterbalance baseline characteristics (sex, home tank, and day of testing). Animals were individually exposed to 200 mL of water or ALS at 2.5, 5 or 10 mg/L for 20 min, and then exposed to either water or 5 μ M MK-801 for another 20 minutes. Social preference, locomotion, and stereotypic behavior were assessed using the social preference (SPT) and the open tank (OTT) tests. The ANY-Maze software was used for outcome assessment by researchers blinded to the treatment groups. Data were analyzed by two-way ANOVA, with ALS pretreatment and MK-801 treatment as the main factors; Bonferroni post hoc test was applied as appropriate. All procedures were approved by the ethics committee at Universidade Federal do Rio Grande do Sul (no. 48858).

Results: In the SPT, MK-801 induced social withdrawal and hyperlocomotion, as indicated by a decrease in the time spent in the interaction zone (MK-801 main effect: $F_{1,112} = 28.73$, $p=0.0001$) and an increase in the total distance traveled (MK-801 main effect: $F_{1,112} = 12.05$, $p=0.0007$) in comparison to the control group. Unexpectedly, 5 and 10 mg/L ALS also

decreased the time spent in the interaction zone (ALS main effect: $F_{3,112} = 4.327$, $p=0.0063$) in comparison to the control group. Moreover, 5 mg/L ALS before MK-801 increased the number of crossings as compared to MK-801 alone (interaction effect: $F_{3,112} = 3.327$, $p=0.0222$). In the OTT, MK-801 decreased the total distance traveled (MK-801 main effect: $F_{1,112} = 40.23$, $p \text{ LESS THAN } 0.0001$), absolute turn angle (MK-801 main effect: $F_{1,112} = 113.2$, $p \text{ LESS THAN } 0.0001$), and clockwise rotations (MK-801 main effect: $F_{1,112} = 34.35$, $p \text{ LESS THAN } 0.0001$), while increased the time spent immobile (MK-801 main effect: $F_{1,112} = 61.34$, $p \text{ LESS THAN } 0.0001$). In this test, ALS was devoid of effects in all parameters. No sex effects were observed, so data were pooled together.

Discussion: Acute exposure to MK-801 induced behavioral alterations of translational relevance to schizophrenia in zebrafish. However, contrasting with results consistently obtained in rodents, ALS did not counteract MK-801-induced behavioral alterations. ALS exerted an effect in the opposite direction than expected in the SPT, decreasing social preference and increasing locomotor behavior. The meaning of such biological effects remains to be elucidated by comparing ALS to known antipsychotics in the same behavioral assays. We tested a limited range of ALS concentrations based on back-calculations from rodent doses, so we cannot rule out that other concentrations could yield different results. These findings highlight the need for a wider characterization of ALS effects as a potential antipsychotic candidate in zebrafish.

Jaguar Health Inc. provided financial support for this work.

S215. EFFECTS OF MK-801 ON SHOAL COHESION IN ADULT ZEBRAFISH

Amanda Patelli-Alves^{*1}, Matheus Gallas-Lopes¹, Thailana Stahlhofer-Buss¹, Stefani M. Portela¹, Angelo Piato¹, Ana P. Herrmann¹

¹*Universidade Federal do Rio Grande do Sul*

Background: Schizophrenia is a heterogeneous neurodevelopmental disorder characterized by positive, negative, and cognitive symptoms. Despite its unclear pathophysiology, several studies implicate a dopaminergic hyperactivity in subcortical circuits associated with the hypofunction of NMDA glutamate receptors in GABAergic interneurons. MK-801, an NMDA receptor antagonist, is frequently used to recapitulate behavioral phenotypes relevant to schizophrenia symptoms in preclinical assays. Zebrafish (*Danio rerio*) is a model organism widely used in neuroscience research as an alternative to rodents. However, there are conflicting and heterogeneous reports regarding the effects of NMDA receptor antagonists on outcomes related to negative symptoms in this species. Therefore, this study aimed to evaluate the impact of acute MK-801 exposure on social behavior as measured by shoal cohesion in adult zebrafish.

Methods: We used 192 wild-type male and female (1:1 ratio) adult zebrafish (ethical approval: CEUA UFRGS #35525/2019). Animals were randomly allocated to two experimental groups: control and MK-801 (5 μ M). Zebrafish were individually exposed to water or MK-801 in a 200-mL beaker for 20 minutes. Subsequently, they were introduced to a test tank in shoals of four fish ($n=24$ shoals) for 6 minutes. The test was recorded for 6 minutes and edited to quantify the shoal behavior using screenshots captured every 15 seconds. The following measures of shoal cohesion were computed by researchers blinded to the treatment groups using the ImageJ software: shoal area, shoal perimeter, mean interfish distance, distance from the nearest

neighbor and distance from the farthest neighbor. Experiments were run in two batches and the pooled data were analyzed by two-way repeated measures ANOVA with time and treatment group as factors.

Results: Acute exposure to MK-801 significantly increased the shoal area ($F(1,46) = 11.48$, $p=0.0014$), shoal perimeter ($F(1,46) = 28.68$, $p \text{ LESS THAN } 0.0001$), mean interfish distance ($F(1,46) = 22.46$, $p \text{ LESS THAN } 0.0001$), and nearest ($F(1,46) = 13.83$, $p=0.0005$) and farthest ($F(1,46) = 27.63$, $p \text{ LESS THAN } 0.0001$) neighbors distance. Effect sizes (Cohen's d) were large for all outcomes, ranging from 0.98 to 1.55. These findings indicate that MK-801 reduced shoal cohesion, manifested by increased shoal dispersion. There was no effect of time or interaction effects between the factors on any of the measured outcomes.

Discussion: The robust reduction in social behavior induced by MK-801 in the shoal cohesion test contrasts with the variable results we obtained with the social preference test, an assay in which the preference of individual animals to swim close to a tank containing a group of ten conspecifics is measured as a proxy for social interaction. The increased shoal dispersion may be considered a phenotype with relevance to the negative symptoms of schizophrenia, which include social withdrawal. These findings underscore the potential of the zebrafish model in elucidating the behavioral consequences of NMDA receptor modulation, reproducing the results of experiments conducted in rodents. However, shoal cohesion may also be influenced by anxiolytic and anxiogenic interventions. Therefore, future research is needed to precisely understand the mechanisms and the interplay between NMDA receptor modulation, anxiety-related pathways and social behavior.

S216. N-METHYL-D-ASPARTATE GLUTAMATERGIC RECEPTOR ANTAGONISTS WITH RELEVANCE TO SCHIZOPHRENIA: A REVIEW OF ZEBRAFISH STUDIES

Matheus Gallas Lopes^{*1}, Radharani Benvenuti¹, Matheus Marcon¹, Cristina R. Reschke², Ana P. Herrmann¹, Angelo Piato¹

¹*Universidade Federal do Rio Grande do Sul*, ²*Royal College of Surgeons in Ireland*

Background: Hypofunction of glutamate NMDA receptors (NMDAR) in GABAergic interneurons and hyperactivation of dopaminergic pathways in subcortical brain regions are linked to the pathophysiology of schizophrenia. The administration of NMDAR antagonists is often used in model organisms to replicate behavioral phenotypes relevant to the positive, negative, and cognitive symptoms of schizophrenia. Nevertheless, the predominant reliance on rodents in such models raises concerns about species-specific biases and limited translatability of the findings. Zebrafish, on the other hand, is increasingly used as a model organism to study evolutionarily conserved aspects of behavior. In this context, our aim was to comprehensively review and integrate key findings reported in the zebrafish literature regarding the behavioral effects of NMDAR antagonists with relevance to schizophrenia.

Methods: Literature searches were conducted in two bibliographic databases (PubMed and Web of Science) including terms that describe the intervention (NMDAR antagonists) and the desired population (zebrafish). Searches were conducted using filters for date limiting the scope for the period between January 1st 2000 and September 30th 2020. After the removal of duplicates, the selection of eligible studies was conducted in a two-step process based, initially, on title and abstract, followed by a full-text analysis based on criteria for the study design, population, intervention, and outcomes of interest.

Results: From the search in the selected databases 590 studies were retrieved altogether. After the removal of duplicates, the total number of records was 393. We then excluded 266 entries based on title and abstract and 83 based on the full-text screening that did not fulfill the eligibility criteria. This resulted in 44 research articles that met our inclusion criteria and were included in the review. Among these, dizocilpine (MK-801) featured in 29 studies, while ketamine was used in 10 studies. Other NMDAR antagonists, namely phencyclidine (PCP), APV, memantine, and tiletamine, were discussed in 6 studies. Frequently reported findings are the social interaction and memory deficits induced by MK-801 and circling behavior induced by ketamine. However, mixed results were described for several locomotor and exploratory parameters in the novel tank and open tank tests.

Discussion: The zebrafish literature examined here consistently highlights deficits in social interaction and memory impairment resulting from MK-801, alongside the prominent circular behavior induced by ketamine. However, the reports of locomotor and anxiety parameters reveal mixed findings, likely influenced by considerable variability in experimental design. Our review synthesizes key findings from the zebrafish literature pertaining to the schizophrenia-related behavioral effects of NMDAR antagonists. Our conclusion underscores the zebrafish as a valuable model organism for investigating drug-induced behavioral phenotypes relevant to schizophrenia. Nevertheless, additional studies are imperative to comprehensively understand the distinct zebrafish behavioral characteristics as compared to mammals.

S217. COMPARISONS OF THE TREATMENT DISCONTINUATION RATES BETWEEN LONG-ACTING INJECTABLE PALIPERIDONE 1-MONTH AND 3-MONTHS IN A NATIONWIDE POPULATION DATABASE

Sung Woo Joo^{*1}, Sun Min Kim¹, Daegeun Kim¹, Jinah Kim¹, Jungsun Lee¹

¹*Asan Medical Center*

Background: Long-acting injectable (LAI) antipsychotics have been shown to be more effective than oral antipsychotics in reducing treatment discontinuation and the risk of psychiatric hospitalization among patients with schizophrenia. In light of this, LAI antipsychotics with extended durations of action have been developed and LAI paliperidone palmitate with a 3-month interval (PP3M) (Invega Trinza) has been introduced. It is expected to improve treatment outcomes due to its extended injection interval of 3 months. However, evidence is lacking to determine whether LAI PP3M leads to better treatment outcomes than LAI paliperidone palmitate with a 1-month interval (PP1M) (Invega Sustenna) in real-world observational studies.

Methods: We analyzed data from the Health Insurance Review and Assessment Service database in South Korea, spanning July 2009 to August 2021. From patients who had at least one insurance claim with a primary diagnosis of F20 during the observation period, we selected those who had been prescribed either LAI PP1M or LAI PP3M. We compared the treatment duration and discontinuation rates following the initiation of each treatment.

Results: We included 13,344 patients with schizophrenia who had been prescribed either LAI PP1M or LAI PP3M. The mean treatment duration was significantly longer in the PP3M group than in the PP1M group ($t = -39.951$, $p < 0.001$). A Cox proportional-hazards model indicated that LAI PP3M was associated with lower treatment discontinuation compared to LAI PP1M (HR=0.594, CI=0.557–0.633).

Discussion: Our study suggests that LAI PP3M is superior to LAI PP1M in reducing treatment discontinuation. Further studies are needed to explore other clinical advantages of PP3M over PP1M, such as long-term benefits derived from sustained treatment adherence.

S218. NALTREXONE-ASSOCIATED VISUAL HALLUCINATIONS: A CASE REPORT

Kwanghun Lee^{*1}, Won-Myong Bahk², MoonDoo Kim³, Bo-Hyun Yoon⁴, Young-Joon Kwon⁵

¹*Dongguk University Hospital*, ²*Yeouido St. Mary's Hospital, The Catholic University of Korea*, ³*Dept. of Psychiatry, School of Medicine, Jeju National University, Jeju, Korea*, ⁴*Naju National Hospital*, ⁵*Soonchunhyang University Chunan Hospital*

Background: Naltrexone is a competitive antagonist of opioid receptors. It has usually been used for the treatment of alcohol dependence and opiate addiction. Recently, the naltrexone–bupropion combination pill for obesity treatment was approved by the US Food and Drug Administration and the European Medicines Agency. Currently, naltrexone has been studied as an anti-obesity agent for general populations and patients with severe mental illnesses, including schizophrenia. In schizophrenia, however, naltrexone-induced visual hallucinations (VHs) are not well known as an adverse effect.

Methods: We report a case which a patient with schizophrenia experienced VHs after taking naltrexone.

Results: A 24-year-old female patient suffering from persecutory delusions, auditory hallucinations (AHs), and aggressive behavior was admitted to the Department of Psychiatry, Yeouido St. Mary's Hospital, in November 2013. She had no history of substance use disorder. She met the diagnostic criteria for schizophrenia according to the Diagnostic and Statistical Manual of Mental Disorders-IV. Antipsychotics were started and her psychotic symptoms gradually decreased. After the last discharge, she was maintained on aripiprazole 25 mg, amisulpride 800 mg, procyclidine 20 mg, propranolol 80 mg, lorazepam 1.5 mg, and valproic acid 250 mg per day, for several years. She had no psychotic symptoms except intermittent AHs (3-4 times/week). In April 2016, the frequency of the AHs increased, and amisulpride was increased to 1,000 mg/day. Two weeks later, AHs were substantially reduced but the patient complained of increased appetite and weight gain. She was prescribed naltrexone 50 mg once a day for 2 weeks. Two weeks later, the patient reported that she had started to see a blurred black object passing by after 2 to 3 days of taking 50 mg of naltrexone, which occurred several times a day. She reported that VHs occurred almost every day while taking naltrexone. The ophthalmic consult was recommended to exclude organic causes for presenting symptoms but refused by her. Naltrexone was ceased. At the next visit, she reported that the VHs had completely disappeared 3 to 4 days after stopping naltrexone.

Discussion: we suggest that naltrexone might be associated the emergence of VHs. Although the pathophysiology of naltrexone-associated VHs remains unclear, clinicians should be aware of the potential emergence of VHs associated with naltrexone.

S219. SEMAGLUTIDE FOR THE TREATMENT OF ANTIPSYCHOTIC-ASSOCIATED WEIGHT GAIN IN PATIENTS NOT RESPONDING TO METFORMIN – A CASE SERIES

Riddhita De*¹, Femin Prasad¹, Vittal Korann¹, Araba Chintoh², Gary Remington¹, Bjorn Ebdrup³, Dan Siskind⁴, Filip K Knop⁵, Tina Villsbøll⁶, Anders Fink-Jensen⁷, Margaret Hahn¹, Sri Mahavir Agarwal¹

¹Centre for Addiction and Mental Health, University of Toronto, ²University of Toronto, ³University of Copenhagen, ⁴Metro South Addiction and Mental Health Service, ⁵Department of Clinical Medicine, Faculty of Health and Medical Sciences, University of Copenhagen; Center for Clinical Metabolic Research, Gentofte Hospital, University of Copenhagen; Steno Diabetes Center Copenhagen, ⁶Copenhagen University; Gentofte Hospital, ⁷Psychiatric Centre Copenhagen, Mental Health Services, Capital Region of Denmark

Background: While antipsychotic (AP) medications are considered the cornerstone of treatment in schizophrenia and other psychiatric conditions, contributing effects of these medications on weight gain have been well-established. Comorbid obesity among individuals with severe mental illness (SMI) have been associated with poorer quality of life, barriers to social engagement, worse adherence, and impaired cognition. Despite this, the available treatment strategies for managing this growing problem are significantly lacking. At present, metformin has the most evidence for modest weight gain mitigation in individuals with SMI who experience antipsychotic-associated weight gain (AAWG). However, it is effective in only approximately 20% of patients, with no clear recommendations for the subgroup failing to respond to metformin. Among agents approved for chronic weight management in Canada, glucagon-like peptide-1 receptor agonists (GLP-1RAs) are associated with reductions in cardiovascular mortality, with the recent addition of once-weekly semaglutide for this indication. The long-acting, once-weekly formulation has shown promising preliminary evidence for both effectiveness and tolerability. Therefore, in this case series involving the SMI population, the primary objective was to study changes in weight over 12 months following the initiation of semaglutide among metformin non-responders.

Methods: A retrospective chart review was conducted for individuals between 2019 and 2021, in the Mental Health and Metabolism clinic at the Center for Addiction and Mental Health (CAMH) in Toronto, Canada. The inclusion criteria consisted of patients who were on a stable dose of an antipsychotic medication, who failed to lose GREATER THAN =5% body weight on metformin (highest tolerated dose) at the end of 3 months or those who continued to meet criteria for metabolic syndrome at the end of 3 months. They were then initiated on semaglutide of up to a 2 mg dose per week. All demographics and metabolic data were collected at baseline, 3, 6 and 12 months.

Results: Twelve patients in total were included with a mean age of 36.09 ± 13.32 years, who were on a mean semaglutide dose of 0.71 ± 0.47 mg/week at the end of 12 months. At baseline, the mean weight was 111.4 ± 31.7 kg, and the BMI was 36.7 ± 8.2 kg/m² with a mean waist circumference of 118.1 ± 19.3 cm. After initiation of semaglutide, weight loss of 4.56 ± 3.15 kg (p LESS THAN 0.001) was noted at 3 months, 5.16 ± 6.27 kg ($p = 0.04$) at 6 months, and 8.67 ± 9 kg ($p = 0.04$) at 12 months. No serious adverse events were reported on the medication, with some experiencing tolerable gastrointestinal side-effects which subsided with time.

Discussion: This case series from a naturalistic, clinical setting suggests that among metformin non-responders, semaglutide appears to be effective in reducing AAWG. However, well-

powered randomized control trials investigating semaglutide for AAWG in the SMI population are required.

S220. NEUROMETABOLITES IN ANTIPSYCHOTIC-RESPONSIVE VERSUS NON-RESPONSIVE PSYCHOSIS: A META-ANALYSIS.

Bridget King^{*1}, Junyu Sun¹, Kate Merritt², Matthew J. Kempton¹, Alice Egerton¹

¹King's College London, Institute of Psychiatry, Psychology and Neuroscience, ²Institute of Mental Health, UCL

Background: Proton magnetic resonance spectroscopy (1H-MRS) is an MRI-based imaging technique which provides measures of neurometabolites which may be relevant to the pathophysiology of schizophrenia. These include glutamate (Glu), glutamine (Gln) and their combined signal (Glx), n-acetyl aspartate (NAA), choline (Cho), myoinositol (mI), GABA and glutathione (GSH). Several studies suggest that regional neurometabolite levels may differ in schizophrenia in relation to antipsychotic treatment response, with a primary finding that a poor response to treatment is associated with elevations in glutamate in the medial frontal cortex (MFC). However, there are differences in findings between individual studies which may relate to variation in patient selection, study design or data acquisition. We therefore conducted a meta-analysis of studies reporting 1H-MRS metabolites in individuals with schizophrenia classified as antipsychotic non-responders compared to responders or healthy controls.

Methods: A systematic literature search was conducted using The Web of Science database. 1H-MRS studies that reported metabolite levels (Glu, Glx, Gln, NAA, Cho, mI, GABA, GSH) in patient groups classified as responders or non-responders to antipsychotic treatment and healthy controls were included. Metabolite levels were compared between groups in random effects models using standardised mean differences (Hedge's g). Regions of interest included the MFC, dorsolateral prefrontal cortex (DLPFC), thalamus, and basal ganglia. Subgroup analyses investigated the impact of differences in patient subgroups (treatment resistant or non-treatment resistant), study design (cross-sectional or prospective) and MFC voxel placement (anterior or mid cingulate cortex).

Results: 20 eligible studies reporting data for 428 treatment non-responders, 484 treatment responders with schizophrenia and 380 healthy controls were included. In the MFC, treatment non-responders showed elevations in mI (Hedge's g = 0.25, P = 0.017) and choline (g = 0.42, P = 0.016) compared to treatment responders, with no significant difference in glutamate (P = 0.148, I² = 56) or Glx (P = 0.145, I² = 52). In the DLPFC, treatment non-responders showed elevations in choline (g = 1.03, P = 0.018) but lower levels of glutamate (g = 0.86, P = 0.002) compared to responders. Subgroup analyses indicated that in the MFC, treatment non-responders had higher levels of mI compared to controls for studies with treatment resistant samples (g = 0.85, P LESS THAN 0.001), csf corrected values (g = 0.74, P = 0.006) and cross-sectional designs (g = 0.85, P LESS THAN 0.001). MFC choline was higher in non-responders compared to responders or controls in studies with treatment resistant samples (g = 0.62, P = 0.006), voxels in the anterior cingulate (g = 0.55, P = 0.014) and cross-sectional designs (g = 0.58, P = 0.003).

Discussion: Elevated choline and mI levels in cortical regions in individuals who show a poor response to treatment could indicate increased glial activation and membrane metabolism in this group. The lack of significant difference and high heterogeneity in MFC glutamatergic metabolites may indicate sensitivity to experimental design. Our findings of elevated and

choline and mI give novel mechanistic insight into the neurobiology of antipsychotic non-response and may provide additional biomarkers for clinical response.

S221. ELEVATED MRNA EXPRESSION AND ACTIVITY OF TOLL-LIKE RECEPTORS AND CYTOKINES IN PATIENTS WITH SCHIZOPHRENIA

Saahithh Redddi Patlola*¹, Laurena Holleran², Akhil Konkoth³, Daniel Kerr³, Gary Donohoe², Aodan Laighneach⁴, Derek Morris⁴, Declan McKernan³

¹University of Galway, ²School of Psychology, University of Galway, ³Dept. of Pharmacology and Therapeutics, University of Galway, ⁴Dept. of Biochemistry, University of Galway

Background: Schizophrenia is a psychiatric disorder with a complex aetiology. There has been growing interest in the role of the immune system in the pathophysiology of schizophrenia. Toll-like receptors (TLRs) are a group of pattern recognition receptors primarily involved in cytokine release in the inflammatory response to pathogens but also to cell damage. TLRs are suspected to play a significant role in neuroinflammation as studies consistently show cytokine imbalance in patients diagnosed with schizophrenia which are also associated with cognitive deficits[1]. This cytokine imbalance is possibly due to changes in Toll-like receptor (TLR) expression/activity. Such altered immune responses might lead to neuroinflammation in patients with schizophrenia[2, 3]. We aim to investigate if there is an altered expression and activity of peripheral cytokines and TLRs in patients with schizophrenia.

[3] Patlola, S.R., Donohoe, G. and McKernan, D.P. (2023), “Counting the Toll of Inflammation on Schizophrenia—A Potential Role for Toll-like Receptors”, *Biomolecules*, MDPI AG, Vol. 13 No. 8, p. 1188, doi: 10.3390/biom13081188.

Methods: A total of 311 (Male/Female - 188/123) human participants were included in this study. We used highly sensitive ELISA kits to detect the peripheral levels of cytokines (IL-6, IL-8, IL-10, IL-12, TNF- α and IFN- γ) and C-reactive protein (CRP) in the plasma extracted from the blood of both healthy volunteers (N = 207) and patients with schizophrenia (N = 104). Whole blood was stimulated with TLR2, 3 and 4 agonists (HKLM, Poly (I:C) and LPS respectively) to investigate cytokine (IL-6, IL-8, IL-10 and TNF- α) activity. mRNA was purified from whole blood and cDNA synthesised from this was used to perform qRT-PCR and using a housekeeping gene (β -actin), we analysed the relative expression of all the aforementioned cytokines and TLR 1- 10.

Results: Results from ELISAs show significantly elevated levels of IL-6 (p LESS THAN 0.001), IL-8 (p LESS THAN 0.001), IL-10 (p LESS THAN 0.01), TNF- α (p LESS THAN 0.01) and CRP (p LESS THAN 0.001) in patients with schizophrenia when compared to controls. Significant higher levels of IL-6 (p LESS THAN 0.01, p LESS THAN 0.001), IL-8 (p LESS THAN 0.001, p LESS THAN 0.001) and IL-10 (p LESS THAN 0.05, p LESS

THAN 0.01) in patients were observed post-TLR2 and TLR4 receptor stimulation respectively. Data obtained from PCR was processed (quality control) and normalised relative to the housekeeping gene (β -actin). Gene (mRNA) expression changes between controls and patients was compared using an unpaired t-test. The resulting analysis illustrated a significantly higher expression of IL-6 (1.3-fold, p LESS THAN 0.06) and IL-8 (1.44-fold, p LESS THAN 0.001) but not TNF- α . A significant upregulation in the mRNA expression of TLR2 (1.1-fold, p LESS THAN 0.05), TLR4 (1.3-fold, p LESS THAN 0.01), TLR6 (1.07-fold, p LESS THAN 0.01) and TLR8 (1.1-fold, p LESS THAN 0.05) was observed but not TLR1, 3, 5, 7, 9 and 10.

Discussion: These results suggest that patients with schizophrenia show altered peripheral inflammatory activity. Upregulation of Toll-like receptors (TLRs) and pro-inflammatory cytokine expression from blood samples indicate increased inflammatory activity. The results also point in the direction of a possible role of Toll-like receptors in the mediation of neuroinflammation in schizophrenia. Further investigation on their molecular pathways and their association with cognitive impairment in Schizophrenia could open up more treatment options.

S222. CHANGES IN IMMUNOGLOBULIN LEVELS DURING THE FIRST SIX MONTHS OF CLOZAPINE TREATMENT

James MacCabe^{*1}, Kira Griffiths¹, María Ruiz Mellado¹, Raymond Chung¹, John Lally¹, Grant McQueen¹, Kyra-Verena Sendt¹, Amy Gillespie², Muhammad Ibrahim³, Alex Richter⁴, Adrian Shields⁴, Mark Ponsford⁵, Stephen Jolles⁵, John Hodsoll¹, Thomas Pollak¹, Rachel Upthegrove⁶, Alice Egerton¹

¹*Institute of Psychiatry, Psychology and Neuroscience, King's College London*, ²*University of Oxford*, ³*Department of Immunobiology, Faculty of Life Sciences and Medicine, King's College London*, ⁴*Institute of Immunology and Immunotherapy, University of Birmingham*, ⁵*Immunodeficiency Centre for Wales, University Hospital of Wales, Cardiff*, ⁶*University of Birmingham*

Background: Clozapine is the only approved pharmacotherapy indicated for treatment-resistant schizophrenia but its mechanism of action is not understood, and it is generally underutilised in clinical practice. One reason for limited use is risk of adverse effects. Several adverse effects involve the immune system, such as severe neutropenia and eosinophilia, increased risk of pneumonia and COVID-19. There is growing evidence that clozapine has multiple immunomodulatory effects, and it has been suggested that immune modulation may play a role in the efficacy of clozapine as well as in its adverse effects.

Circulating immunoglobulins (Igs), also known as antibodies, are an essential component of the adaptive immune response. Cross-sectional analyses have found a higher prevalence of Ig deficiency (hypogammaglobulinaemia) in patients prescribed clozapine compared to those prescribed non-clozapine antipsychotics. Since hypogammaglobulinaemia increases risk of infection, this association could have important safety implications. Any clozapine-associated changes in immunoglobulin levels may also have implications for the mechanism of action of clozapine. However, since clozapine is prescribed almost exclusively to patients with treatment-resistant schizophrenia, the results of existing cross-sectional studies are compatible with hypogammaglobulinaemia being part of the phenotype of treatment-resistant schizophrenia,

rather than being specific to clozapine. Prospective studies are required to establish temporal relationships between clozapine treatment and changes in immunoglobulin levels.

We tested two hypotheses: (1) that reductions in immunoglobulin levels occur over the first 6 months following initiation of clozapine treatment, and (2) that any changes in Ig level would be correlated with clinical response.

Methods: This prospective observational study measured immunoglobulin levels (IgA, IgM and IgG) in 56 patients with treatment-resistant schizophrenia at 6-, 12- and 24-weeks following clozapine initiation. Clinical symptoms were measured at baseline and 12 weeks using the positive and negative syndrome scale (PANSS). The main analysis used linear mixed models with maximum likelihood estimation to model the effect of clozapine treatment on immunoglobulin levels over time. Four separate models were applied, with level of IgA, IgG or IgM and total Ig as the outcomes. In each model, time was modelled as a fixed effect and treated as a categorical variable (baseline, week 12, and week 24). Models were adjusted for baseline smoking status and exposure to non-clozapine antipsychotic treatment. The correlation between Ig and percentage change in PANSS total scores after 12 weeks of clozapine treatment was calculated.

Results: IgA, IgG and IgM all decreased during clozapine treatment. For IgA and IgG the reduction was significant at 24 weeks (IgA: $\beta = -32.66$, 95% CI = -62.38, -2.93, $p = 0.03$; IgG: $\beta = -63.96$, 95% CI = -118, -9.31, $p = 0.02$). For IgM the reduction was significant at both 12 and 24 weeks (12 weeks: $\beta = -23.48$, 95% CI = -39.56, -7.42, $p = 0.004$; 24 weeks: $\beta = -33.12$, 95% CI = -50.30, -15.94, $p = \text{LESS THAN } 0.001$). There were no significant differences in baseline IgA, M or G levels between participants who dropped out of the study compared to those who continued. Reductions in both IgA and IgG levels were significantly correlated with reductions in PANSS total score from baseline to week 12 ($n = 32$, IgA $r = 0.59$, $p = 0.005$; IgG $r = 0.48$, $p = 0.03$).

Discussion: For the first time, we have demonstrated that clozapine treatment is associated with reductions in immunoglobulin levels over the first six months of treatment. These findings build on cross-section evidence of secondary antibody deficiency, by showing that reductions in immunoglobulins are associated with clozapine treatment, rather than merely with treatment resistant schizophrenia, and that they occur progressively during the first 6 months of treatment. The results suggest that assessment of immunoglobulin levels should be recommended for patients treated with clozapine, particularly those with a history of infections, as this could promote timely management. The association between Ig reduction and symptom improvement suggests that clozapine may be achieving its clinical efficacy via its immunomodulatory effects. Taken together, these data suggests that immune mechanisms contribute to both desirable and undesirable effects of clozapine.

S223. GLP-1 AGONISTS FOR WEIGHT MANAGEMENT IN ANTIPSYCHOTIC-INDUCED WEIGHT GAIN: A SYSTEMATIC REVIEW AND META-ANALYSIS

Maarten Bak^{*1}, Bea Campforts¹, Patrick Domen¹, Therese Van Amelsvoort¹, Marjan Drukker¹

¹*Maastricht University*

Background: Managing body weight in patients with antipsychotic-induced weight gain (AIWG) is challenging. Besides lifestyle interventions, pharmacological interventions may contribute to weight loss. Relatively new are the Glucagon-Like-Peptides 1 (GLP1) agonists. GLP-1 agonist receive currently in great media attention, as in non-diabetic obese patients have

shown to lose a substantial amount of body weight. This systematic review and meta-analysis evaluated the effect on weight loss and adverse effects of GLP-1 agonists in patients with AIWG.

Methods: Following PRISMA guidelines, we performed a meta-analysis of blinded and open-label randomised controlled trials (RCTs), non-randomised controlled trials and cohort studies that evaluated treatment with GLP-1 in patients with AIWG, regardless of psychiatric diagnosis. PubMed, Embase, PsycINFO and Cochrane Library databases were searched. Primary outcome measures were changes in body weight and BMI. Secondary outcomes were changes in adverse effects and severity of psychopathology due to GLP-1 agonists.

Results: Only data for exenatide and liraglutide could be included, i.e. 5 RCTs and 1 cohort study. For exenatide the mean weight loss was -2.48 kg (95% Confidence Interval (CI) -5.12 to +0.64; $p=0.07$), for liraglutide the mean weight loss was -4.70 kg (95% CI -4.85 to -4.56; $p < 0.001$). The mean change in BMI was -0.82 (95% CI -1.56 to -0.09; $p=0.03$) in the exenatide groups and -1.52 (95% CI -1.83 to -1.22; $p < 0.001$) in the liraglutide groups. Exenatide and liraglutide did not adversely affect psychopathology. The most common adverse events were nausea, vomiting, and diarrhea.

Discussion: The GLP-1 agonists exenatide and liraglutide are promising drugs for inducing weight loss in patients with AIWG. The adverse effects are acceptable, and the addition of GLP-1 does not increase the severity of psychopathology. However, more research is needed to assess the effect of GLP-1 agonist in AIWG and long term effects on body weight. Also, research on the effect on body weight development after stopping GLP-1 medication in AIWG patient is needed.

S224. ISLANDS OF CALLEJA: THE HIDDEN NEUROANATOMICAL SUBSTRATE IN THE MECHANISM OF CARIPRAZINE

Susanne Prokop^{*1}, Péter Ábrányi-Balogh², Benjámín Barti¹, Márton Vámosi¹, Miklós Zöldi¹, László Barna¹, Gabriella M. Urbán¹, Barna Dudok³, Attila Egyed², Hui Deng⁴, Gian Marco Leggio⁵, András D. Tóth⁶, László Hunyady⁶, Mario van der Stelt⁴, György M. Keserű², István Katona¹

Background: A comprehensive understanding of the mechanisms of existing clinical compounds is crucial to enhance the efficacy and minimize the side effects of future neuropsychiatric treatments. While in vitro pharmacological assays can provide the exact receptor binding profile of drugs, it is increasingly acknowledged that the same drug-target interaction can differently modulate complex neuronal networks in the brain, depending on its cell-type and subcellular compartment-specific localization. On the other hand, a significant gap exists in the availability of techniques capable of visualizing cell-type specific drug-target interactions within complex tissue specimens.

Methods: A comprehensive understanding of the mechanisms of existing clinical compounds is crucial to enhance the efficacy and minimize the side effects of future neuropsychiatric treatments. While in vitro pharmacological assays can provide the exact receptor binding profile of drugs, it is increasingly acknowledged that the same drug-target interaction can differently modulate complex neuronal networks in the brain, depending on its cell-type and

subcellular compartment-specific localization. On the other hand, a significant gap exists in the availability of techniques capable of visualizing cell-type specific drug-target interactions within complex tissue specimens.

Results: We presented our workflow by the investigation of cariprazine, a rapidly emerging new medication (Vraylar™/Reagila™). Cariprazine displays unique efficacy against the negative symptoms of schizophrenia and is approved for acute manic/mixed, or depressive episodes associated with bipolar I disorder. However, the neuroanatomical substance that mediates its unique therapeutic effectiveness remains elusive. We demonstrated that the majority of fluorescent cariprazine molecules bind to a largely understudied subregion of the ventral striatum, the Islands of Calleja (IoC) in the mouse brain. Moreover, our three-dimensional reconstruction of high-affinity drug binding sites unveiled that the IoC represents an unexpectedly large continuous network of granule cells. Cell-type specific nanoscale PharmacostORM imaging revealed that fluorescent cariprazine molecules bind D3 dopamine receptors (D3Rs) on the axons of granule cells, which represent the principal cell-type of this enigmatic brain region. We further showed that the IoC is densely innervated by dopaminergic fibers and found that D3Rs localized mostly extrasynaptically, suggesting that these receptors play a key role in dopaminergic volume transmission. Additionally, we demonstrated that the nanoscale binding sites of fluorescent compound in the IoC represent real in vivo targets of the original, unlabeled antipsychotic, cariprazine.

Discussion: Our results highlight the potential importance of IoC granule cells in neuropsychiatric diseases and their enormous potential as future pharmacological targets.

S225. MANAGEMENT OF OBESITY WITH SEMAGLUTIDE IN ANTIPSYCHOTIC-INDUCED WEIGHT GAIN (MOSA) - PRELIMINARY RESULTS FROM A NON-RANDOMISED, OPEN-LABEL PILOT STUDY

Bea Campforts^{*1}, Maarten Bak¹, Marjan Drukker¹, Therese van Amelsvoort¹

¹*Maastricht University, Department of Psychiatry and Neuropsychology*

Background: Social media and newspapers are full of stories about a new generation of weight loss drugs, such as semaglutide and tirzepatide. These antidiabetic medications have been studied in non-diabetic obese patients and have shown significant weight loss. A significant number of patients treated with antipsychotics also suffer from antipsychotic-induced weight gain (AIWG) and obesity (1). Current guidelines focus primarily on lifestyle interventions, such as improving physical activity and diet (2). However, lifestyle interventions are often difficult to implement in these patients because of motivation problems. In addition, the effect of lifestyle interventions on weight loss in patients with SMI is limited (3). Pharmacological interventions, such as the addition of metformin and topiramate, are options that have been shown to result in modest weight loss (4). Semaglutide, a glucagon-like peptide-1 (GLP-1) antidiabetic agent with a mild side-effect profile (mainly nausea and vomiting), showed a weight loss of about 15% in 6 months (5). Semaglutide has not yet been tested in patients with AIWG. The primary objective of our study was to test the feasibility of providing semaglutide to patients with AIWG. Second, we assessed efficacy in terms of weight loss. Thirdly, we assessed tolerability, side effects and psychiatric symptoms.

Methods: We conducted an open-label cohort study with 2 study arms of active medication, semaglutide versus metformin. Both cohorts were followed for 16 weeks. In addition to physical measurements (weight, waist circumference, blood pressure, venipuncture), psychiatric symptoms and side effects were assessed.

Results: Preliminary results show that after 16 weeks, patients on semaglutide lost an average of 5 kg (-1.9 BMI points), or about 4% of their body weight. Patients on metformin lost an average of 2.8 kg (-0.8 BMI points), or 2.5% of their body weight. Side effects were generally mild, mainly gastrointestinal. There was a small but significant improvement in psychiatric symptoms and quality of life after 16 weeks.

Discussion: Semaglutide seems promising for promoting weight loss in patients with AIWG. More research is needed, especially on longer-term follow-up and stopping strategies.

S226. IN-PERSON VS. TELEHEALTH COGNITIVE TRAINING AND PHYSICAL EXERCISE INTERVENTIONS: COMPARISON OF EFFECTS ON ATTENDANCE, COGNITION, AND ROLE AND SOCIAL FUNCTIONING

Keith Nuechterlein^{*1}, Joseph Ventura¹, Kenneth Subotnik¹, Trudy Niess¹, Juliane Nguyen¹, Luana Turner¹, Laurie Casaus¹, Margaret Distler¹, Michael Zito¹

¹*UCLA Semel Institute for Neuroscience and Human Behavior*

Background: Both systematic cognitive training and physical exercise interventions have shown promise for improving the severe cognitive deficits and functional impairments of individuals with schizophrenia. These interventions have usually been delivered through in-person group sessions with a trained leader. The COVID-19 restrictions on in-person group treatments forced a transition to Zoom videoconference treatments within our ongoing randomized controlled trial examining the impact of physical exercise and computerized cognitive training. This transition provided data on the impact of these interventions in in-person vs. telehealth formats.

Methods: Our computerized cognitive training used web-based neurocognitive and social cognitive programs from Posit Science, 4 hours/week for 6 months and then 2 hours/week for another 6 months. Initially all sessions were in-person in groups of 4-6 participants, but switched to videoconference sessions from their homes, again with 4-6 participants per group. Both included monitoring by cognitive coaches. Group physical exercise sessions led by a certified fitness trainer were initially in-person at our clinic, but were converted to Zoom videoconferences, typically with 4-6 participants. Two 45-min group exercise sessions/week and two 30-min sessions/week of individual exercise homework were assigned for 6 months, with half that dosage for another 6 months. The group exercise sessions included combined moderate-intensity aerobic conditioning (1-min intervals) and moderate-to-high-intensity strength and calisthenic conditioning (1-min intervals). A comparison group attended a didactic healthy living group of comparable duration to the physical exercise. Participants with a recent first episode of schizophrenia were randomized to either cognitive training plus physical exercise (n = 60) or cognitive training plus the healthy living group (n = 57). Sixty-four participants were treated in-person, and 53 participants were treated via telehealth sessions.

Results: Attendance at our cognitive training and aerobic exercise sessions did not differ between in-person sessions and telehealth videoconference sessions (cognitive training: 72.2% vs. 71.7%; exercise: 86.7% vs. 87.3%). Average heart rate during group exercise sessions was also similar for in-person and telehealth sessions (mean of 126.2 vs. 129.7 beats per minute). Repeated measures ANOVA across the full 12 months showed greater cognitive improvement in telehealth than in-person treatment (MCCB Overall Composite T score; $F = 3.52$, $p < 0.02$), but no interaction with the randomized treatment condition. At 12 months the T score gain was 4.2 for in-person and 7.4 for telehealth ($d = 0.53$). Work/school functioning across the full 12 months also showed greater improvement in telehealth than in-person treatment (Global Functioning Scale: Role; $F = 3.93$, $p < 0.01$), with a mean gain of 1.7 for in-person and 3.0 for telehealth by 12 months ($d = 0.48$). Social functioning (Global Functioning Scale: Social) showed no differential effects of mode of delivery.

Discussion: Telehealth delivery of computerized cognitive training and physical exercise interventions for individuals in the early course of schizophrenia is feasible and produces very similar attendance and exercise intensity levels. The improvements in overall cognition and work/school functioning were significantly larger in telehealth than in-person delivery by 12 months, encouraging further work with telehealth interventions as that delivery mode should be easier to disseminate across clinical settings. Advantages of videoconference group interventions include individual breakout rooms and decreased travel burden, which may increase impact.

S227. EFFICACY OF THE COMBINATION OF WATER AEROBICS AND METACOGNITIVE TRAINING ON PSYCHOLOGICAL AND PHYSICAL HEALTH VARIABLES AND THEIR RELATIONSHIP WITH SP1 AND SP4 BIOMARKERS IN PEOPLE WITH PSYCHOSIS: A RANDOMIZED TRIAL STUDY PROTOCOL

Susana Ochoa¹, Marina Verdaguer-Rodríguez^{*2}, Núria Batlle³, Francesc Garreta³, Berta Garcia³, Èlia Vila-Andreu⁴, Maria José Hernández³, Maria José Escandell⁴, Ana Muñoz⁴, Sònia Vilamala⁴, Sandra Marcos³, Laura Bassolas³, Maria Pascua³, Belén Ramos¹

¹*Institut de Recerca Sant Joan de Déu; Parc Sanitari Sant Joan de Déu; Investigació Biomèdica en Red de Salud Mental, CIBERSAM*, ²*Institut de Recerca Sant Joan de Déu; Parc Sanitari Sant Joan de Déu; Departament de Psicologia Clínica i de la Salut, Facultat de*

Background: Metacognitive Training (MCT) is widely used and effective in reducing positive symptoms in psychosis. Physical exercise, such as water aerobic exercise (WAE), could be a good option for improving general health, quality of life and symptoms with a low impact activity that allows social interactions. Preliminary results suggest a relationship between dopamine and psychotic symptoms, through SP transcription factors, SP1 and SP4 biomarkers. The aims of the project are to evaluate the efficacy of a combined intervention (WAE and MCT) in people with schizophrenia in psychotic symptoms, physical health, and transcription levels of SP biomarkers.

Methods: This will be a unicentric randomized controlled trial of 3 parallel intervention groups: MCT, WAE and combined intervention. The estimated sample will be 48 patients with a diagnosis in the psychotic spectrum. The assessment will be performed at baseline and at 3-months' follow-up. The instruments used for the assessment will be clinical, cognitive, metacognitive, social cognitive and psychosocial variables.

Results: The results of this study may have clinical implications, contributing to the improvement of treatment selection for psychosis. By incorporating physical exercise, we hypothesize the benefits of psychological interventions will be enhanced. Results are not presented since this is a protocol article.

Discussion: This will be the first time studying the impact of the combination of Metacognitive Training and Water Aerobic Exercise in people with psychosis. Moreover, it will be the first study that analyzes the changes in the transcriptional biomarkers SP1 and SP4 after both interventions.

Background: Exercise can be a preventive means for the increased prevalence of cardiometabolic morbidity and premature mortality in people with schizophrenia spectrum disorder (SSD). When delivered in community-based settings, exercise may also serve as an opportunity to provide life-skill training and reduce loneliness and stigma while promoting overall physically active behaviors in one single intervention. However, long-term engagement in community-based exercise among people with SSD requires intensive practical and emotional support. Hence, instructors delivering and supervising community-based exercise are essential; however, knowledge about their roles and required training is lacking. We investigated stakeholders' perspectives on components needed for an educational program for non-health professional exercise instructors delivering community-based exercise targeting young adults SSD.

Methods: We conducted six focus groups comprising a total of 30 individuals representing five different stakeholder groups, namely clinical staff within mental health, physiotherapists, exercise instructors, young adults in antipsychotic treatment, and relatives to young adults in antipsychotic treatment. Qualitative content analysis as described by Graneheim and Lundman, was applied to analyze the data using Nvivo 12 software.

Results: We identified the following three main categories to be considered in an educational program for exercise instructors delivering community-based exercise to young adults with SSD: (i) acknowledging mental illness, (ii) applying a resource-oriented approach, and (iii) promoting exercise as a shared activity. Furthermore, the analysis comprised an overarching theme, entitled, Instructors as guardians of an inclusive culture. The finding contributed to developing an educational program for non-health professional exercise instructors delivering community-based exercise targeting young adults SSD, which is currently implemented in the Vega Exercise Community trial (ClinicalTrials.gov ID: NCT05461885) The educational program encompasses: a) a written exercise instructor manual, b) a one-day educational course, and c) the possibility of a continuous exchange of experiences between instructors.

Discussion: An educational program for exercise instructors delivering community-based exercise targeting young adults with SSD includes educational content that enables instructors to promote exercise as a shared activity while acknowledging mental illness and having a resource-oriented approach. Indeed, instructors must act as guardians of an inclusive culture supporting personal recovery. Our results may be transferable to the education of non-health professional exercise instructors in other areas of mental health care where the aim is to facilitate sustainable, recreational, community-based activities.

S229. ECT-RELATED MICROSTRUCTURAL CHANGE IN THE GRAY MATTER OF THE LIMBIC SYSTEM IN PSYCHOSIS PATIENTS: EVIDENCE FROM MRI TEXTURE ANALYSIS

Eugenie Choe^{*1}, Minah Kim¹, Jun Soo Kwon¹

¹*Seoul National University Hospital*

Background: Although electroconvulsive therapy (ECT) is an important treatment modality for psychosis, the mechanism and effect of ECT in psychosis has been underinvestigated. Most studies that described structural brain changes related to ECT in psychosis patients focused on

macrostructural changes, such as volume change. However, as it has been reported from non-human studies that ECT may induce histopathological alterations in the gray matter, such macrostructural measures may not suffice to capture subtle changes in tissue characteristics. We therefore aimed to quantify microstructural changes induced by ECT in psychosis patients, by leveraging texture analysis, a methodology known to reflect microstructures of the brain in many pathological conditions, such as brain tumor or Alzheimer's disease. More specifically, we focused on changes in limbic structures, which have widely been implicated in studies on macrostructural changes after ECT in psychosis, and in studies on ECT in depression, an affective psychiatric condition more extensively explored in ECT research. We hypothesized that, psychosis patients would exhibit both macrostructural and microstructural changes in the gray matter of limbic structures following ECT, and these changes would correlate with clinical response.

Methods: Our dataset comprises schizophrenia and schizoaffective disorder patients who were treated either with both ECT and medication, or with medication only. It also includes healthy control individuals. Structural MRI data were collected before and after ECT for the ECT group and twice for the medication-only group, with the same time intervals as the ECT group. After preprocessing and segmentation, regions of interest (ROI) constituting the limbic system were identified. For each ROI, timepoint, and participant, gray matter volume was estimated, and MRI texture was computed using the Gray Level Size Zone Matrix (GLSZM). Values of each feature in the patient group were normalized based on the values of the control group, and feature selection from multiple GLSZM features was performed. Group-time interactions of each of volumetric or normalized texture feature changes were estimated using repeated-measures mixed models. Repeated-measures correlations between clinical variables and texture features that showed significant group-time interactions were calculated. Statistical significance was set at FDR-adjusted $p \leq 0.05$.

Results: In this study, 36 of the psychosis patients treated with both ECT and medication, 27 of the patients treated only with medication, and 70 healthy controls were included as study sample. Among the twelve limbic system ROIs, seven exhibited significant group-time interactions in terms of volumetric changes in the ECT group. Regarding GLSZM feature-ROI pairs, group-time interactions of Large Area Emphasis of the left hippocampus and the right amygdala reached statistical significance. In the ECT group, repeated-measures correlation revealed a negative correlation between changes in multiple clinical variables and changes in the Large Area Emphasis feature for both the left hippocampus and right amygdala. On the other hand, the medication-only group did not show any significant correlation between clinical changes and texture changes.

Discussion: Our findings are in line with existing literature highlighting the hippocampus and amygdala as key regions for ECT-related macrostructural alterations. Furthermore, our results suggest that these regions also undergo more subtle, microstructural changes, which correlate with clinical responses. This study therefore implies that structural alterations in limbic structures may be related to pivotal effects of ECT as a treatment of psychosis. It also supports the idea that changes in tissue characteristics resulting from ECT-induced neuroplasticity constitute a core mechanism of ECT.

S230. VIRTUAL REALITY THERAPY FOR VOICE HEARING (VR-VOICES): A RANDOMIZED CONTROLLED TRIAL

Chris Geraets*¹, Wim Veling¹

¹University Medical Center Groningen

Background: Auditory verbal hallucinations (AVH) are common in mental illnesses. Studies suggest that empowering psychological therapy using computer simulations representing the AVH (avatars) can be effective in reducing AVH distress and frequency. Virtual reality (VR) has the potential to improve this treatment. Therefore, we aim to investigate the effects of a VR treatment for AVH (VR-VOICES) in a broad spectrum of voice hearers, transdiagnostically, who have experienced distressing AVH for at least 3 months, and are 16 years or older. Effects on symptoms, quality of life, and healthcare costs will be investigated, as well as moderators.

Methods: The study is an assessor-blind randomized controlled intervention trial (RCT) with two arms: VR-VOICES and treatment as usual (TAU) as a control condition. The VR-VOICES intervention concerns 7-10 sessions (personalized to the needs of the patient) of 45 minutes of individual VR assisted therapy and two booster sessions. Participants allocated to VR-VOICES choose an avatar as a digital representation and create the voice of the avatar with the therapist. Patients have dialogues with the avatar, voiced by the therapist.

Assessments will be obtained at baseline, within VR-VOICES sessions, posttreatment (3 months after baseline), and 6-month follow-up. The primary outcome: severity of AVH at post-treatment. Secondary outcomes concern in-depth characteristics of AVH, and impact on daily life as measured with questionnaires and diary assessments in the flow of daily life, as well as clinical symptoms, cost-effectiveness and quality of life.

Results: The RCT is currently enrolling, in total 10% has been included.

Discussion: Voicehearing can have pronounced effects on people's lives, therefore it is important to investigate novel treatments in broad groups. The current study will inform on efficacy in such a broad group and enable to explore for whom this type of intervention works.

S231. ONE-YEAR ASSESSMENT OF PATIENT-CENTERED DIGITAL PSYCHOSOCIAL INTERVENTION (DIALOG+) IN OUTPATIENTS WITH PSYCHOSIS SPECTRUM DISORDERS: INSIGHTS FROM SERBIA

Sanja Andric Petrovic^{*1}, Nadja Maric², Ivan Ristic³, Stefan Jerotic⁴, Bojana Savic⁴, Mirjana Zebic⁵, Vuk Vukovic⁶, Tatjana Voskresenski⁶, Manuela Russo⁷, Nikolina Jovanovic⁸

¹*Institute of Mental Health, Faculty of Medicine, University of Belgrade*, ²*Institute of Mental Health, Faculty of Medicine, University of Belgrade*, ³*Institute of Mental Health*, ⁴*University Clinic for Psychiatry, Clinical Centre of Serbia, Faculty of Medicine, University of Belgrade*, ⁵*University Clinic for Psychiatry, Clinical Centre of Serbia*, ⁶*Special Hospital for Psychiatric Diseases "Dr Slavoljub Bakalović"*, ⁷*Unit for Social and Community Psychiatry, Wolfson Institute of Population Health, Queen Mary University of London*, ⁸*Centre for Implementation Science, Health Services and Population Research Department, Institute of Psychiatry, Psychology; Neuroscience, King's College London*, ⁸*Wolfson Institute of Population Health, Queen Mary University of London*

Background: In Serbia and the Balkans, conventional treatment for patients with psychosis spectrum disorders (PSD) largely relies on pharmacotherapy, with limited access to psychosocial interventions due to human and financial resource constraints. Addressing this gap, we introduce DIALOG+, a digital psychosocial intervention grounded in patient-centered communication theories, quality of life (QoL) research and solution-focused therapy principles, designed to enhance the therapeutic efficacy of routine care.

This study aimed to compare the effectiveness of DIALOG+ against standard care in treating PSD concerning QoL, clinical symptoms and treatment satisfaction, evaluating its potential as an innovative solution for holistic care challenges.

Methods: Our study was part of a multicounty, pragmatic, hybrid type II effectiveness–implementation, cluster-randomized, clinical trial (ISRCTN 11913964) aiming at implementing the psychosocial intervention DIALOG+ for patients with PSD in low- and middle-income countries in Southeastern Europe (grant agreement No 779334). It involved 71 adult outpatients (ICD-10 F20-29, F31) from two Serbian sites: a university hospital in an urban setting and a general psychiatric hospital in an urban/rural area. The participants had a history of at least one psychiatric hospitalization and were capable of providing informed consent (mean age 44.1 ± 11.0 years, 56.3% male). Clinicians were randomized 1:1 to the intervention arm ($n=35$, received DIALOG+ six times over 12 months during routine clinical appointments) and control arm ($n=36$, received usual care following the same delivery schedule). Session content varied based on patients' preferences allowing them to discuss various aspects of their life in each session. Primary outcomes were subjective QoL (Manchester Short Assessment of QoL - MANSA), clinical symptoms (Brief Symptom Inventory - BSI), and treatment satisfaction (Client Satisfaction Questionnaire - CSQ-8). Two-level multilevel regression models were employed to allow for data clustering by sites and clinicians. Initial analysis compared baseline arm characteristics, followed by a 12-month outcome measure comparison. Mean differences in outcomes between the arms, reflecting effect magnitude, were calculated, adjusting for potential confounders.

Results: No significant differences existed between intervention and control arms in terms of age, sex, diagnoses, or previous psychological treatment. No significant between-group differences occurred in self-reported mental health problems (BSI, $p=0.74$). Intervention arm improvements included higher MANSA total scores indicating a better QoL (5.2 ± 0.8 vs. 4.4 ± 0.6 , 95% CI 0.6 [0.2, 0.9], $p=0.004$) and greater treatment satisfaction as evidenced by higher scores on the CSQ-8 scale compared to the control group (29.2 ± 2.9 vs. 26.3 ± 4.2 , 95% CI 2.0 [0.6, 3.5], $p=0.007$).

Discussion: This study contributes to a limited body of nonpharmacological RCTs for PSD, demonstrating improvements with DIALOG+ in two important patient-reported outcome measures: subjective QoL and treatment satisfaction over 12 months. These findings bear clinical relevance given the scarcity of interventions addressing QoL enhancement for individuals with PSD. Despite the observed increased session duration with DIALOG+ in a recent study, providing structured interventions and ongoing patient evaluation could offer additional long-term care and QoL benefits for PSD patients.

In conclusion, the study suggests that DIALOG+ shows promise as a structured, integrative approach for individuals with PSD, particularly in routine mental health care settings and resource-constrained environments.

S232. RISK OF PSYCHOTIC AND BIPOLAR PRODROMAL SYMPTOMS IN CHILDREN AND ADOLESCENTS OFFSPRING OF PATIENTS DIAGNOSED WITH SCHIZOPHRENIA OR BIPOLAR DISORDER

Hospital General Universitario Gregorio Marañón. IiSGM. School of Medicine, Universidad Complutense. CIBERSAM. Madrid, Spain, ¹⁰Instituto de Investigaciones Biomédicas de Barcelona, CSIC-IDIBAPS-CIBERSAM, ¹¹Hospital Clínic de Barcelona. Centro de Investigación Biomédica en Red de Salud Mental, CIBERSAM Barcelona

Background: Previous literature have showed that offspring of patients diagnosed with schizophrenia (SZoff) or bipolar disorder (BDoff) had higher prevalence of psychotic experiences and mood prodromal symptoms than controls (CCoff) (Ellersgaard et al., 2021; Setieman et al., 2023). BASYS is a longitudinal, naturalistic study which aims to assess clinical, cognitive, genetic and neuroimaging characteristics of SZoff, BDoff and CCoff. The aim of this study is to analyze the risk of sub-clinical psychotic and bipolar symptoms in SZoff and BDoff compared with a community control sample (CCoff). We will also study the effect of some of the parents' characteristics on the risk of developing sub-clinical psychotic and bipolar symptoms.

Methods: At baseline, BASYS included 41 SZoff, 90 BDoff and 104 CCoff between the ages of six and 17 years. At four-year follow-up 169 offspring (71% of the sample) underwent clinical assessment (60 BDoff, 23 SZoff and 86 CCoff). Prodromal psychotic symptoms were assessed with the Semi-structured Interview for Prodromal Syndromes (SIPS) and scored on the Scale of Prodromal Symptoms, SOPS (Miller et al., 2002). Prodromal bipolar symptoms were assessed with the K-SADS-PL (Kaufman et al., 1997; Ulloa et al., 2006). The presence of sub-clinical psychotic and bipolar symptoms was also dichotomized (yes/no) based on the SIPS/SOPS and K-SADS-PL semi-structured interviews, respectively. Thus, having sub-clinical psychotic symptoms was defined as any SOPS positive or negative item rated greater than or equal to 3. Having sub-clinical bipolar symptoms was defined as a score of 2 (sub-threshold level) in any item of any mood disorder on the K-SADS-PL. Cumulative incidence of sub-clinical psychotic/bipolar symptoms at four-year follow-up were checked with the Kaplan-Meier method with the log rank test to determine differences between the groups (SZoff, BDoff and CCoff). Moreover, the association of some offspring and parents' variables and risk of sub-clinical psychotic/bipolar symptoms was also studied using the univariate Cox regression analysis. Offspring variables analyzed included: group (SZoff, BDoff or CCoff) gender, SES, age and being an adolescent. Parental variables studied were global functioning, SES and age at birth, all of them treated as continuous variables.

Results: There were significant differences between SZoff, BDoff and CCoff in the incidence of sub-clinical psychotic symptoms (SPS) (Log Rank test: $\chi^2=13.101$; $p=0.001$). At four-year follow-up, the incidence of SPS was 30.6% in the SZoff, 20.5% in the BDoff and 9.1% in the CCoff. Only the SZoff group showed higher risk of developing SPS compared to the CCoff group. No other offspring variables were significantly associated with risk of SPS. Higher scores of mothers' global functioning was associated with lower risk of SPS. The incidence of

sub-clinical bipolar symptoms was significantly different between the three groups (Log Rank test: $\chi^2=7.728$; $p=0.021$). Thus, 29.2% of BDOff, 17.8% of the SZoff and 12.5% of the CCOff had sub-clinical bipolar symptoms at four-year follow-up. BDOff showed twice the risk of developing sub-clinical bipolar symptoms compared with the CCOff group. No significant differences were detected between SZoff and CCOff. Any parental or family variable showed an association with the risk of sub-clinical bipolar symptoms in the offspring

Discussion: The primary findings of this study indicate that SZoff showed higher risk for sub-clinical psychotic symptoms, while the BDOff displayed a heightened risk for sub-clinical bipolar symptoms when compared to CCOff. Moreover, higher parental psycho-social functioning emerged as protective factor against sub-clinical psychotic symptoms. These results are in line with previous literature that observed a higher prevalence of psychotic experiences in SZoff and BDOff than in CCOff (Ellersgaard et al., 2021). Regarding sub-clinical bipolar symptoms, our results partially agreed with the study by Setieman et al. (2023), since this study observed more mood sub-clinical symptoms in SZoff and BDOff compared with the control group. Interestingly, SZoff showed even more mood sub-clinical symptoms than BDOff. This study has been funded by Instituto de Salud Carlos III (ISCIII) through the project "20/00654" and co-funded by the European Union.

S233. AN ACUTE EXERCISE INTERVENTION TO AMELIORATE BEHAVIORAL AND NEUROPHYSIOLOGICAL INDICES OF INHIBITORY CONTROL DEFICITS IN SCHIZOPHRENIA: A MOBILE BRAIN/BODY IMAGING (MOBI) STUDY

Victoria Popov^{*1}, Edward Freedman¹, John Foxe¹

¹*University of Rochester*

Background: Inhibitory control deficits are a core feature of schizophrenia spectrum disorders (SSDs), with clear manifestations seen in both psychophysiological and electrophysiological measures of these processes. Addressing these symptoms is of critical clinical relevance since they are a main predictor of negative vocational and psychosocial outcomes. An intriguing set of findings has suggested physical activity and exercise can have a positive effect on SSD symptomatology, but the exercise-linked neural changes that may result in improved inhibitory control are unknown.

Methods: Male and female individuals with SSDs ($n=16$) and neurotypical, age-matched healthy controls (HCs) ($n=14$) completed the Go/NoGo response inhibition (RI) task while sitting and walking. The emergence of Mobile Brain/Body Imaging (MoBI) technologies allowed for the successful assessment of cognitive control processes through high density electroencephalography (hd-EEG), behavioral performance on the RI task, and motoric function through motion capture technologies while participants were engaged in treadmill walking or were sitting. Here, we leverage MoBI to ask whether a single acute exercise intervention, particularly treadmill walking in this study, would lead to improved performance on a canonical RI task, and if previously well-characterized deficits in the generation of inhibition-related event-related-potential (ERP) components can be ameliorated in individuals with SSDs.

Results: A two-way repeated measures ANOVA was performed to compare the effect of groups (HCs, SSDs) or motion state (sitting, walking) on d' scores (RI task performance). Simple main effects analysis showed that groups had a statistically significant effect on d' scores ($F(1, 29) = 11.30$, $p = .001$) and motion state did not ($F(1, 29) = 0.20$, $p = .65$). Preliminary data suggest, overall, HCs had better inhibitory control than SSDs, and walking

did not improve inhibitory control performance of SSDs to be like those of HCs. The cluster-based permutation approach allowed for exploring the existence of walking-related effects on ERPs in the entire electrode set and at all the epoch timepoints. The effects this approach revealed were significant ERP amplitude increases during walking over frontal and frontocentral scalp regions and reductions over parietal and occipital scalp regions during the RI related ERP component intervals for HCs and SSDs. Additionally, in HCs there was substantial reconfiguration over RI related scalp regions when walking relative to sitting that happened earlier than SSDs.

Discussion: Preliminary findings suggest a single intervention of treadmill walking showed no improvement in inhibitory control performance but normalization of neurophysiological processes in SSDs to those of HCs. We expect when we are sufficiently powered SSDs will show inhibitory control performance like those of controls when walking. To our knowledge, this is the first study of its kind to date to examine inhibitory control in real time during an acute exercise intervention. A longer-term fitness intervention trial could assess whether these positive outcomes can be established more durably.

S234. TYPES OF MEDIA USE AND THEIR ASSOCIATIONS WITH PARANOIA: AN ECOLOGICAL MOMENTARY ASSESSMENT STUDY

Vincent Paquin*¹, Robert A. Ackerman², Colin A. Depp³, Raeanne C. Moore³, Philip D. Harvey⁴, Amy E. Pinkham²

¹*McGill University*, ²*The University of Texas at Dallas*, ³*University of California San Diego*,
⁴*University of Miami*

Background: Paranoia is a spectrum of fear-related experiences that spans diagnostic categories and is shaped by the environment. Traditional media (e.g., books) and digital media (e.g., social media) enable cognitive and social possibilities that may have various effects on paranoia; however, the extent to which media use is associated with paranoia remains unknown. We aimed to examine associations between media use and paranoia at the within- and between-person levels.

Methods: Participants were 409 adults (245 [59.5%] female) diagnosed with schizophrenia spectrum (n=189) or bipolar disorder (n=220). Measures included sociodemographic and clinical characteristics at baseline, followed by ecological momentary assessments (EMA) collected three times daily over 30 days. EMA evaluated paranoia and five types of media use: TV viewing, social media use, listening to music, reading or writing, and other internet or computer use. Logistic regression was used to examine sociodemographic and clinical characteristics associated with any vs. no media use. Then, generalized linear mixed models were used to examine paranoia as a function of each type of media use and vice-versa.

Results: Female (vs. male) gender was associated with higher odds of social media use (OR=2.19; 95% CI: 1.45, 3.33). Black or African American individuals (vs. White group) had lower odds of other internet or computer use (OR=0.34; 95% CI: 0.21, 0.53). Diagnosis of bipolar disorder vs. schizophrenia (OR=2.53; 95% CI: 1.63, 3.94) and having a college degree or higher (OR=8.29; 95% CI: 4.57, 15.69) were associated with higher odds of other internet or computer use. In the schizophrenia group, a within-person increase in social media use was associated with a 10% reduction in paranoia at the next time point: fold-change=0.900; 95% CI: 0.840, 0.965. In the bipolar disorder group, a within-person increase in listening to music was associated with a 5% reduction in paranoia at the next time point: fold-change=0.949; 95%

CI: 0.906, 0.995. Other associations, including those at the between-person level or involving TV viewing, reading or writing, and other internet or computer use, were not significant. Across models, there was no significant interaction with gender.

Discussion: Media use was either associated with no significant change in paranoia, or some improvement, depending on the type of media and diagnostic group. By modeling associations between media use and paranoia at the within-person level, we were able to remove potential influences from time-invariant confounders such as sociodemographic features. The associations of social media use and listening to music with reductions in paranoia may reflect clinical benefits of social interaction and distraction. Of course, the strength and direction of effect of media use on paranoia is likely to vary according to the specific contents of use, such as using social media to connect with family vs. to watch videos of distressing news. Better understanding the ecological effects of media as a function of individual and content features may help guide the development of media-based interventions for paranoia. Future research, however, should also consider the impacts of gender, racialized group, education, and diagnosis on the accessibility of media-based interventions, especially since the same systemic inequities that limit access to media technologies may also contribute to the progression of illness.

S235. ANESTHESIA WITH DEXMEDETOMIDINE AND NITROUS OXIDE IN ELECTROCONVULSIVE THERAPY

In Won Chung^{*1}, Hee Yeon Jung², Jun Hee Lee³, Heung Sik Kim¹, Kyuyoung Lee⁴, Yong Sik Kim⁴

¹*Yong-In Mental Hospital*, ²*Department of Psychiatry, SMG-SNU Boramae Medical Center*, *Department of Psychiatry, Seoul National University College of Medicine, Seoul, Republic of Korea*, ³*Department of Psychiatry, Uijeongbu Eulji University Hospital*, ⁴*Department of Psychiatry, Nowon Eulji University Hospital*

Background: Most anesthetic agents used in modern electroconvulsive therapy (ECT) produce anticonvulsant effects by increasing the seizure threshold over repeated sessions in the course of acute ECT. This requires an increase in charge, which eventually raises the risk of adverse cognitive effects.

Methods: We present a case of acute ECT in which anesthesia induction with nitrous oxide and dexmedetomidine was able to produce adequate seizure duration while maintaining up to 16 sessions without a significant increase in charge in a patient with schizoaffective disorder. The patient had received 14 sessions of acute ECT at another university hospital but was transferred to our hospital because they could no longer continue ECT. Propofol was used for anesthetic induction, and the charge was increased to 576 mC after the 11th session. The patient resumed ECT sessions at our hospital 11 days after the last session. The ECT procedure was the same with upward titration, bilateral electrode placement, and use of succinylcholine as a muscle relaxant.

Results: The mean charge of 14 sessions at the previous hospital was 542.0 ± 270.9 mC, and the mean durations of motor and EEG seizures were 23.8 ± 8.0 and 34.9 ± 8.3 seconds, respectively. For comparison, the mean charge (242.0 ± 51.9 mC, $t = 5.6463$, $p < 0.0000$) and motor seizure duration (35.3 ± 11.1 sec, $t = -2.5339$, $p = 0.0070$) at our hospital were respectively significantly different, but not the EEG seizure duration (38.1 ± 14.1 mC, $t = -0.5374$, $p = 0.5954$).

Discussion: The combined use of dexmedetomidine and nitrous oxide as anesthetics in acute ECT allowed us to maintain an effective seizure duration without an increase in charge.

S236. PRAGMATIC LANGUAGE DISORDER IN SCHIZOPHRENIA: ASSESSMENT THROUGH A NOVEL BRIEF TOOL

Margherita Bechi^{*1}, Gulia Agostoni², Luca Bischetti³, Giorgio Arcara⁴, Mariachiara Buonocore⁵, Francesca Martini², Marco Spangaro⁶, Valentina Bambini³, Roberto Cavallaro⁷, Marta Bosia⁸

¹IRCCS H.S. San Raffaele, DSNP, ²IRCCS San Raffaele University Scientific Institute, ³Center for Neurocognition, Epistemology and theoretical Syntax (NEtS), University School for Advanced Studies IUSS, ⁴IRCCS San Camillo Hospital, ⁵Department of Clinical Neurosciences, IRCCS San Raffaele Scientific Institute, ⁶IRCCS San Raffaele University Scientific Institute, ⁷Vita Salute San Raffaele University, ⁸IRCCS San Raffaele Scientific Institute

Background: Pragmatics is a communicative ability that allows appropriately using and interpreting language in a wide range of contexts and situations. Pragmatic disruption is a main feature in schizophrenia, which affects around 80% of patients and contributes to the functional disability associated with the illness. Despite its relevance, pragmatic impairment is seldom considered in assessment, as the available tests share the limitation of a significantly long administration time, thus making them unfeasible into routine evaluation.

This study aims at testing a novel and brief tool for pragmatics (APACS Brief) in schizophrenia compared with healthy controls, to evaluate its feasibility as well as the equivalence with a previous and standardized tool (APACS test).

Methods: We enrolled 56 patients affected by schizophrenia and 56 healthy controls matched for age and education. The patients' assessment include a cognitive evaluation (Brief assessment of cognition in schizophrenia- BACS) a Theory of mind (ToM) evaluation (Picture sequencing task –PST) a clinical evaluation (PANSS) APACS long and APACS Brief for pragmatics' evaluation, while healthy controls were evaluated for APACS Brief. Several ANOVAs were run to compare APACS Brief between patients with schizophrenia and healthy controls. To explore the discriminatory power of APACS Brief Total score in differentiating people with schizophrenia from healthy subjects, we run a ROC curve analysis. Then, we run a Pearson correlation analysis between APACS Total score and APACS Brief Total score in the schizophrenia group, to further confirm the correlation between APACS long and short versions. Lastly, the interplay between pragmatic abilities and cognitive and ToM abilities was evaluated with Pearson correlations.

Results: Results showed significant differences between patients and controls in all APACS Brief scores (Total score F55.59, p LESS THAN .0001), and the ROC curve showed that an APACS Brief Total score (AUC = 0.83, p LESS THAN 0001) of 0.89 had the best discriminant validity (sensitivity = 95%, specificity = 69%) in differentiating patients vs controls. Significant correlations between APACS long and brief versions (Pearson r = 0.65, p LESS THAN .0001), as well as between the latter and both cognitive (Pearson r = 0.32, p = .01) and sociocognitive (Pearson r = 0.38, p = .004) data, were found, further confirming the validity of the tool.

Discussion:

Overall, data suggest that APACS Brief is a tool able to evaluate pragmatic disruption in schizophrenia and that, if supported by other studies, it could be considered equal to a long and validated task such as the APACS test. The brief administration time makes APACS Brief a useful and adaptable task for numerous contexts, including the National Health System services, where the time constraints do not allow for longer evaluations. The identification of people with schizophrenia showing a pragmatic deficit could maximize the application of the available rehabilitative interventions, such as PragmaCom, with significant consequence on people's daily functioning and quality of life. As functional disruption is still a major issue in schizophrenia, contributing to the economic burden associated with the disorder, the identification of treatment targets and the availability of tools to assess them is crucial. Clinical implications of APACS Brief also include its use for refined diagnosis and treatment outcome prediction, as well as for monitoring the course of the disorder in chronic patients.

S237. TESTOSTERONE USE AS A TREATMENT OF CACHEXIA IN PATIENTS WITH SCHIZOPHRENIA

Naista Zhand¹, Fatima Al Quraish^{*2}

¹*Schizophrenia Program, The Royal Ottawa Mental Health Centre,* ²*Royal Ottawa Hospital*

Background: Aberrant feeding behaviors in schizophrenia, which could result in cachexia and starvation status, have been described in the literature. Testosterone is used as an adjunct treatment in patients with cancer and HIV-induced cachexia to increase lean body mass and could be considered as a potential option for management of cachexia due to other causes such as schizophrenia. In this case report, we describe use of adjunct testosterone in a patient with schizophrenia and significant weight loss.

Methods: We present a case report of a patient with chronic schizophrenia who was admitted to our Schizophrenia inpatient unit with relapse of psychosis, catatonia and significant weight loss/malnutrition. His weight on admission was 38.2 kg with a body mass index (BMI) of 14. He was treated with antipsychotic medication and ECT, to which he responded favorably. However, after 6 months in hospital and despite improvement of his mental status, his oral intake and weight were still suboptimal. He was started on intramuscular testosterone to enhance muscle mass, address low weight and improve energy.

Results: An improvement in energy, appetite and weight was observed. Following 13 weeks of regular treatment with testosterone, his weight increased from 45 kg to 52 kg, correlating to a 15.5% increase in total body weight. There were no adverse effects.

Discussion: Supplementary testosterone can be considered as an adjunct option for treatment of persistent cachexia in patients with schizophrenia who continue to struggle with low body weight and low energy, despite optimized psychiatric treatment.

S238. NETWORK ANALYSIS OF SOCIAL COGNITIVE AND INTERPERSONAL BIASES RELATED TO SUICIDAL THOUGHTS AND BEHAVIOR IN PEOPLE WITH SERIOUS MENTAL ILLNESS

Emma Parrish^{*1}, Kevin Kuehn², Amy Pinkham³, Raeanne C. Moore², Philip D. Harvey⁴, Eric Granholm⁵, Scott Roesch⁶, Thomas Joiner⁷, Varsha D. Badal², Colin A. Depp⁵

¹San Diego State University / University of California San Diego Joint Doctoral Program in Clinical Psychology, ²University of California San Diego, Department of Psychiatry, ³The University of Texas at Dallas, ⁴University of Miami Miller School of Medicine, Research Service Miami VA Medical Center, ⁵University of California San Diego, Department of Psychiatry; Veterans Affairs San Diego Healthcare System, ⁶San Diego State University Department of Psychology, ⁷Department of Psychology, Florida State University

Background: People with serious mental illness (SMI; i.e., schizophrenia, schizoaffective disorder, bipolar disorder, and major depressive disorder with psychosis) are at an increased risk of suicidal ideation (SI) and behavior. There is limited understanding of the factors contributing to suicide in SMI nor are there many suicide prevention interventions developed or adapted for this group. Interpersonal biases (i.e., perceived burdensomeness [PB] and thwarted belongingness [TB]) are key to contemporary theories of suicide, and social cognitive biases such as over-attribution of threat that accompany SMI may foster sustained SI. Social motivations (i.e., approach and avoidance) may strengthen the association between PB, TB, and sustained SI. Due to the complex, dynamic, and interconnected associations between these variables, a network analysis provides a novel approach for hypothesis-generation and deeper understanding of these relationships.

Methods: Participants with SMI (N=273) completed three in-lab visits (baseline, 6-month, and 12-month) and ten days of ecological momentary assessment (EMA; 3x/day) immediately following the baseline visit. At all timepoints, participants were stratified as having SI (SI+) or no SI (SI-), and over 12-months participants were classified as having sustained SI if they reported SI at all three timepoints or had attempted suicide since the baseline visit. Mean EMA variables were compared between sustained SI+/- groups using independent samples t-tests. Network analyses identify partial correlations between variables represented as weighted connections and adjust for relationships between all variables in the network model. Network analysis was used to compare SI+/- participants' baseline EMA data in contemporaneous and temporal (time-lagged, lag-1) networks including PB, TB, social approach, social avoidance, and psychotic symptom EMA variables. Missing data was managed using multiple imputation.

Results: Baseline EMA variables were significantly different between sustained SI +/- groups. Contemporaneous models in groups with or without sustained SI indicate strong links between momentary interpersonal variables related to suicide and psychotic symptoms, with little difference in correlation direction or significance. Comparisons of time-lagged networks between sustained SI+/- groups revealed much denser connections between momentary variables in the sustained SI+ group than the sustained SI- group. The sustained SI+ group model included time-lagged links between mistrust to increased burdensomeness ($B=.10$, $SE=.03$, $p=.003$) and mistrust to decreased belongingness ($B=-.09$, $SE=.03$, $p=.007$) that were not present in sustained SI- model. Additionally, the sustained SI+ group model included time-lagged links between social approach motivation to decreased voices ($B=-.06$, $SE=.03$, $p=.008$) and social approach motivation to decreased social avoidance ($B=-.123$, $SE=.04$, $p=.001$) that were not present in the SI- model.

Discussion: Baseline network analysis of EMA was related to sustained SI over 12 months, suggesting the potential predictive ability of relationships between these variables in long-term SI trajectory. Network analyses revealed strong links between mistrust and other variables, particularly PB and TB, in the sustained SI+ group that were not evident in the sustained SI- group. These networks disentangle a complex set of interactions between variables, highlighting the links between mistrust, PB, TB, and social motivations, to identify potential suicide prevention treatment targets for people with SMI.

S239. SYSTEMATIC REVIEW AND META-ANALYSIS ON THE EFFECTS OF CHRONIC PERI-ADOLESCENT CANNABINOID EXPOSURE ON SCHIZOPHRENIA-LIKE BEHAVIOUR IN RODENTS

Zhikun Li^{*1}, Diptendu Mukherjee¹, Bea Duric¹, Isabelle Austin-Zimmerman¹, Giulia Trotta¹, Edoardo Spinazzola¹, Diego Quattrone¹, Robin Murray¹, Marta Di Forti¹

¹*King's College London*

Background: Epidemiological studies consistently establish a strong correlation between early-onset cannabis use and an increased risk of schizophrenia. In contrast, findings from rodent models exploring this association exhibit significant variability. This meta-analysis investigates the impact of adolescent cannabinoid exposure on diverse schizophrenia-like behaviours in rodents and explores the influence of experimental variables on outcomes.

Methods: We conducted a comprehensive review of English-language rodent studies up to June 2022. Synthesising data from 291 experiments across 91 articles, we assessed nine distinct schizophrenia-like behaviours following repeated adolescent (P23-45) cannabinoid exposure in rats and mice.

Results: Our analysis revealed that adolescent exposure to CB1R agonists induced pronounced schizophrenia-like alterations in cognition, memory, social motivation, sensorimotor gating, and anhedonia. However, locomotor hyperactivity, a proxy for positive symptoms of schizophrenia, exhibited negligible effects. These outcomes remained consistent across sexes and species. Moreover, substantial variations in experimental protocols and moderate-to-high heterogeneity in behavioural outcomes were observed across studies. Limited data also hinted at potential beneficial effects of CBD on specific phenotypes.

Discussion: This work provides the first meta-analytic evidence linking adolescent cannabinoid exposure to schizophrenia-like changes in rodents, contributing to the expanding body of research implicating cannabis use in schizophrenia. Our findings underscore the translational validity and robustness of animal models while emphasising the urgent need for standardising experimental protocols, which is essential for enhancing reproducibility and facilitating meaningful cross-study comparisons.

S240. REDUCED FORWARD HEAD POSTURE AND THE RELATIONSHIP WITH CARDIO-RESPIRATORY FUNCTION IN INDIVIDUALS WITH PSYCHOSIS SPECTRUM DISORDER, COMPARED TO AUTISM SPECTRUM DISORDER AND HEALTHY VOLUNTEERS

Ilona van de Meent¹, Lisanne Koomen¹, Arija Maat², Edwin van Dellen³, Wiepke Cahn⁴, Wiepke Cahn^{*5}

¹*UMC Utrecht*, ²*University Medical Center Utrecht, NL*, ³*Department of Psychiatry, University Medical Center Utrecht and Brain Center Rudolf Magnus, the Netherlands*, ⁴*Department of Psychiatry, Brain Center Rudolf Magnus, University Medical Center Utrecht, Utrecht, the Netherlands.*, ⁵*University Medical Center Utrecht*

Background: A forward head posture is often associated with both inactivity and immobility, reflecting characteristics commonly associated with sedentary lifestyles in individuals

diagnosed with psychotic disorders. A forward head posture, induces stress and muscle weakness in the cervical spine, potentially leading to respiratory problems. We examined the prevalence of forward head posture in individuals with psychosis. Individuals with Autism Spectrum Disorder receiving the same supporting household care and healthy volunteers were studied as independent control groups. Subsequently, we explored whether age and diminished cardio-respiratory fitness results serves as a prognostic indicator for reduced forward head posture.

Methods: A total of 85 participants with psychosis-spectrum disorder N=32, autism spectrum disorder N=26, and healthy volunteers N=27 were recruited. Photogrammetric quantification was employed to measure the craniocervical angle regarding a forward head posture. Information for Descriptive analyses was collected and contains information about, BMI, sex, age, psychotropic medication. The Sint Hans Rating Scale was assed to determine motor disturbances, Symptom severity was assessed by the brief symptom inventory and overall wellbeing by the world health organization quality of life questionnaire. The Åstrand bike test (VO₂ max) was employed to assess oxygen uptake in cardio-respiratory fitness.

Results: Individuals with psychosis had mean difference of GREATER THAN 11 degrees in craniovertebral angle, indicating a forward head position of 36.07C ($\pm$ 10.85) compared to individuals with autism spectrum disorder 47.45C ($\pm$ 9.09, P= 0.02) and healthy volunteers 48.13C ($\pm$ 6.39, P= LESS THAN 0.00). A linear relation with diminished cardio-respiratory fitness and reduced craniovertebral angle was particularly found in participants with psychosis spectrum disorder (R²= 0.45, P= LESS THAN 0.00). Age exhibited no significant predictive factor for the reduced craniovertebral angle in participants with psychosis spectrum disorder.

Discussion: Individuals with psychosis demonstrate a reduction of more than 11 degrees in vertebral angle compared to the control groups in this study, categorized as severe forward head posture. This correlates with diminished cardio-respiratory fitness. Recognizing the presence of a forward head posture in individuals with psychosis is crucial, as it may influence daily activities and potentially serve as a hindrance to initiating and sustaining physical exercises. Further research is recommended to investigate the underlying causes of this phenomenon, investigate potential treatment and its relation with cardiovascular and respiratory systems.

S241. ADDRESSING METABOLIC COMORBIDITY IN INDIVIDUALS WITH INTELLECTUAL AND DEVELOPMENTAL DISABILITY ON ANTIPSYCHOTICS: A CLINICAL CASE SERIES

Nicolette Stogios*¹, Margaret Hahn², Yona Lunskey³, Pushpal Desarkar³, Sri Mahavir Agarwal⁴

¹*Institute of Medical Science, University of Toronto, Centre for Addiction and Mental Health,*
²*Center for Addiction and Mental Health; University of Toronto,* ³*Centre for Addiction and Mental Health, University of Toronto,* ⁴*Centre for Addiction and Mental Health; University of Toronto*

Background: Individuals with intellectual and developmental disabilities (IDDs) have exceedingly high rates of serious metabolic comorbidities. This risk is further compounded by the use of antipsychotic (AP) drugs in this population. Despite the high prevalence, there is a lack of effective treatment options for metabolic comorbidity in IDD, particularly in the context of AP use. To date, metformin is the best researched agent for treating AP-induced weight

gain in severe mental illness; however, there is a paucity of literature examining the use of metformin for this purpose in individuals with IDD. This case series reports on the clinical use of metformin in patients with IDD on APs.

Methods: We conducted a retrospective review of patients in the Adult Neurodevelopmental Services Mental Health and Metabolic Clinic at the Centre for Addiction and Mental Health in Toronto, Canada. This is a novel clinical service for adults with IDD experiencing AP-related weight gain and other metabolic aberrations. We included patients of all ages that had an IDD diagnosis and were being treated with APs. Clinical records were reviewed for demographic, anthropometric, and metabolic data. These data were extracted for each patient at 2 timepoints: pre-metformin (values at the time of clinic referral/consolation) and post-metformin (their most recent follow-up data, as available). All variables were determined to have a normal distribution using the Shapiro-Wilk test; therefore, parametric tests were conducted. Categorical data were handled with Chi-squared tests and quantitative data with paired t tests.

Results: Eleven patients (8 male; mean age = 29.5 years) were enrolled into this program and were initiated on metformin to address metabolic concerns. All patients were on second-generation AP medications, including clozapine, olanzapine, and risperidone, for an average duration of about 7 years. Before commencing metformin, the mean weight of the group was 101.2 kg, which demonstrates a weight gain trajectory of approximately 34 kg compared with their mean weight of 67.2 kg before starting APs; the mean BMI was 34.5 kg/m² and the waist circumference was 112.5 cm before metformin. Four patients had a constellation of metabolic aberrations that met criteria for metabolic syndrome, whereas the remaining patients met at least 1 criterion. Mean weight loss while on metformin treatment was 11.1 kg, with over 50% of the sample achieving clinically meaningful weight loss of GREATER THAN 7% (p=0.01). Additional adaptive changes were observed for fasting glucose (p=0.049), glycated hemoglobin (p=0.01), triglycerides (p=0.01), and high-density lipoprotein cholesterol levels (p=0.08). One patient no longer met the criteria for metabolic syndrome. Furthermore, no significant tolerability concerns were reported by patients.

Discussion: In line with its use in severe mental illness, metformin may be a safe, effective, and accessible treatment option for patients with IDD experiencing metabolic adverse effects of AP medication. Clinically meaningful weight loss is associated with many favourable outcomes, including reduced rates of cardiometabolic comorbidities and improved quality of life. Lifestyle interventions demonstrate effectiveness in reducing obesity; however, people with IDD often experience barriers in the initiation and maintenance of such interventions, which limits the utility of lifestyle interventions in this population. Taking this into consideration, pharmacological interventions may be a necessary adjunctive strategy for weight loss for individuals with IDD who gain weight with AP use. Further research and randomized controlled trials are needed to examine the efficacy of metformin in this population.

S242. EXCESSIVE MORTALITY-TO-INCIDENCE RATIO OF CANCER RELATE TO HEALTH CARE DISPARITIES IN PATIENTS WITH SCHIZOPHRENIA: A NATIONWIDE COHORT IN TAIWAN

Chian-Jue Kuo^{*1}, Chu-Syuan Cheng¹, Shang-Ying Tsai², Chiao-Chicy Chen³

¹Taipei City Psychiatric Center, Taipei City Hospital, ²Taipei Medical University Hospital,

³Department of Psychiatry, Mackay Memorial Hospital

Background: Research on the occurrence and fatality of cancer in individuals with schizophrenia has yielded inconsistent results. In this study, we simultaneously investigated cancer incidence and mortality in patients with schizophrenia and evaluated the cancer mortality-to-incidence ratio (MIR), which is rare in the literature.

Methods: We collected the data of 107,489 patients who received a diagnosis of schizophrenia between 2000 and 2019 from the Taiwan National Health Insurance Database. Data regarding cancer incidence and mortality were obtained from the Taiwan Cancer Registry and National Mortality Database, respectively. In total, 3881 incident cancer cases and 2288 cancer mortality cases were identified. Standardized incidence ratios (SIRs), mortality rate ratio (MRRs), and MIRs were compared between patients with schizophrenia and the general population.

Results: Patients with schizophrenia showed a slightly lower cancer incidence rate (SIR: 0.95; 95% confidence interval [CI]: 0.92–0.98; $p < 0.001$) and a higher cancer mortality rate (MRR: 1.29; 95% CI: 1.23–1.3; $p < 0.001$) compared to the general population. The MIR for overall cancer was significantly higher in patients with schizophrenia. The relative MIR (MIR of patients with schizophrenia divided by that of the general population) was 1.36; 95% CI: 1.30–1.42. Several site-specific cancers were with excessive relative MIR: oral cavity, nasopharyngeal, stomach, colorectal, laryngeal, lung, breast, cervical, uterine, ovarian, and bladder cancers.

Discussion: Patients with schizophrenia exhibited lower cancer incidence but higher cancer mortality rates than the general population. The significantly higher MIR in patients with schizophrenia suggests disparities in cancer-related healthcare compared to the general population, potentially stemming from underdiagnosis and undertreatment of cancer in this patient group. Notably, potential healthcare disparities appeared to be greater for several cancers covered by Taiwan's nationwide population-based screening program, including oral cavity, colorectal, breast, and cervical cancers.

S243. EFFECT OF STAGE AT DIAGNOSIS, TREATMENT, AND PHYSICAL COMORBIDITIES ON MORTALITY FOLLOWING CANCER DIAGNOSIS AMONG PEOPLE WITH NON-AFFECTIVE PSYCHOTIC DISORDERS: A CAUSAL MEDIATION ANALYSIS

Jared Wootten^{*1}, Lucie Richard², Melody Lam³, Phillip Blanchette⁴, Igor Karp⁵, Marco Solmi⁶, Kelly Anderson¹

¹University of Western Ontario, ²MAP Centre for Urban Health Solutions, ³ICES Western, ⁴London Health Sciences Center, ⁵Western University, ⁶Department of Psychiatry, University of Ottawa

Background: People with psychotic disorders—which include schizophrenia and bipolar disorder—have a 10- to 15-year shorter life expectancy compared to the general population; concurrent medical illnesses such as cardiovascular disease and cancer account for much of this disparity (Hjorthøj et al., 2017). It has been previously suggested that the effect of having a psychotic disorder on mortality following cancer diagnosis is mediated through delayed stage at diagnosis, treatment disparities, and other physical comorbidities. (Mahar et al., 2020). Prior research has attempted to estimate the indirect effects through each of these factors using traditional regression methods. However, the structure of these variables in relation to one

another poses several challenges in traditional analyses. Namely, stage at diagnosis acts as a post-exposure confounder of the indirect effects through treatment. Conditioning on stage using traditional regression analyses results in collider bias.

Methods: We constructed a retrospective cohort of cases of non-affective psychotic disorder (NAPD) and a general population comparison group using Ontario health administrative data. We identified cases of cancer diagnosed between 1995 and 2019 and obtained information on stage at diagnosis, cancer-related treatment, comorbidities, and mortality. We will construct marginal structural Cox models with G-computation to estimate the Randomized Interventional Analogues of Indirect Effects (RIANIE) from diagnosis with NAPD to mortality following cancer diagnosis through stage at diagnosis, treatment received, and physical comorbidities, adjusting for baseline covariates.

Results: We anticipate that a large proportion of the total causal effects of prior diagnosis with NAPD on mortality following cancer diagnosis are mediated through these 3 variables.

Discussion: Conclusion: This study will be the first to examine the indirect effects of having a NAPD through stage at diagnosis and treatment using marginal structural models, which are equipped to manage post-exposure confounding, unlike traditional regression mediation analyses. Providing an estimate of these indirect effects through stage at diagnosis and treatment will determine the proportion of the mortality gap among people with NAPD can be accounted for by delays in diagnosis and treatment disparities. By identifying how these variables account for mortality, we can work to develop effective programs to target these disparities, in turn reducing the mortality gap.

S244. PHYSICAL HEALTH COMORBIDITIES AMONG PERSONS WITH UNTREATED PSYCHOTIC DISORDER IN DIVERSE SETTINGS OF THE GLOBAL SOUTH

Akin Ojagbemi^{*1}, Idowu Olufemi¹, Bola Olley¹, Georgina Miguel Esponda², Tessa Roberts², Sujit John³, Vijaya Raghavan³, Joni Lee Pow⁴, Casswina Donald⁴, Olatunde Ayinde¹, Joseph Lam², Paola Dazzan², Fiona Gaughran², Alex Cohen⁵, Helen Weiss⁵, Robin Murray², Rangaswamy Thara³, Gerard Hutchinson⁴, Craig Morgan², Oye Gureje¹

¹University of Ibadan College of Medicine, ²King's College London, ³Schizophrenia Research Foundation, Chennai, India, ⁴University of the West Indies, Saint Augustine, Trinidad, ⁵London School of Hygiene and Tropical Medicine

Background: There is limited information on the prevalence and profile of comorbid physical health conditions in persons with untreated psychotic disorder in the Global South.

Methods: Data were collected as part of the International Research Programme on Psychoses in Diverse Settings (INTREPID II), a population-based incidence and case-control study conducted in selected catchment areas in India, Nigeria and Trinidad. Cases were aged 18-64 years with an untreated psychotic disorder diagnosed according to ICD 10 criteria. Controls were matched for age, sex, and recruited from the same neighbourhood as cases. Physical health measurements were acquired using the WHO STEPwise approach to non-communicable disease risk factors surveillance instrument (WHO STEPS). We estimated adjusted odds ratios (aOR) using unconditional logistic regression.

Results: We enrolled 225, 209, and 212 case-control pairs in India, Nigeria, and Trinidad, respectively. Among cases and controls across all sites, high cholesterol and raised C-reactive protein were common (i.e., over 50% for both in all groups and sites), but with no consistent

associations with psychotic disorder. Undernutrition was more common among cases compared with controls in India (26.9% vs 8.4%, aOR= 2.86, 95% C.I=1.56 – 5.28) and Nigeria (24.9% vs 10.1%, aOR= 3.01, 95% C.I= 1.70 - 5.33). Hypertension was less common among cases compared with controls in India (Self report: 6.7% vs 22.2%, aOR=0.24, 95% C.I=0.13 - 0.45) and Nigeria Measured: 8.9% vs 22.0%, aOR=0.30, 0.16 - 0.57). Differences between cases and controls were more modest (albeit in the same direction) for both undernutrition and hypertension in Trinidad.

Discussion: We found a unique pattern of elevated physical health comorbidity with untreated psychotic disorder in three diverse settings of the Global South. Elevated cardiometabolic risk was not evident, but cases were more likely to be undernourished, possibly reflecting increased association of psychotic disorder with severe economic and social disadvantage in these settings.

S245. EXPLORING THE IMPACT OF PSYCHOTHERAPY ON PTSD SYMPTOMS IN PATIENTS WITH A PSYCHOTIC DISORDER: A NON-TRAUMA-FOCUSED INTERVENTION APPROACH

Vanessa McGrory*¹, Danielle Penney², Pascale Brillon¹, Martin Lepage³

¹*Université du Québec à Montréal*, ²*Douglas Mental Health University Institute and L'Université du Québec à Montréal*, ³*McGill University, Douglas Mental Health University Institute*

Background: Addressing post-traumatic stress symptoms (PTSS) in patients with psychotic disorders presents a critical dichotomy. On one hand, interventions are offered and focused primarily on targeting PTSS. On the other, PTSS are either overlooked in the treatment of psychosis, fearing adverse outcomes such as symptom exacerbation or relapse, or fall under the radar. In fact, research reports that 96.9% of comorbid PTSD in this population remains undiagnosed; therefore, PTSS prevail untreated. With a lack of evidence-based treatments for addressing post-traumatic effects in the early stages of psychosis, and with the routine exclusion of individuals with psychotic disorders from research trials for PTSS, there is a need to develop a deeper understanding of appropriate interventions, and barriers to recovery in a population with comorbid trauma and psychotic symptoms. Considering these circumstances, exploring the effects of psychosocial interventions for individuals with psychosis on comorbid PTSS would be beneficial to estimate whether interventions that are not explicitly trauma-focused are associated with improvement in these comorbid symptoms.

Methods: We sought to uncover the relationship between completion patterns in psychosocial interventions for psychosis, and the presence and severity of comorbid PTSS pre- and post-intervention. Data were collected from adults (n=39) receiving different group-based interventions for psychosis from the Psychotic Disorders Program at the Douglas Mental Health University Institute in Montreal, Canada. PTSS severity was collected using the PTSD Checklist for DSM-5 (PCL-5) both prior to and following the intervention. Participants attended either of the following psychotherapies: Social Cognition and Interaction Training (SCIT; n=4), Cognitive Restructuring Therapy (CRT; n=11), or Cognitive Behavioural Therapy (CBT; n=24).

Results: Results revealed that 64.1% (n=25) of participants qualified as completers for their respective intervention, whereas 35.9% (n=14) did not. Intervention completion status was determined based on attending more than 50% of sessions of a given intervention. On average,

participants qualifying as completers attended 83% of psychotherapy sessions. Furthermore, results indicated that receiving a psychological intervention for psychosis, albeit non-trauma focused, was associated with a significant decrease in PTSS ($t(19) = 3.63$, $p < .001$) for therapy completers and the effect size was large (Cohen's $d = 0.81$; CI: 0.30, 1.31). Moreover, decrease in symptom severity was most pronounced for the hyperarousal ($t(19) = 4.02$, $p < .001$) and negative alteration ($t(19) = 2.71$, $p = .007$) dimensions and these results showed large (Cohen's $d = 0.90$; CI: 0.37, 1.41) and medium (Cohen's $d = 0.61$; CI: 0.12, 1.08) effect sizes, respectively.

Discussion: The significant finding that a non-trauma-focused psychosocial intervention is associated with a marked reduction in PTSS challenges existing notions about the management of comorbid PTSD in patients with psychosis. This underscores the potential of general psychosocial support in addressing broader psychopathological issues beyond primary psychotic symptoms. The pronounced decrease in hyperarousal and negative alteration symptoms could indicate that certain components of psychosocial therapy may inadvertently target mechanisms that maintain PTSS. These findings argue against the prevailing hesitancy to engage individuals with psychotic disorders in PTSD treatment.

S246. SCHEMA CHARGE AND PERMEABILITY IN SCHIZOPHRENIA SPECTRUM DISORDERS

Jessica D'Arcey^{*1}, Michael Best²

¹University of Toronto Scarborough, Centre for Addiction and Mental Health, ²University of Toronto Scarborough

Background: Cognitive models of psychopathology, including psychosis, highlight cognitive schemas and biases as key cognitive mechanisms in the development and maintenance of symptoms. Schemas provide the organizational structure to our beliefs and, when maladaptive, are characterized by a pattern of over-activation (i.e., schema charge) and rigidity (i.e., low schema permeability). Cognitive biases, such as externalizing biases and attention to threat bias, are skewed information processing mechanisms. Maladaptive schemas give rise to cognitive biases, which serve as the basis of delusional and hallucinatory belief systems through interpretation. The current study investigated whether schema charge and permeability differ in individuals with schizophrenia-spectrum disorders (SSDs) compared to healthy controls to provide potential insights into the role of these mechanisms in psychosis. Secondary aims investigated the relationship between schema permeability and charge and whether it's mediated by cognitive biases.

Methods: This study uses an experimental design consisting of two computerized manipulations designed to increase and decrease the activation of maladaptive cognitive schemas and biases. Participants first participated in an exclusion version of Cyberball (a computerized game of toss/catch) wherein participants were tossed the ball twice at the beginning of the task and subsequently completely excluded. Following is an inclusion version wherein one of the computerized players apologized, provided an explanation for the prior exclusion, and subsequently fully included the participant. Measures of cognitive mechanisms were conducted prior to the exclusion version, between the exclusion and inclusion version, and the post-inclusion version. Primary measures included the Brief Core Schema Scale (negative self and other subscales), the Davos Assessment of Cognitive Biases Scale (DACOBS) and the Bias Against Disconfirmatory Evidence (BADE) task. Group differences

across the three different time points were investigated using ten mixed methods 2X2 ANOVAs, and eight mediations were used to investigate relationships between schema charge, permeability and cognitive biases.

Results: Seventeen individuals with SSDs and 16 controls completed the experimental visit to date. Interim analyses show the following results. Individuals with SSDs endorsed stronger negative schemas (other schemas $2 = .20$, $p = .009$, self-schemas $2 = .19$, $p = .013$) and self-reported cognitive biases (DACOBS $2 = .197$, $p = .01$) than controls across experimental conditions, and no significant interactions with Cyberball conditions were found. The BADE did not show significant differences between groups. The bias against disconfirmatory evidence significantly mediated the relationship between schema charge and schema permeability ($b = .13$, CI [.02, .29]). No other mediation models were significant.

Discussion: Results of this study suggest that cognitive schemas and biases can be successfully manipulated in brief periods of time using stressful stimuli such as Cyberball, which has important implications for future study design. Further, overall, results support the cognitive theory that negative cognitive schemas are more activated in individuals with SSDs and have important relationships with cognitive biases. Results should be interpreted considering the small sample size, which impacts generalizability. Larger longitudinal trials are required to further elucidate these relationships. Further, future studies may consider including other types of psychopathologies, such as depression, as a comparison group in addition to psychiatrically healthy controls.

S247. FAMILY METACOGNITIVE TRAINING (MCT-F): ADAPTING MCT TO MOTHERS WITH PSYCHOSIS AND THEIR ADOLESCENT CHILDREN

Victoria Espinosa^{*1}, Paula Arin-González², Alba Jiménez Lafuente², Nerea Pardo², Raquel López Carrilero², Irene Birulés², Ana Barajas³, Trinidad Pélaez², Luciana Díaz-Cutraró¹, Marina Verdaguer-Rodríguez¹, Alfonso Gutiérrez Zotes⁴, Carolina Palma-Sevillano⁵, Paloma Varela Casals⁶, Miriam Salas-Sender⁷, Ana Aznar⁸, Rosa Ayesa-Arriola⁹, Esther Pousa¹⁰, Manuel Canal-Rivero¹¹, Nathalia Garrido-Torres¹¹, Clara Montserrat¹², Laura Muñoz-Lorenzo¹³, Josep Maria Crosas¹⁴, Susana Ochoa¹

¹Institut de Recerca Sant Joan de Déu, ²Parc Sanitari Sant Joan de Déu, ³Departament de Psicologia, Facultat de Psicologia Clínica I de la Salut. Serra Húnter Programme, Universitat Autònoma de Barcelona, Bellaterra, Cerdanyola del Vallès, ⁴Hospital Universitari Institut Pere Mata, Institut d'Investigació Sanitària Pere Virgili-CERCA, Universitat Rovira i Virgili, ⁵Psychology Department, FPCEE Blanquerna, Universitat Ramon Llull, ⁶Hospital de Mataró, Consorci Sanitari del Maresme, ⁷Miriam Salas-Sender Parc Sanitari Sant Joan de Déu, ⁸Departament de Psicologia, Facultat de Psicologia Clínica I de la Salut. Serra Húnter Programme, Universitat Autònoma de Barcelona, ⁹Department of Psychiatry, Marqués de Valdecilla University Hospital, IDIVAL. School of Medicine, University of Cantabria, ¹⁰Department of Psychiatry, Hospital de la Santa Creu i Sant Pau, Institut d'Investigació Biomèdica-Sant Pau (IIB-Sant Pau), ¹¹Virgen del Rocío University Hospital, Network Centre for Biomedical Research in Mental Health (CIBERSAM), Institute of Biomedicine of Seville (IBiS), University of Seville, First-episode Psychosis Research Network of Andalusia (Red PEPSur), ¹²Hospital del Mar Medical Research Institute (IMIM) of Barcelona, Autonomous University of Barcelona, ¹³Departamento de Psiquiatría, IIS-Fundación Jiménez Díaz,

Background: Over half of women with psychosis are mothers, a similar percentage to that found in females without a mental disorder diagnosis. Research suggests that mothers with psychosis face unique challenges affecting both their mental health prognosis and the relationship with their children. Symptoms are associated with deficits in social cognitive skills, potentially affecting patients' relationship with their children. Furthermore, in comparison to their male counterparts, mothers with psychosis were more likely to be a single parent, perform most parenting tasks or report having parenting-related stress. In consequence, custody loss is experienced more often than in mothers without mental health problems and their children have a higher risk of developing a mental health disorder. Notwithstanding, interventions specifically tailored to mothers with psychosis and their adolescent children remain largely uncovered. The Metacognitive Training has demonstrated its efficacy in improving cognitive insight, symptom management and social cognition in people with psychosis. Additionally, MCT has shown better results in females than males with psychosis. However, there is no evidence of the efficacy of MCT in a family setting (MCT-F).

Methods: This study describes the formative phases, processes, and methods used to adapt the evidence-based MCT for mothers with psychosis and their adolescent children in an online group setting. The paper presents how the phases (assessment, decision, adaptation, production, topical experts-integration) of the ADAPT-ITT model were systematically applied through a participatory approach (n=22), including first-person perspective and involving qualitative (e.g., topical expert literature review and consensus groups, interviews, thematic analyses) and quantitative methods.

Different types of triangulations were implemented to ensure the validity and transferability of the adaptation process.

Results: Patients, relatives, adolescents, and experts broadly perceived the intervention to be helpful, acceptable, and necessary. While MCT's core components were retained, participants guided adaptations both in the structure, format, content and delivery of the intervention, optimizing acceptability and feasibility of implementation.

Discussion: A main limitation of the study was the relatively low number of mothers with psychosis or adolescents involved in adaptation step. Nevertheless, participants' suggestions were congruent with topical expert's opinions. Findings suggest the importance of community engagement and sharing decision-making to demonstrate the acceptability and feasibility of the adapted intervention. Employing a structured approach such as the ADAPT-ITT model ensures readiness and suitability of the new training for efficacy trials. Implementation of MCT-F could enhance mothers with psychosis and adolescents' functioning and better understanding of the disease. Additionally, it may have a protective and preventive effect on adolescents, who are known to be at higher risk of developing severe mental disorders.

S248. "I AM PROUD OF HOW I HANDLED IT." EXPLORING THE IMPACT OF THE COVID-19 PANDEMIC AND RELATED RESTRICTIONS ON WELL-BEING OF ADULTS WITH SEVERE MENTAL ILLNESS USING PARTICIPATORY ACTION RESEARCH

Lotte van Rijn*¹, Margot Metz², Pip van der Velden², Pleun Mathijssen², Wilma Swildens³, Arnt Schellekens⁴, Wiepke Cahn⁵, Megan Milota⁶, Janneke Zinkstok⁴

¹*Radboud University Nijmegen*, ²*GGz Breburg, Institute for Mental Health Care, Breda, The Netherlands*, ³*Altrecht, Institute for Mental Health Care*, ⁴*Department of Psychiatry, Radboud University Medical Center, Donders Institute For Brain, Cognition, and Behavior*, ⁵*Department of Psychiatry, University Medical Center Utrecht*, ⁶*Julius Center for Health Sciences and Primary Care, University Medical Center Utrecht*

Background: The COVID-19 pandemic and related restrictions globally impacted mental health, particularly for those with pre-existing severe mental illness (SMI) including schizophrenia. This qualitative study examined how adults with SMI perceived the effects of the COVID-19 pandemic and related restrictions in the Netherlands, focusing on their personal recovery, well-being and daily life, including an exploration of factors influencing these effects.

Methods: Semi-structured interviews were conducted, audio-recorded and transcribed verbatim. Reflexive thematic analysis was applied. The study used a participatory action research approach, with experts-by-experience involved in every stage of the project as part of the research team.

Results: Twenty participants (median age 45 (SD: 12,8) ; 11 female) were interviewed between May and July 2023. Findings revealed a wide range of experiences: while some individuals reported a negative impact on their existing psychiatric symptoms, others described adaptability, resilience, and even positive effects of COVID-restrictions on their mental health and well-being. Factors influencing the heterogeneous perceptions of COVID-19 pandemic and related restrictions include the availability of trusted social relationships and enduring interactions with health professionals.

Discussion: Personalized support, both socially and professionally, is crucial for addressing fears, building resilience, reducing isolation, and encouraging positive coping strategies for individuals with SMI during external crises. In this project, a participatory research approach that integrated the lived experience perspective helped uncover the unique perceptions of people with SMI with regards to the pandemic and related restrictions.

S249. BURDEN AND MANAGEMENT OF TARDIVE DYSKINESIA (TD): A CROSS-SECTIONAL, INTERNATIONAL SURVEY STUDY TO ASSESS THE PERCEPTIONS AND EXPERIENCES OF PHYSICIANS AND PATIENTS WITH TD

Rinat Ribalov¹, Ayelet Yaari*², Aviva Peyser Levin³, Amy Yang⁴, Dahbia Horchi⁵, Erwan Berjonneau⁵, Perrine Le Calvé⁵, Marc Tian⁶, Shoshana Reshef⁷, Suzanne Reed⁵

¹*Teva Pharmaceutical Industries Ltd., Global Health Economics and Outcomes Research*, ²*Teva Pharmaceutical Industries, Ltd.*, ³*Teva Pharmaceutical Industries Ltd., International Markets Medical Affairs*, ⁴*Teva Branded Pharmaceutical Products R and D, Inc., Global Health Economics and Outcomes Research*, ⁵*Oracle, Paris, France*, ⁶*Teva Branded Pharmaceutical Products R and D, Inc., Real World Evidence Statistics*, ⁷*Teva Branded Pharmaceutical Products R and D, Inc., Epidemiology and Global Health Economics and Outcomes Research*

Background: Data on the perceptions of physicians and patients in Australia, Brazil, China, Israel, and South Korea toward TD management and impact on daily living are limited, particularly on patient quality of life (QoL). This study assessed physician and patient perceptions of the management of TD and its impact on daily life.

Methods: Patients (aged ≥ 18 years) who self-reported a physician diagnosis of TD, experienced TD-related movements, and had a diagnosis of schizophrenia or schizoaffective disorder, bipolar disorder, or major depressive disorder were recruited via online panels, social media, or physician referral to participate in a 20-minute online survey (27 June through 17 October 2022). Certified neurologists and psychiatrists (in practice ≥ 3 years, $\geq 60\%$ of time in direct patient care, treating ≥ 3 patients with TD in prior 2 years) were invited via panels to participate in a separate 20-minute online survey (27 June through 27 July 2022). Physician and patient data were unlinked.

Results: 435 patients and 340 physicians from Australia, Brazil, China, South Korea, and Israel (physicians only) were included in the study. 29% of patients reported that TD always/often interfered with treatment adherence for their underlying psychiatric condition, 25% reported that TD always/often worsened their underlying psychiatric condition, and 47% reported that they developed additional psychiatric conditions. In comparison, most physicians reported a moderate to very strong impact of TD on worsening adherence with treatment for the underlying condition (75%), an effect of TD on underlying psychiatric condition symptoms (71%), and development of other psychiatric symptoms (78%). While the majority believed that TD had a moderate to strong impact on QoL (85% patients, 88% physicians), 63% of patients reported strong impact on their QoL compared with 46% of physicians.

Discussion: In this survey, both patients and physicians agreed that TD has a substantial impact on patient QoL. These results indicate that TD could undermine psychiatric stability by worsening underlying psychiatric conditions and treatment adherence. The difference between the level of importance that patients and physicians give to the impact of TD highlights the need for better dialogue between them.

S250. THE RELATIONSHIPS BETWEEN PSYCHOLOGICAL RESILIENCE, SCHIZOPHRENIA, AND SUICIDAL EXPERIENCES: A LONGITUDINAL STUDY

Kamelia Harris^{*1}, Gillian Haddock¹, Sarah Peters¹, Patricia Gooding¹

¹*University of Manchester*

Background: Schizophrenia is a severe mental health problem which is associated with a considerably higher risk of suicide death compared to that in the general population. In addition, experiencing suicidal thoughts and attempts is even more frequent in people with schizophrenia. Suicide deaths in that population present a significant healthcare concern. Research suggests that schizophrenia and the associated distress heighten the risk of suicidal experiences, while psychological resilience mitigates the impact of key suicide precursors, such as defeat, entrapment, and hopelessness. However, there is a gap in longitudinal testing regarding the moderating roles of psychosis symptoms, the associated distress, and psychological resilience in the relationships between defeat, entrapment, hopelessness, and suicidal thoughts and behaviours.

Methods: Participants (N=100) with schizophrenia-spectrum diagnoses (including schizophrenia, schizophreniform disorder, schizoaffective disorder, delusional disorder, or

unspecified psychotic disorders) and a history of suicidal thoughts, plans, and/or acts, were recruited from community mental health and inpatient services in Northern England, UK. This three-month longitudinal study used moderated mediation analyses to examine two key aspects: (1) the influence of defeat/entrapment and hopelessness on suicidal thoughts and behaviours, and (2) the moderating effects of psychosis, the associated distress, and psychological resilience in the associations between defeat/entrapment, hopelessness, and suicidal thoughts and behaviours.

Results: Of the 100 participants at baseline, 80% were female, 73% were White British, approximately 60% had a diagnosis of schizophrenia, and their mean age was 41 years. Ninety participants completed the three-month follow-up assessment. Baseline data revealed that most participants had experienced one or more lifetime suicide attempts. Suicidal thoughts and behaviours scores were significantly lower at follow-up compared to baseline. Delusions and hallucinations severity strengthened the relationship between defeat/entrapment and subsequent suicidal thoughts and behaviours. Additionally, the baseline level of distress associated with delusions and hallucinations strengthened the link between defeat/entrapment and suicidal thoughts and behaviours at follow-up. These associations were significant when the severity of baseline delusions and hallucinations, coupled with distress, was of moderate to high levels, and baseline resilience was low.

Discussion: The relationship between baseline defeat/entrapment and suicidal thoughts and behaviours at follow-up was not mediated by hopelessness. This finding contrasts with prior studies that have identified hopelessness as a significant precursor to suicidal thoughts and behaviours. One possible explanation for this result is the overlap of defeat, entrapment, and hopelessness as constructs within the current sample. In addition, there is an argument that perceptions of hopelessness may precede or follow experiences of defeat and entrapment. To achieve conceptual clarity on the roles of defeat, entrapment, and hopelessness in suicidal experiences among individuals with schizophrenia, further research is warranted. The combined impact of defeat/entrapment, psychosis, the associated distress, and psychological resilience should be considered in interventions aimed at reducing suicidal experiences. These findings emphasise the need to tailor suicide prevention interventions to address the complex dynamics of psychosis and resilience in individuals with schizophrenia diagnoses.

S251. DIFFERENTIAL RISK: HOW RACIAL DISCRIMINATION LEADS TO VARYING RISK IN THE RELATIONSHIP BETWEEN TRAUMA AND MULTIDIMENSIONAL SCHIZOTYPY

Mahogany Monette^{*1}, Madisen Russell², Danielle Abel², Jarrett Lewis³, Jessica Mickens², Evan Myers⁴, Megan Hricovec⁵, David Cicero⁵, J Wolny⁶, William P. Hetrick⁶, Michael Masucci⁷, Alex Cohen⁷, Christopher Burgin⁸, Kyle S. Minor⁹, Thomas R. Kwapil¹⁰

¹Indiana University Purdue University Indianapolis, ²Indiana University- Purdue University, Indianapolis, ³University of Illinois at Urbana-Champaign, ⁴Indiana University - Purdue University Indianapolis, ⁵University of North Texas, ⁶Indiana University, ⁷Louisiana State University, ⁸Tennessee Technological University, ⁹Indiana University Purdue University, ¹⁰Department of Psychology, University of Illinois at Urbana-Champaign

Background: Traumatic experiences are associated with experiencing positive schizotypy. This may be especially important for People of Color, who endorse higher rates of trauma and

racial discrimination. The present study aimed to examine racial disparities in how multidimensional schizotypy traits (positive, negative, and disorganized) are observed.

Methods: 770 Black, Asian, and Latine college students from six universities completed measures of trauma (Life Events Checklist and Post Traumatic Stress Disorder Checklist 5), racial discrimination (Experiences of Discrimination Scale), and multidimensional schizotypy (Multidimensional Schizotypy Scale). One-way ANOVAs were conducted to examine racial and gender differences in trauma, racial discrimination, and multidimensional schizotypy. Stepwise hierarchical regression analyses were used to examine if racial discrimination moderated the relationship between trauma and multidimensional schizotypy.

Results: As hypothesized, Black students endorsed significantly higher racial discrimination than Latine and Asian students. Furthermore, Black and Latine students endorsed significantly higher multidimensional schizotypy and trauma than Asian students. Racial discrimination and trauma explained 8 to 23% of the variance in each dimension of schizotypy. Only one moderation model approached significance: trauma X racial discrimination predicting disorganized schizotypy ($\beta=.13$, $p=0.09$).

Discussion: Our findings suggest that racial discrimination and trauma account for up to nearly a quarter of the variance in multidimensional schizotypy. Additionally, there were race and gender differences in the severity of trauma, discrimination, and schizotypy. Psychological interventions must account for how racial discrimination and trauma may impact symptom presentation.

S252. FINANCIAL DISSATISFACTION IN PEOPLE WITH PSYCHOTIC DISORDERS- A SHORT REPORT ON ITS PREVALENCE AND CORRELATES IN A LARGE NATURALISTIC PSYCHOSIS COHORT

Josephien Jansen^{*1}, Richard Bruggeman², Henk Kiers¹, Marieke (Gerdina) Pijnenborg³, Stynke Castelein⁴, Wim Veling⁵, Ellen Visser⁶, Lydia Krabbendam⁷, Janneke Koerts¹

¹University of Groningen, ²University of Groningen / University Medical Center Groningen, ³University of Groningen / GGZ Drenthe Mental Health Institute, ⁴Lentis Research / University of Groningen, ⁵University Medical Center Groningen, ⁶Rob Giel Research Center of University Medical Center Groningen, ⁷Vrije Universiteit Amsterdam

Background: Psychotic disorders have a strong negative impact on multiple aspects of daily life, including people's financial situation. This exploratory study examines the level of financial dissatisfaction and its correlates in a large cohort of people with psychotic disorders.

Methods: Data from the first assessments of people with psychotic disorders ($n = 5271$) who were included in the Pharmacotherapy Monitoring and Outcome Survey (PHAMOUS; 2006-2020), which is conducted in the northern Netherlands, were used. The Manchester Short Assessment of Quality of Life (MANSA) was used to measure financial dissatisfaction. In addition, sociodemographic and psychiatric characteristics, substance use and global and social functioning were assessed.

Results: One-fifth to one-third of people with psychotic disorders report financial dissatisfaction, fluctuating over the year in which they were assessed. These proportions are three to four times higher than in the general Dutch population. Cannabis and other substance use were associated with higher levels of financial dissatisfaction (small to medium effect). Financial dissatisfaction appears to be relatively independent of sociodemographic and

psychiatric characteristics, and global and social functioning in people with psychotic disorders.

Discussion: These findings are an important first step for increasing knowledge on financial dissatisfaction among people with psychotic disorders. The findings can also contribute to raising awareness about the topic for healthcare professionals working in this field, as financial dissatisfaction seems a crucial stressor to consider in clinical practice.

S253. WORKING WITH SCHIZOPHRENIA: A MIXED-METHOD STUDY OF EMPLOYMENT STATUS AND EMPLOYABILITY AMONG THE PEOPLE LIVING WITH SCHIZOPHRENIA IN CHINA

Yilu Li*¹

¹*Xiangya School of Public Health, Central South University*

Background: People living with schizophrenia (PLS) have long challenged the presumption that having schizophrenia means that a person cannot work. They hope, and strive to prove, that they can work, regain independence and recover. It is not surprising that so many PLS express a strong desire to work and regard getting a job as their goal of recovery. Too often, however, PLS are unwelcome and invisible in the labor market. Employment rates for PLS have been particularly low. To date, the employment status of PLS in China is still unclear, and explanations of PLS unemployment generally focus only on supply-side factors. New evidence and understanding of potential external and internal factors on the employment outcomes of PLS are needed. The purpose of this mixed-methods study was to assess the employment status of PLS in China and identify factors related to their employability.

Methods: To answer the research questions, the mixed methods approach was used in this study. This study used a sequential explanatory mixed methods design. At the first stage, the quantitative data is collected and analyzed to understand employment status and identify potential influenced factors on the PLS' employment. Then, the qualitative data is collected and analyzed to explain why the employment status of PLS presents the current picture and to explain what factors may affect PLS's employability. Quantitative results on employment status were obtained from a survey of 823 PLS from four cities in China. The working status during the last month and before the diagnosis of schizophrenia of PLS were measured by self-administered questionnaires. In addition, in-depth interviews were conducted with 24 purposively selected respondents. The techniques of thematic analysis were adopted in qualitative data analysis.

Results: Quantitative findings indicate that 15.2% of PLS are competitively full-time employed and 3.5% are competitively part-time employed. Only 13.5% of PLS maintained their competitive employment after being diagnosed with schizophrenia. Competitively employed PLS reported higher levels of social functioning, lower levels of disability, and less severe symptoms than unemployed PLS. Qualitative findings explain the employment status of PLS and illustrate what factors influence the employability of PLS in China. This study proposes a framework for the employability of PLS based on individual factors, personal circumstances, and external factors. Individual factors, including health and well-being, work skills, work experience, educational attainment, "guanxi" network, gender and age are important factors influencing the work motivation and work performance of PLS in China. Personal circumstances, such as socioeconomic contextual factors in PLS's family and family caregiving responsibilities, are a contextual factor in PLS's consideration of whether to seek and maintain competitive employment. External factors, including the labor market and

macroeconomic context, stigma and discrimination, mental health services and policy factors, determine how likely PLS are to be employed and what types of jobs they are likely to obtain. PLS also internalize their perceptions and opinions about the external employment environment (e.g., whether the market is buoyant, whether employers discriminate against PLS), which affects their motivation and incentives to work. Individual factors, personal circumstances, and external factors interact with each other, and a multifaceted combination of these factors shape the employability of PLS.

Discussion: This study suggests that PLS in China face considerable difficulties in maintaining employment after being diagnosed with schizophrenia. Although the government has increased its commitment to supporting the employment of PLS in recent years, the employment rate of PLS in China remains low. The PLS employability framework in this study suggests how PLS households, the macroeconomic context, mental health systems, and social welfare systems influence PLS employment. The employed PLS in China mainly work in the low-skilled service sector, reflecting the large increase of low-skilled service employment in China. However, a large number of workers have been laid off from the manufacturing sector due to its decline and have flocked to the service sector to find employment. Moreover, wages in the low-skilled service sector have been declining in China since 2014. This means that PLS have to facing increased competition and declining wages, which greatly reduces their willingness to work. There is an urgent need to implement targeted employment support programs for PLS. Based on the findings of this study, several recommendations have been made to support the employment of PLS. First, the findings of this study suggest that the "supply-side orthodoxy" in employment support policy and practice needs a significant shift. The development of employment support programs should explore more effective ways to expand employment opportunities for PLS. Second, mental health services should provide employment support for PLS, such as helping PLS cope with work stress and medication management. Finally, in addition to workplace stigma, associated and structural stigma are equally important to the employment of PLS.

S254. HUMANISTIC BURDEN OF COGNITIVE IMPAIRMENT AMONG PATIENTS WITH SCHIZOPHRENIA USING UNITED STATES MEDICAL EXPENDITURE PANEL SURVEY DATA

Tavneet Singh¹, Mona Nili², Briana Choi¹, Cindy Lam¹, Pin Xiang^{*2}, November McGarvey¹, Christoph Correll³

¹BluePath Solutions, ²Boehringer Ingelheim, ³The Zucker Hillside Hospital

Background: Cognitive impairment is a critical yet often overlooked aspect of schizophrenia. Individuals with schizophrenia frequently struggle with memory, attention, and executive functioning. These challenges can significantly impair their ability to plan, adapt, solve problems, or engage in social interactions. This study aims to assess the impact of cognitive impairment on humanistic outcomes in patients with schizophrenia.

Methods: This cross-sectional study analyzed data from the 1997-2021 Medical Expenditure Panel Survey (MEPS), which represents non-institutionalized individuals in the United States. This study included adults (≥ 18 years old) with schizophrenia. For capturing cognitive impairment, two variables, cognitive limitations (CL) and cognitive difficulties (CD) were used. CL included reports of interferences with daily activities due to confusion/memory loss, problems making decisions, or requiring supervision for their own safety (data available from 1997-2021). CD included reports of difficulty in concentration, memory, or decision-making

(data available from 2013-2021). Patient characteristics and health-related quality of life measures such as the short form 12 physical component score (SF-12 PCS) and short form 12 mental component score (SF-12 MCS) were analyzed in this study. The complex survey design of MEPS was accounted for in all analyses.

Results: The study included 1,827 participants, representing 661,243 adults with schizophrenia in the United States. The average age was 45.6 years, with 56.7% being male. Among the participants, 57.6% reported having CL, and 53.5% had CD. Those with CL had significantly lower scores in SF-12 PCS (0.64 vs. 0.71, p LESS THAN 0.01), SF-12 MCS (0.75 vs. 0.96, p LESS THAN 0.01), and SF-6D (0.61 vs. 0.74, p LESS THAN 0.01) compared to individuals without CL. Additionally, a higher percentage of individuals with CL reported poor perceived physical health status (15.8% vs. 5.7%, p LESS THAN 0.01) and poor perceived mental health status (29.5% vs. 10.0%, p LESS THAN 0.01) compared to those without CL. Individuals with CL also experienced more limitations in activities of daily living (ADL) (16.4% vs. 3.1%, p LESS THAN 0.01) and instrumental activities of daily living (IADL) (53.8% vs. 19.2%, p LESS THAN 0.01). Limitations in social/recreational activities (62.0% vs. 18.7%, p LESS THAN 0.01) and in work/house/school activities (89.0% vs. 49.9%, p LESS THAN 0.01) were also more reported among those with CL. Similarly, individuals with CD had lower SF-12 and SF-6D health utility scores, poorer perceived health, and greater limitations in various activities compared to those without CD.

Discussion: This study is representative of the United States population and highlights the profound impact of cognitive impairment on individuals with schizophrenia. The association between cognitive limitations and reduced quality of life, as well as limitations in daily activities, underscores the need for healthcare strategies tailored to the humanistic outcomes of cognitive impairment in schizophrenia. These findings reinforce the importance of cognitive impairment management in overall treatment plans for individuals living with schizophrenia.

S255. CONCEPTUALISATION AND DEVELOPMENT OF THE SELF-DEHUMANISATION IN PSYCHOSIS SCALE (DIPS)

Tom Jenkins*¹, Pamela Jacobsen¹, Bethany O'Brien-Venus², Paul Chadwick¹

¹University of Bath, ²Aneurin Bevan University Health Board

Background: People with psychosis have reported that a distressing aspect of their experience is self-dehumanisation – feeling less, or other than human. These feelings may arise from how people with psychosis are perceived and treated in society, and from the nature of psychosis itself. Existing measures of self-dehumanisation have not been developed with input from people with lived experience, or properly validated. The aim of the present study is to first build a conceptual framework of self-dehumanisation in psychosis, and second to develop a measure of self-dehumanisation in psychosis.

Methods: We first conducted semi-structured interviews with people who hear distressing voices to understand the phenomenology of self-dehumanisation and build a conceptual framework of the experience. We then used this model, along with interview transcripts and a literature review to develop a long list of items with potential to be included in the measure. PPI consultations with people with psychosis were conducted to discuss these items and develop the list further. A Delphi consensus study asked a team of expert stakeholders (people with psychosis, mental health professionals, academics, and carers) to rate the importance of each item for measuring self-dehumanisation. This whittled down the number of items, and

determined those which are most reflective of the construct. Cognitive interviews using the ‘think aloud’ method were also conducted to improve the comprehensibility of the measure.

Results: The experience of self-dehumanisation in psychosis is one characterised by a loss in personal agency, reduced sense of belonging with others, distressing sensory experiences, lower self-worth, a diminished sense of self, and a loss in trust in oneself. Self-dehumanisation theory suggests the experience may comprise denying the self ‘human nature’ or ‘uniquely human’ attributes. We have generated items pertaining to each of these domains to form the Dehumanisation in Psychosis Scale (DiPS).

Discussion: Self-dehumanisation could be a target for psychological therapies for psychosis, such as mindfulness or Cognitive Behavioural Therapy (CBT). Group-based mindfulness for psychosis in particular has been posited as a ‘humanising’ therapeutic process (Chadwick, 2019). A well-developed measure is useful both within clinical formulation to understand how a person feels, and research to understand mechanisms of change in therapy.

S256. SELF-STIGMA IN INTIMATE RELATIONSHIPS OF PERSONS WITH SERIOUS MENTAL ILLNESS: SCALE DEVELOPMENT AND VALIDATION

Meryl Caiada*¹, Simon Felix¹, Sarah Guionnet¹, Justin Lamontagne², Emma Tison¹, Kevin Marc Valery¹, Luc Vigneault³, Antoinette Prouteau¹, Tania Lecomte²

¹University of Bordeaux, ²University of Montreal, ³University of Laval

Background: Persons with Serious Mental Illness (SMI) frequently report difficulties in developing and maintaining Intimate Relationships (IR, McCann, 2010; White et al., 2021). Several barriers, such as stigma, including self-stigma, have been identified (Cloutier et al., 2021). Previous studies have highlighted i) a negative association between IR and self-stigma (Sariso et al., 2013; Stewart et al., 2013) and ii) that specific stereotypes related to IR might be internalized by persons with SMI (Elkington et al., 2013; Wainberg et al., 2016 ; Wright et al., 2007). However, there is a scarcity of literature on self-stigma in the context of IR, and, to date, there is no validated tool specifically designed to assess self-stigma within this field. This study aims to develop and validate a scale assessing self-stigma in IR, among persons with SMI (major depression, schizophrenia, bipolar disorder).

Methods: The scale’s items were collaboratively developed through focus groups involving peer supporters. Subsequently, a validation protocol was then disseminated online among adults with SMI. The study will evaluate psychometric properties, including structural validity, convergent validity, internal consistency, and test-retest reliability.

Results: In total, 40 items were generated, and six themes were qualitatively described: incompetence in IR (e.g., "I am not able to keeping my commitments in my relationship"), negative self-image (e.g., "I have nothing to offer to a partner"), fear of losing control (e.g., "When I fall in love, I lose my mind"), hopelessness (e.g., "It is impossible for me to find love"), concerns about mental health (e.g., "A romantic partner could harm my recovery"), and disclosure of the disorder (e.g., "My partner will not accept my diagnosis if I reveal my condition to him/her"). Analyses of the psychometric properties of the tool are ongoing and will be presented at the Schizophrenia International Research Society in 2024.

Discussion: This study will provide a novel scale assessing self-stigma in IR among persons with SMI. The development of tools evaluating IR and the associated barriers could encourage professionals to support persons expressing need in this area. Furthermore, on a research level,

the development of this scale will contribute robust data on i) the phenomenon of self-stigma in IR, ii) the underlying processes involved.

S257. ADHD AND PSYCHOTIC DISORDER: MULTIDISCIPLINARY PERSPECTIVES AND POSSIBLE THERAPEUTIC AVENUES

Catherine Lehoux*¹, Olivier Corbeil², Élisabeth Anderson³, Charles Desmeules⁴, Luc Vigneault⁵, Catherine Beaulieu⁶, Amélie M Achim⁷, Marie-France Demers⁸, Marc-André Roy⁹, Caroline Cellard¹⁰

¹Centre Intégré de Santé et de Services Sociaux de Chaudière-Appalaches et Centre Intégré Universitaire de Santé et de Services Sociaux de la Capitale-Nationale, ²Faculty of Pharmacy, Université Laval, ³School of Psychology, Laval University, ⁴Université Laval Faculty of Medicine, ⁵Laval University, ⁶Clinique Notre-Dame des Victoires, Institut Universitaire en Santé Mentale de Québec, CIUSSS-CN, ⁷Université Laval, CERVO Brain research center, Vitam – Centre de recherche en santé durable, ⁸Pharmacy Faculty, Laval University, ⁹Département de psychiatrie et neurosciences, Faculté de Médecine, Université Laval. Institut universitaire en santé mentale de Québec., ¹⁰École de Psychologie, Université Laval

Background: ADHD remains neglected and undertreated in psychotic disorders, while an estimated 10% to 47% of adults with a psychotic disorder also meet criteria for ADHD. Although DSM-5 diagnostic criteria for ADHD do not exclude the possibility of a co-occurrence with a psychotic disorder, they may contribute to a reluctance in clinical practice to diagnose ADHD in this population. Moreover, psychostimulants are still generally avoided in psychotic disorder, due to a fear of psychotic relapse. However, this concern is largely based on studies in which psychostimulants were used to explore abnormalities in dopaminergic transmission rather than for therapeutic purposes. More recent observational studies have not found significant associations between psychotic relapse and the use of psychostimulants in people with psychotic disorders, suggesting that this risk is lower than generally perceived. Recent observational data from a Québec Province registry also reveal that nearly 5% of people with a psychotic disorder receive a psychostimulant even though this practice is not supported by formal guidelines, and that this practice is not associated with an increased risk of hospitalization for psychosis in the following year in more than 2,200 people also receiving an antipsychotic.

Methods: We conducted a narrative literature review and consulted various clinical, scientific, and experiential knowledge experts, to provide multidisciplinary clinical recommendations aimed at better supporting people dealing with ADHD co-occurring with a psychotic disorder.

Results: The latest recommendations that emerged from this procedure are as follows. First, the diagnosis of ADHD should follow a rigorous approach, including a developmental history taken with parents and a comprehensive diagnostic interview. Second, the treatment of ADHD co-occurring with psychotic disorder should be undertaken using a comprehensive, interdisciplinary approach, which includes the following: 1) Psychotic symptoms should be adequately treated with antipsychotic and psychological therapy; 2) Antipsychotic treatment should aim for the use of the lowest possible effective dose and minimal recourse to polypharmacy to prevent detrimental effects on cognition; 3) Recognition and correction of adverse effects of drug treatment should be part of treatment targets; 4) Various concomitant clinical conditions also associated with possible cognitive difficulties should also be managed, such as, at the psychiatric level, substance use disorders or anxiety and mood disorders and, at

the physical level, sleep apnea or nutritional deficiencies; 5) Clinical support should be provided for the maintenance and development of healthy lifestyle habits given their known impact on cognition; 6) various psychosocial therapeutic options should be considered, including cognitive remediation; and 7) finally, if manifestations of ADHD persist and interfere significantly with functioning, a specific pharmacological treatment of ADHD manifestations should be discussed. Long-acting formulations should be preferred to short-acting ones. Clinical discussion should take place in a shared-decision making process with patients and their relatives, where the advantages and disadvantages of the different therapeutic options are set out in relation to the person's values, preferences and life goals.

Discussion: Further studies are needed to develop treatment guidelines specific to ADHD co-occurring with psychotic disorder. Pending such clear clinical recommendations, and from a recovery-oriented perspective, certain actions should nevertheless be taken to support people struggling with these co-occurring conditions.

S258. IS THERE EVIDENCE OF COGNITIVE DECLINE 5+ YEARS AFTER THE ONSET OF PSYCHOSIS? A SYSTEMATIC REVIEW AND META-ANALYSIS.

Joseph Ghanem*¹, Christy Au-Yeung¹, Samantha Aversa², Marie Starzer³, Katie M. Lavigne¹, Martin Lepage¹

¹*McGill University*, ²*Douglas Mental Health Research Institute*, ³*Copenhagen University Hospital, Mental Health Center Copenhagen, Copenhagen Research Center for Mental Health - CORE*

Background: In addition to positive and negative symptoms that have historically served as the hallmarks of psychotic disorders, cognitive impairments are also a distinct symptom dimension that is apparent prior to psychosis onset and persistent thereafter. However, whether these cognitive impairments decline, stabilize, or improve in the long-term remains contentious. Previous systematic reviews and meta-analyses were focused on the first 5 years following psychosis onset and identified improvements in cognition – improvements that appeared to reflect practice effects. Some studies with follow-ups of a decade have suggested that cognitive decline may be apparent in some cognitive domains, but others observed that although cognition was impaired early in the course of illness, it stabilized over time. In the present review, we aimed to synthesize evidence from longitudinal studies with follow-ups of 10+ years to evaluate whether cognition declines, stabilizes, or improves over time.

Methods: The present review followed the Preferred Reporting Items for Systematic Reviews and Meta-analyses (PRISMA) guidelines and was registered on PROSPERO (CRD42023447589). MEDLINE, SCOPUS, and PsycINFO were searched for articles that evaluated neurocognition in individuals with psychotic disorders over a period of 10 years or more. Included studies were written in English; reported longitudinal neurocognitive data; had a minimum follow-up period of 10 years; used standardized neuropsychological tests; included a minimum of 85% of individuals with psychotic disorders. Excluded studies were those reporting multiple reports of the same data; unpublished studies, reviews, and conference abstracts; studies using non-standardized cognitive tests. Two authors (JG, SA) conducted title and abstract screening as well as full-text screening on Covidence. Discrepancies were resolved through discussion with each other and with another author (CA). Extraction of relevant data including study characteristics, demographics, cognition data, and main findings was

performed by two authors (JG and SA). The same two authors also assessed the quality of the studies using the Mixed Methods Appraisal Tool.

Results: Twelve studies with independent samples met inclusion criteria for the review and were included in the present study (N Patients= 1028 (range: 21 – 244) and N Controls = 601 (range: 8 – 260)). The patient sample was 61% male, with an average age at first assessment of 26.3 (SD= 6.5). The control sample was 56% male, with an average age at first assessment of 29.41 (SD=7.21). The mean follow-up period was 11.9 years (range: 10-20). Of the 12 studies, 6 were first episode psychosis samples, 5 assessed schizophrenia spectrum disorders, and 1 assessed schizophrenia only.

Most studies (8 out of the 12) identified that cognition was stable over follow-up when evaluating the patient group as a whole, consistent with previous reviews and studies with shorter follow-up periods. In studies with control groups that observed stability, patients and controls did not significantly differ in degree of cognitive change over time. In studies that identified progressive cognitive decline (4 out of the 12), the decline was of small to moderate magnitude. In one study, cognitive decline was associated with worsening of negative symptoms and work functioning, specifically being unemployed. Furthermore, the specific cognitive domains that declined varied significantly from study to study, and the inconsistent use of control groups in those studies did not allow for the proper identification of age-dependent cognitive change. In general, baseline cognitive performance emerged as a strong predictor of long-term cognitive performance. In addition to a systematic review, a meta-analysis will be conducted and presented at the congress to quantify the degree of cognitive change per cognitive domain (e.g., verbal memory, attention, executive functioning).

Discussion: The present review is novel in systematically synthesizing evidence from longitudinal studies with follow-ups ranging from a decade to two decades. When evaluating samples globally, our findings are consistent with the neurodevelopmental model of psychotic disorders, which suggests that cognitive impairment is present prior to and at the onset of the disorder but stabilizes over time. However, trajectory analysis studies to identify subgroups that may be susceptible to cognitive decline over time are needed, to better understand the heterogeneity of psychotic disorders and the predictors of long-term cognitive outcomes. When studies identified cognitive decline over time, the decline was small to moderate in effect but identifying predictors of decline was not always possible. That short-term cognitive performance was predictive of later cognitive outcomes emphasizes the importance of early intervention in the critical period, in addition to longer-term treatments that target cognitive impairment such as cognitive remediation.

S259. SYMPTOMATIC REMISSION, CLINICAL SEVERITY, COGNITIVE FUNCTIONS IN THE LONG-TERM COURSE OF SCHIZOPHRENIA AND POTENTIAL COGNITIVE PREDICTORS FOR SYMPTOMATIC REMISSION STATUS

Eldem Güvercin^{*1}, Banu Değirmencioğlu², Tufan Buran³, Tolga Binbay³, Emre Bora⁴, Köksal Alptekin⁴, Berna Binnur Akdede⁴

¹Dokuz Eylul University, Faculty of Medicine, ²İzmir University of Economics, Department of Neuroscience, ³Dokuz Eylul University, Faculty of Medicine, Department of Psychiatry, ⁴Dokuz Eylul University Department of Neuroscience, Dokuz Eylül University, School of Medicine, Department of Psychiatry

Background: Schizophrenia is a severe mental disorder that negatively effects quality of life and increases morbidity and mortality. Cognitive impairments mostly occurred at early phase of disease, had already been before the presentation of the diagnostic symptoms and persisted for a long time, regarded as a core symptom of schizophrenia. Clinical severity, cognitive functions and symptomatic remission status change in time and long-term course of disease may not be predictable.

Methods: 64 schizophrenia patients, who applied Dokuz Eylül University Hospital outpatient Psychiatry Unit were included into the study. Both baseline and follow-up evaluations include clinical severity, cognitive functions and their association with symptomatic remission status. Median follow-up period were 132 months. Clinical severities were assessed by Positive and Negative Symptom Scale (PANSS), symptomatic remission status was determined by the Remission in Schizophrenia Working Group (RSWG) criterion. Cognitive tests include Trail-Making Test A and B (TMT-A, TMT-B), Digit Symbol Substitution Test (DSST), Wisconsin Card Sorting Test (WCST), Digit Span Test (DST), Auditory Consonant Trigrams Test (ACT), Stroop Color and Word Test (SCWT), Rey Auditory Verbal Learning Test (RAVLT), Controlled Oral Word Association Test (COWAT), Category Fluency Test, Wechsler Memory Scale- Revised (WMS-R) Visual Reproduction Test.

Results: 25 of 64 patients (%39.06) were in symptomatic remission, both baseline and follow-up cognitive evaluation. During follow-up period, Positive and Negative Symptom Scale (PANSS) total score, and PANSS general psychopathology subscale has significantly decreased compared to baseline evaluation. Cognitive evaluation revealed that verbal and visual memory functions (significantly poor RAVLT and WMS-R Visual Reproduction Test) consistently deteriorated both remitted and non-remitted patients. SCWT word+color+interference completing time were found significantly longer after the follow-up period, pointed out impaired processing speed and executive functions. On the other hand, patients displayed better DST forward and total score performance after the follow up period, indicating improvement of simple attentional skills performance in time. ACT, COWAT/ total word score, DST backward score and TMT-A/ error score was better in remitted patients than non-remitted patients, in connection with better verbal fluency, working memory and complex attention performance.

Discussion: Positive symptoms and general psychopathology improve in the natural course of schizophrenia, but negative symptoms tend to be persisted and do not display satisfactory improvement. Memory, executive functions, processing speed and visuospatial functions may get worse, but simple attention may improve in time. On the other hand, verbal fluency, working memory and complex attentional performance depend on symptomatic remission status and it may be considering potential cognitive predictors of symptomatic remission status in schizophrenia.

S260. QUALITY OF RESIDENTIAL FACILITIES IN ITALY: SATISFACTION AND QUALITY OF LIFE OF RESIDENTS WITH SCHIZOPHRENIA SPECTRUM DISORDERS

Alessandra Martinelli^{*1}, Helen Killaspy², Cristina Zarbo¹, Sara Agosta³, Letizia Casiraghi⁴, Manuel Zamparini¹, Fabrizio Starace³, Matteo Rocchetti⁴, Giovanni de Girolamo¹

¹IRCCS St. John of God Clinical Research Centre, ²UCL, ³Mental Health and Dependence, AUSL of Modena, ⁴Department of Mental Health and Dependence, ASST of Pavia

Background: Recovery and human rights promotion for people with Schizophrenia Spectrum Disorders (SSDs) is fundamental to provide good care in Residential Facilities (RFs). However, there is a concern about rehabilitation ethos in RFs. This study aimed to investigate the care quality of Italian RFs, the quality of life (QoL) and care experience of residents with SSD.

Methods: Forty-eight RFs were assessed using a quality assessment tool (QuIRC-SA) and 161 residents with SSD were enrolled. Seventeen RFs provided high intensity rehabilitation (SRP1), 15 medium intensity (SRP2), and 16 medium-low level support (SRP3). Staff-rated tools measured psychiatric symptoms and psychosocial functioning; user-rated tools assessed QoL and satisfaction with services. RFs comparisons were made using ANOVA and Chi-squared.

Results: Over two-thirds patients (41.5 y.o., SD 9.7) were male. Seventy-six were recruited from SRP1 services, 48 from SRP2, and 27 from SRP3. The lowest QuIRC-SA scoring was Recovery Based Practice (45.8%), and the highest was promotion of Human Rights (58.4%). SRP2 had the lowest QuIRC-SA ratings and SRP3 the highest. Residents had similar psychopathology ($p=0.140$) and functioning ($p=0.537$). SRP3 residents were more employed (18.9%) than SRP1 (7.9%) or SRP2 (2.2%) ones and had less severe negative symptoms ($p=0.016$) and better QoL ($p=0.020$) than SRP2 residents. There were no differences in the RF therapeutic milieu and their satisfaction with care.

Discussion: Residents of the lowest supported RFs in Italy had less severe negative symptoms, better QoL and more employment than others. The lowest ratings for Recovery Based Practice across all RFs suggest more work is needed to improve recovery.

S261. EFFICACY AND TOLERABILITY OF BLONANSERIN IN SCHIZOPHRENIA: A SYSTEMATIC REVIEW AND META-ANALYSIS OF RANDOMIZED CONTROLLED TRIALS

Jing Tian^{*1}, Johannes Schneider-Thoma¹, Shimeng Dong¹, Xiao Lin¹, Nobuyuki Nomura¹, Hui Wu¹, Spyridon Sifas¹, Mengchang Qin¹, Stefan Leucht¹

¹*School of Medicine, Technical University of Munich,*

Background: Blonanserin is currently approved for the treatment of schizophrenia in Japan, South Korea, and China. However, the efficacy and safety of blonanserin in managing schizophrenia remain subjects of debate and scrutiny. This study aimed to perform a comprehensive meta-analysis to assess the efficacy and safety related to blonanserin treatment in individuals with schizophrenia.

Methods: We searched in duplicate the study-based trial register of the Cochrane Schizophrenia Group, encompassing studies up until Jun 25, 2023. The inclusion criteria comprised open, single, and double-blinded randomized controlled trials (RCTs) with a minimum duration of 3 weeks comparing blonanserin to other antipsychotics in participants with schizophrenia. We extracted 28 efficacy and tolerability outcomes, with the primary outcome being overall symptoms of schizophrenia. Secondary outcomes included response to treatment, positive, negative, and depressive symptoms of schizophrenia, discontinuation, functioning, quality of life, and side effects. These outcomes were analysed in random-effects pairwise inverse variance meta-analyses. The study was registered in Open Science Framework (<https://osf.io/e7jfa/>).

Results: The analysis included 17 studies with 2903 participants. The antipsychotics included in the analysis were olanzapine, haloperidol, risperidone, paliperidone, aripiprazole, and amisulpride, which were compared with blonanserin. In the primary outcome “overall symptoms of schizophrenia”, there were no significant differences between blonanserin and other antipsychotics. In secondary outcomes, blonanserin demonstrated a lower risk of weight gain (RR= 0.57; 95%CI= 0.35-0.93) and hyperprolactinemia (SMD= -1.11, 95% CI= -2.22 to -0.01) compared to risperidone. However, it had a higher risk of akathisia (RR= 1.65, 95% CI= 1.20-2.25) and dropout (RR= 1.36, 95% CI= 1.07-1.71) compared to risperidone. Blonanserin was superior to paliperidone in hyperprolactinemia (RR= -0.06, 95% CI= 0.00-0.99). Blonanserin was found to be superior to haloperidol in terms of depressive symptoms (SMD= -0.35, 95% CI= -0.60 to -0.10) and negative symptoms (SMD= -0.28, 95% CI= -0.48 to -0.07). Additionally, it had a lower risk of akathisia (RR= 0.66, 95% CI= 0.48-0.91) and parkinsonism (RR= 0.59, 95% CI= 0.40-0.87) compared to haloperidol.

Discussion: The results of this meta-analysis indicate that blonanserin is comparable to other commonly used antipsychotics in terms of overall symptom improvement in individuals with schizophrenia. This suggests that blonanserin can be considered a viable treatment option for managing symptoms of schizophrenia. Blonanserin offers advantages in terms of weight gain, hyperprolactinemia, depressive symptoms, negative symptoms, and certain movement-related side effects. However, the higher risk of akathisia and drop-out rates should be taken into consideration. Further research, including head-to-head comparisons and long-term studies, is needed to consolidate these findings and guide clinical decision-making regarding the use of blonanserin in the management of schizophrenia.

S262. THE RELATIONSHIP BETWEEN LONELINESS AND MOMENTARY NEGATIVE PSYCHOTIC EXPERIENCES: AN EXPERIENCE SAMPLING STUDY IN NON-CLINICAL YOUNG ADULTS

Anson Kai Chun Chau*¹, Suzanne Ho-wai So²

¹*The University of New South Wales*, ²*Department of Psychology, The Chinese University of Hong Kong*

Background: Loneliness refers to the negative experience arising from the mismatch between perceived and actual social relationships. When loneliness is left unsolved, it could be expressed as a trait-like phenomenon, potentially leading to psychopathology including psychosis. Findings from previous studies offer converging evidence for the association between loneliness and positive symptoms (such as paranoia and hallucinations) in clinical populations, as well as their subclinical manifestations in the general population. However, the relationship between loneliness and negative symptoms is less often examined. In particular, loneliness is proposed to be maintained by social withdrawal and reduced pleasure in current and anticipated social interactions, corresponding to asociality and social anhedonia respectively. The experience sampling method (ESM) is suitable for capturing moment-by-moment negative psychotic experiences in daily life. Using ESM, the present study examined the relationship between loneliness and negative psychotic experiences (i.e., asociality and social anhedonia), in a sample of non-clinical young adults who were at a life stage most vulnerable to developing psychosis.

Methods: Participants aged 18-30 were recruited from either the subject pool of introductory psychology courses or campus mass email. Consented participants without any past and current

psychiatric diagnosis (confirmed with the Structured Clinical Interview for DSM-IV Axis I Disorders) completed the University of California Los Angeles Loneliness Scale-Version 3 and the Patient Health Questionnaire-9 as baseline measures of trait loneliness and depression respectively. Ten times per day over six days, participants were asked to fill in the same ESM questionnaire on a mobile phone app, which measured positive affect (PA, i.e., happy, relaxed, contented), negative affect (i.e., irritated, low, anxious), current social company, anticipated social company, and anticipated pleasantness of being with others (vs. being alone). Asociality was operationalized as being alone. Consummatory social anhedonia was operationalized as the within-moment association between PA and being with others (vs. being alone), whereas anticipatory social anhedonia was operationalized as the anticipated pleasantness of being with others (vs. being alone). Only participants who completed at least one-third of the ESM questionnaires were included in the data analysis. The associations between loneliness and momentary negative psychotic experiences were tested with multilevel modelling.

Results: The final sample consisted of 134 participants (58.2% female, mean age = 20.3 (SD= 2.91)). The mean compliance rate was 72.1% (range: 36.7-100%). Trait loneliness was associated with anticipatory social anhedonia ($B = 0.02$, $p = .011$), even after controlling for baseline level of depression ($B = 0.02$, $p = .010$). Trait loneliness was not associated with asociality or consummatory social anhedonia (p s GREATER THAN .050).

Discussion: Using ESM to assess negative psychotic experiences, we found that loneliness was uniquely associated with anticipatory social anhedonia (above and beyond the effect of depression), but not with asociality or consummatory social anhedonia. The specificity of the relationship between loneliness and individual negative psychotic experiences warrants further investigation.

S263. THE CHANGE OF ADMISSION PATTERN IN PSYCHIATRIC INPATIENTS FOLLOWING REVISION OF MENTAL HEALTH ACT IN KOREA

Jong-Ik Park^{*1}, Sun-hwan Lee²

¹Kangwon National University, ²Chuncheon National Hospital

Background: The main purpose of this study was to investigate the change of hospitalization type, length of hospitalization, readmission rates, and patient attributes of psychiatrically hospitalized patients since total revision of Mental Health Act in 2017.

Methods: We retrospectively reviewed medical records of 1,396 cases of inpatients who were hospitalized and discharged in both one national mental hospital and one private mental hospital from 1 year before revision to 1 year after one. We used either the t-test and chi square test, or the one-way analysis of variance to compare characteristics between each group and examined how revision of Mental Health Act has influenced.

Results: The rate of voluntary admission markedly increased from 32.8% to 86.7% without any significant change in patient attributes. The length of stay in a mental hospital significantly decreased from 84.9 (± 70.8) days to 54.6 (± 53.6) days. Individual factors affecting the length of stay were female sex, schizophrenia, unemployment, and involuntary admission type. However, the readmission rate significantly increased from 15.5% to 21.1%.

Discussion: The findings of this study suggests that the total revision of Mental Health Act resulted in voluntary admission and shorter length of stay, heightening of getting back to the community but the activation of community mental health service system should be prepared in Korea.

S264. THE RELATIONSHIP BETWEEN SELF-STIGMA AND QUALITY OF LIFE IN LONG-TERM HOSPITALIZED PATIENTS WITH SCHIZOPHRENIA: A CROSS-SECTIONAL STUDY

Jiabao Chai^{*1}, Ying Li²

¹*Beijing Huilongguan Hospital, Peking University Huilongguan Clinical Medical School,*

²*Department of Psychiatry, Beijing Children's Hospital, Capital Medical University, National Center for Children Healthy*

Background: Schizophrenia is a profoundly debilitating chronic condition that markedly diminishes the quality of life for those afflicted. Numerous elements contribute to the life quality of individuals with schizophrenia, with self-stigma standing out as a pressing societal issue. This research delves into the repercussions of self-stigma on the quality of life in schizophrenia patients, further examining the intermediary factors at play.

Methods: This study employed a cross-sectional design, selecting 170 hospitalized schizophrenia patients at random for evaluation. The assessment instruments comprised the Positive and Negative Syndrome Scale (PANSS), Self-Esteem Inventory (SEI), Connor-Davidson Resilience Scale (CD-RISC), Internalized Stigma of Mental Illness Scale (ISMI), Schizophrenia Quality of Life Scale (SQLS), Coping Questionnaire for Schizophrenia Patients (CQSP), and the Social Support Rating Scale (SSRS). We utilized correlation analysis, regression analysis, and mediation analysis to investigate correlations and discern mediation effects.

Results: Self-stigma significantly influences the quality of life ($T = 8.13$, $p < 0.001$). Both self-esteem ($T = -2.11$, $p = 0.04$) and specific coping strategies, namely problem-solving ($T = -2.58$, $p = 0.01$) and avoidance ($T = 4.65$, $p < 0.001$), exert pronounced effects on self-stigma. With self-stigma acting as a mediator, the problem-solving aspect of coping strategies indirectly affects the quality of life, and this effect is statistically significant ($AB = -0.16$, $P = 0.02$). Conversely, the avoidance aspect of coping strategies directly ($C' = 0.54$, $p < 0.001$) and indirectly ($AB = 0.25$, $p < 0.001$) impacts the quality of life.

Discussion: Self-stigma profoundly influences the quality of life for individuals with schizophrenia. To enhance the quality of life for these patients, clinical interventions should prioritize addressing self-stigma and its underlying determinants, with particular emphasis on self-esteem and adaptive coping strategies.

S265. INFLAMMATORY MARKERS OF SYMPTOMATIC REMISSION AT 6 MONTHS IN PATIENTS WITH FIRST-EPISODE SCHIZOPHRENIA

Honey Kim¹, Seon-Hwa Baek¹, Ju-Wan Kim¹, Seunghyong Ryu¹, Ju-Yeon Lee¹, Jae-Min Kim¹, Young-Chul Chung², Ji-Min Yoo¹, Joon-An Yoo³, Sung-Wan Kim^{*1}

¹*Chonnam National University Medical School,* ²*Chonbuk National University Medical School,* ³*St. John Hospital*

Background: Neuroinflammation contributes to the pathophysiology of various mental illnesses, including schizophrenia. We investigated peripheral inflammatory cytokines as a biomarker for predicting symptomatic remission in patients with first-episode schizophrenia.

Methods: The study included 224 patients aged 15-60 years who fulfilled the criteria for schizophrenia spectrum disorder with a treatment duration ≤ 6 months. Serum levels of tumor necrosis factor (TNF)- α , interferon- γ , interleukin (IL)-1 α , IL-1 β , IL-6, IL-8, IL-10, and IL-12 were measured. Psychotic symptoms, depressive symptoms, and general functioning were assessed using the Positive and Negative Syndrome Scale (PANSS), Beck Depression Inventory (BDI), Calgary Depression Scale for Schizophrenia (CDSS), and Personal and Social Performance scale (PSP), respectively. Duration of untreated psychosis (DUP) was also recorded. We investigated the factors associated with remission for each sex in logistic regression analysis.

Results: Our study included 224 patients (46.0% males and 54.0% females) with first-episode schizophrenia. Table 1 shows the clinical characteristics and cytokine levels in relation to remission for each sex among patients with psychosis. In total, 174 patients achieved remission at the 6-month follow-up (males, 70.9%; females, 83.5%). Remission was associated with baseline scores on PANSS, PSP, BDI, and CDSS in male patients. Among female patients, baseline scores on PANSS, PSP, DUP, and TNF- α were associated with remission. Multivariate logistic regression analysis results indicate that a higher potential for symptomatic remission in men was associated with older age ($p = 0.042$) and lower baseline BDI scores ($p = 0.013$). For women, shorter DUP ($p = 0.025$) and lower baseline peripheral TNF- α levels ($p = 0.006$) were associated with a higher likelihood of symptomatic remission (Table 2).

Discussion: Our findings suggest that peripheral TNF- α levels may serve as a predictor of poor response to antipsychotic treatments in females with first-episode schizophrenia spectrum disorder. This could contribute to enhancing our understanding of the role of inflammation in the course of schizophrenia. Additionally, we observed that depressive symptoms in males and a longer DUP in females may be poor prognostic factors for early remission in patients with first-episode schizophrenia.

S266. EXPLORING THE INTERPLAY BETWEEN PSYCHOSIS VULNERABILITY, FUNCTIONAL SOMATIC SYMPTOMS AND HEALTH ANXIETY IN CHILDHOOD AND ADOLESCENCE – A LONGITUDINAL COHORT STUDY

Martin Køster Rimvall^{*1}, Charlotte Ulrikka Rask², Jens Søndergaard Jensen³, Else Marie Olsen⁴, Lars Clemmensen⁵, Anne Mette Skovgaard⁶, Frank Verhulst⁷, Jim van Os⁸, Pia Jeppesen⁹

¹Department of Child and Adolescent Psychiatry, Copenhagen University Hospital - Psychiatry Region Zealand; Child and Adolescent Mental Health Centre, Copenhagen University Hospital - Mental Health Services CPH, ²Aarhus University Hospital Psychiatry, Department of Child and Adolescent Psychiatry, Research Unit; Aarhus University, Department of Clinical Medicine, ³Research Clinic for Functional Disorders and Psychosomatics, Aarhus University Hospital, ⁴Psychiatric Center Ballerup, Copenhagen University Hospital - Mental Health Services CPH; Center for Clinical Research and Prevention, the Capital Region of Denmark, ⁵VIRTU Research Group, Copenhagen Research Center on Mental Health (CORE), Copenhagen University Hospital, ⁶National Institute of Public Health, Faculty of Health Sciences, University of Southern Denmark, ⁷Child and

Adolescent Mental Health Centre, Copenhagen University Hospital - Mental Health Services CPH; Department of Clinical Medicine, Faculty of Health and Medical Sciences, University of Copenhagen; Department of Child Psychiatry/Psychology, Erasmus University Medical Center, ⁸Department of Psychiatry, Brain Center Rudolf Magnus, University Medical Centre Utrecht; Department of Psychiatry and Psychology, Maastricht University Medical Centre; Department of Psychosis Studies, King's College London, King's Health Partners, Institute of Psychiatry, ⁹Department of Child and Adolescent Psychiatry, Copenhagen University Hospital - Psychiatry Region Zealand; Child and Adolescent Mental Health Centre, Copenhagen University Hospital - Mental Health Services CPH; Department of Clinical Medicine, Faculty of Health and Medical Sciences, University of Copenhagen

Background: Similarities exist between contemporary explanatory models underlying psychosis development, functional somatic symptoms, and health anxiety; namely aberrant attribution of salience and errors in top-down information processing. Functional somatic symptoms are bodily symptoms which cannot be attributed to a well-defined physical illness, whereas health anxiety is characterized by excessive and medically unwarranted fears regarding one's health. In the current study, we aimed to examine the potential interplay between functional somatic symptoms and psychosis vulnerability on the outcome of health anxiety in youths from the general population.

Methods: We utilized data from the 11- and 16-year follow-ups of the Copenhagen Child Cohort 2000. Psychosis vulnerability was assessed by interview- and self-report measures of psychotic experiences (ages 11 and 16), aberrant attribution of salience using the White Noise Task (age 11), and anomalous self-experiences assessed by self-report using the Self-Experience Life-time Frequency scale (age 16). Functional somatic symptoms and health anxiety were assessed by self-report using age-appropriate standardized questionnaires at both ages 11 and 16 years. We assessed the associations between psychosis vulnerability and functional somatic symptoms both cross-sectionally at both ages, and longitudinally from age 11 to 16, and examined if there was an interaction between psychosis vulnerability and functional somatic symptoms on the outcome of health anxiety. To quantify the potential interaction effect, we used the interaction contrast ratio, estimating the relative excess risk due to interaction.

Results: A total of 1122 participants contributed with data from both time points. In cross-sectional analyses, functional somatic symptoms and psychotic experiences were strongly associated with health anxiety at both ages 11 and 16, also after adjustment for general psychopathology. Aberrant attribution of salience (age 11) and anomalous self-experiences (age 16) were also associated with health anxiety. Additionally, there was some evidence of interaction between psychosis vulnerability and functional somatic symptoms on the outcome of health anxiety at age 16. In the longitudinal analyses, functional somatic symptoms, and psychotic experiences at age 11 were not individually associated with health anxiety at age 16 but having both functional somatic symptoms and psychotic experiences was: odds ratio 3.9, 95% CI 1.7-8.9. This association was attenuated after adjustment for general psychopathology: odds ratio 2.6, 95% CI 1.0 to 6.4.

Discussion: The strong associations between the domains support the notion of possible overlapping mechanisms underlying psychosis vulnerability, functional somatic symptoms, and health anxiety. While the current study could not unravel potential causal mechanisms, the findings highlight the importance of clinical attention and comprehensive assessment to address a broad spectrum of vulnerabilities among children presenting with mental health problems.

S267. VULNERABILITY AND RESILIENCE TO MENTAL PATHOLOGIES: EVALUATION OF THE EFFECTS OF EARLY LIFE STRESS EXPOSURE ON MENTAL HEALTH

Veronica Begni*¹, Kerstin Camile Creutzberg¹, Rodrigo Grassi Oliveira², Marco Andrea Riva¹

¹*University of Milan*, ²*Aarhus University*

Background: Early life stress (ELS) exposure is considered a major risk factor for mental disorders. However, the alterations produced by adverse experiences are highly variable and not all individuals exposed to stress develop a pathologic phenotype, since some of them appear to be resilient to the consequences of such experiences. We have recently reported (Creutzberg, Begni et al., 2023 10.1038/s41398-023-02653-6) that offspring exposed to ELS showed an overall emotional impairment during adolescence, as seen by depressive- and anxiety-like behaviors and a decreased sociability. Although these alterations were similar between male and female offspring, we could discriminate between vulnerable (PNS-V) and resilient (PNS-R) phenotypes during adolescence. Individual animals showed indeed different responses to stress exposure; among stressed animals we found that 30% showed low levels of anxiety-like behaviors and high levels of social interactions, while the remaining 70% displayed significant dysfunctions in anxiety-related and social behaviors.

In this respect, several open questions still exist regarding how ELS programs emotional and biological functions. Clarifying these mechanisms is vital as it could pave the way for identifying stress-vulnerable and resilient molecular phenotypes in offspring.

Methods: To tackle these points, I applied a well-characterized model of prenatal stress (PNS) exposure in rats, consisting of a restraint stress protocol during the last week of pregnancy as previously published (Creutzberg, Begni et al., 2023 10.1038/s41398-023-02653-6). To address the gap in knowledge of specific pathways that could be potentially involved in stress vulnerability and resilience, I employed a omics approach to provide a more comprehensive and in-depth explanation. Whole-genome RNA sequencing analysis was conducted using the Illumina NextSeq550 platform. Differentially expressed genes (DEGs) ($p_{adj} \text{ LESS THAN } 0.1$, $FC \text{ GREATER THAN } |1.2|$) were identified in the prefrontal cortex (PFC) of PNS and control (CT) animals.

Results: We found that 6 genes were significantly altered in the PFC of PNS female offspring during adolescence, while PNS exposure significantly altered the expression of 34 genes in the PFC of male offspring. Interestingly, 2 genes were commonly altered in the brain of male and female PNS offspring regardless of vulnerable or resilient phenotype, namely Catalase (Cat) and Mitochondrial Ribosomal Protein L48 (Mrpl48). Specifically, we found that PNS exposure significantly upregulated the expression of both Cat and Mrpl48 in both sexes.

When looking for DEGs in PNS-V and PNS-R separately, we found that the expression of 5 genes was significantly altered in the brain of both male PNS-V and PNS-R animals, as compared to CTs, and that these genes were mostly involved in mitochondria.

On the contrary, when focusing on differences between PNS-V and PNS-R rats, we found 9 and 3 DEGs in the PFC of female and male offspring respectively, although not strictly involved in mitochondria functionality.

Discussion: Overall, these data showed that mitochondria seem to be affected by ELS exposure, regardless of the presence or not of a pathological outcome, mainly in male adolescent offspring. Alterations of mitochondria-related mechanisms might therefore represent a permanent scar of ELS exposure, that may ultimately be a predisposing factor for

developing a full-blown pathologic condition later in life. Understanding the mechanisms by which stressors determine a pathological outcome will not only enhance our knowledge of normal development but will also open avenues for early interventions, either during pregnancy or the early postpartum period.

S268. POSITIVE FRAMING OF FEEDBACK ABOUT BEING AT-RISK FOR PSYCHOSIS IS SEEN BY CLINICIANS AS A PROMISING MEANS TO IMPROVE ITS BENEFICIAL TO HARMFUL EFFECTS: AN EXPERIMENTAL SIMULATED FEEDBACK SESSION STUDY

Yamit Sol-Nottes¹, Dan Koren*¹, David Roe¹, Shlomo Mendelovich²

¹University of Haifa, ²Shalvata Mental Health Center

Background: Recent studies, including a pioneering pre-post feedback one, show that feedback on clinical high-risk for psychosis (CHR-p) can offer relief, yet often triggers negative stereotypes in patients. Inspired by Tversky and Kahneman's (1981) seminal work on the framing effect and examples the way analog high-risk conditions in general medicine are framed (e.g., 'life-threatening condition'), this study aimed to explore if positive re-framing of CHR-p as 'residual health abilities (e.g., common sense) at high risk' could address these concerns. Specifically, the study aimed to assess mental health professionals' (MHPs) perceptions regarding feedback provided with negative versus positive framing. A secondary goal was to evaluate the extent to which the level of familiarity and experience with the concept of CHR-p influences these perceptions.

Methods: To achieve the above goal, the study implemented an experimental design, utilizing a simulated feedback session, recorded on video, involving a clinician, an adolescent, and their mother to compare negative versus positive feedback framing. Specifically, the study compared the impact of feedback provided with a negative versus positive framing on MPHs' perceptions of its potential benefits (such as mobilization towards help-seeking and the instillation of hope) versus its potential adverse effects (such as the provocation of stress and self-stigma) on the adolescent and mother. One hundred and forty-eight MPHs were randomized to view one of the two videotaped simulated feedback sessions. Upon completing watching the video, they were asked to respond to a questionnaire that evaluated their views on how the feedback session affected the adolescent and his mother.

Results: Consistent with our main hypothesis, the results showed significant differences in perceptions based on framing type, favoring positive framing in sensitivity, stress, stigma, mobilization to seek help, and hope. Contrary to our second hypothesis, the results did not show a significant framing type by subjective familiarity with the CHR-p concept interaction effect.

Discussion: The present results suggest that MPHs respond more favorably to positively framed feedback about psychosis risk. Furthermore, in contrast to our initial prediction, the results imply that this increased faith in positive framing is not diminished by the MPH's subjective familiarity and experience with the concept of CHR-p. However, these results need replication through studies with larger and more diverse samples. If future research replicates and validates the present findings, they will establish a solid conceptual and methodological basis for valuable new research directions. Most notably, they will lay the groundwork for randomized controlled trials to test the effectiveness of positively reframing risk for psychosis in real-world settings. The presentation will highlight and discuss possible misconceptions of

positive framing, such as re-labeling, positive psychology, and de-medicalization of normal human experience.

S269. EARLY AND LATER REMISSION FROM CLINICAL HIGH RISK OF PSYCHOSIS. A LATENT CLASS AND PREDICTOR ANALYSIS

Jone Bjornestad*¹, Tore Tjora², Inge Joa³, Jan Olav Johannessen³, Sjur Skjærshammer Sætre⁴, Wenche ten Velden Hegelstad⁵

¹*Faculty of Social Sciences, University of Stavanger /TIPS – Centre for Clinical Research in Psychosis, Stavanger University Hospital,* ²*Faculty of Social Sciences, University of Stavanger,* ³*TIPS – Centre for Clinical Research in Psychosis, Stavanger University Hospital, Stavanger, Norway. Network for Medical Sciences, Faculty of Social Sciences, University of Stavanger, Norway.,* ⁴*TIPS – Centre for Clinical Research in Psychosis, Stavanger University Hospital, Stavanger, Norway.,* ⁵*TIPS – Centre for Clinical Research in Psychosis, Stavanger University Hospital*

Background: In research on high-risk for psychosis (CHR-P) much focus has been on the transition to psychosis. However, the desired outcome remains symptomatic and functional remission as early as possible. This study aims to investigate predictors of sub-groups of remission and functional outcomes.

Methods: A two-year prospective follow-up study of 104 CHR-P participants recruited in Norway using systematic early detection strategies. The Structural Interview for Prodromal Syndromes (SIPS) was used to assess CHR-P. Participants were classified as remitted or non-remitted based on their SIPS scores. A latent class analysis was performed on the dichotomous data to identify latent classes with regard to timing of remission. T-tests and chi-squared tests were used to assess the association between class affiliations, predictors and outcomes.

Results: The latent class analysis showed moderate fit and divided the participants into three remission classes: "poor chance of remission" (16.7%), "later remission" (34.3%), and "early remission" (49.0%). The "early remission" class had the highest probability of fast and stable remission, and had better premorbid, baseline and 2-year global functioning than the "later remission" class. Baseline predictors such as age, SIPS symptoms, drug use, years in school and gender were not significantly associated with remission class.

Discussion: The study's main finding is the division of CHR-P remission into "early remission" and "later remission" and predictors of class affiliation. The monthly follow-up during the first six months allowed for the detection of this division. The findings highlight the importance of considering functioning in models of remission from CHR-P.

S270. SCREENING AND INTERVENTION FOR CARDIOMETABOLIC RISK IN PATIENTS TREATED IN A FIRST-EPISODE PSYCHOSIS PROGRAM: A RETROSPECTIVE CHART REVIEW

Felix Audet*¹, Olivier Corbeil², Laurent Béchard³, Chantale Thériault⁴, Colombe Claveau⁵, Lauryann Bachand⁴, Anne-Marie Essiambre⁴, Marc-André Roy⁶, Marie-France Demers³

¹University Laval, ²Faculty of Pharmacy, Laval University, ³Pharmacy Faculty, Laval University, ⁴CERVO Brain Research Centre, ⁵Psychology School, Laval University, ⁶Université Laval Faculty of Medicine

Background: Individuals with psychotic disorders have a reduced life expectancy, mainly associated with increased cardiovascular mortality. However, cardiometabolic complications are not routinely screened and treated in practice. Therefore, the objective was to describe the adherence to a cardiometabolic risk screening and intervention algorithm implemented in an early intervention service (EIS) for first-episode psychosis in Quebec City.

Methods: A retrospective chart review was conducted on 218 users followed in EIS between November 1, 2019, and March 31, 2023. Screenings and interventions performed during follow-up or until prolonged discontinuation of antipsychotic medication were recorded up to a maximum of 36 months.

Results: A total of 41% of users were screened on admission to the program. The proportion of screenings performed varied between 54% and 65% for the rest of the follow-up (average follow-up time of 16 months). Screenings were complete in 79 to 95% of cases. Among incomplete screenings, apolipoprotein-B and glycated hemoglobin accounted for 46% and 30% of missing elements, respectively. The percentage of patients with a metabolic syndrome increased over time, from 13% at admission to 19% at 12 months, 30% at 24 months and 47% at 36 months. A total of 34 patients developed dyslipidemia. Of these, 79% received at least one intervention, but only 18% were prescribed a lipid-lowering agent. Few patients developed impaired glucose tolerance.

Discussion: Screening, and particularly intervention, for cardiometabolic complications remains a challenge in practice, despite the introduction of a systematic algorithm. Efforts must be made in these regards to reduce long-term cardiovascular mortality.

S271. BLOOD CELL COUNT RATIOS AT BASELINE ARE ASSOCIATED WITH INITIAL CLINICAL RESPONSE TO CLOZAPINE IN TREATMENT-RESISTANT, CLOZAPINE-NAÏVE, SCHIZOPHRENIA-SPECTRUM DISORDER

Vicent Llorca-Bofi¹, Miquel Bioque*², Santiago Madero³, Andrea Mallorquí⁴, Cristina Oliveira⁵, Marina Garriga⁶, Eduard Parellada⁷, Clemente Garcia-Rizo⁸

University of Barcelona. ²University of Barcelona, Hospital Clinic, ³Barcelona Clinic Schizophrenia Unit, Institute of Neurosciences, University of Barcelona, IDIBAPS, CIBERSAM, ⁴Psychiatry Department, Neuroscience Institute, Hospital Clinic, ⁵University of Coimbra, ⁶Bipolar and Depressive Disorder Unit. Institute Neuroscience. Hospital Clinic Barcelona, ⁷Barcelona Clinic Schizophrenia Unit (BCSU). Neurosciences Institute. Hospital Clinic of Barcelona. University of Barcelona. CIBERSAM, IDIBAPS. ⁸Barcelona Clinic Schizophrenia Unit (BCSU). University of Barcelona. IDIBAPS; CIBERSAM

Background: Clozapine is the recommended treatment for managing treatment-resistant schizophrenia (TRS) and immunological mechanisms may be involved in its unique antipsychotic efficacy. Here, we investigate whether baseline immune abnormalities measured with blood cell count ratios can predict the clinical response after initiating treatment with clozapine in patients with clozapine naïve TRS.

Methods: A naturalistic longitudinal design, involving 32 patients diagnosed with treatment-resistant, clozapine-naïve schizophrenia-spectrum disorder was developed. Patients were evaluated at baseline before clozapine starting and 8 weeks of follow-up. Psychopathological status and immune abnormalities (blood cell count ratios: neutrophil-lymphocyte ratio [NLR], monocyte-lymphocyte ratio [MLR], platelet-lymphocyte ratio [PLR] and basophil-lymphocyte ratio [BLR]) were evaluated in each visit.

Results: Baseline NLR ($b = -0.364$; $p = 0.041$) and MLR ($b = -0.400$; $p = 0.023$) predicted the change in positive symptoms over the 8-week period. Patients who exhibited a clinical response showed higher baseline NLR (2.38 ± 0.96 vs. 1.75 ± 0.83 ; $p = 0.040$) and MLR (0.21 ± 0.06 vs. 0.17 ± 0.02 ; $p = 0.044$) compared to non-responders. In the ROC analysis, the threshold points to distinguish between responders and non-responders were approximately 1.62 for NLR and 0.144 for MLR, yielding AUC values of 0.714 and 0.712, respectively. No statistically significant differences were observed in the blood cell count ratios from baseline to the 8-week follow-up.

Discussion: Our study emphasizes the potential clinical significance of baseline NLR and MLR levels as predictors of initial clozapine treatment response in patients with TRS. Future studies with larger sample sizes and longer follow-ups should replicate our results.

S272. COMPUTATIONAL MODELING OF BELIEF UPDATING ACROSS SOCIAL VERSUS NON-SOCIAL CONTEXTS IN INDIVIDUALS WITH HIGH VERSUS LOW PARANOIA

Antonia Bott^{*1}, Julian L. Faße¹, Tania M. Lincoln¹

¹*Universität Hamburg, Institute of Psychology, Clinical Psychology and Psychotherapy*

Background: Predictive processing accounts propose that delusions arise from aberrant belief updating, particularly characterized by an overestimation of the volatility (rate of change) associated with the environment. Given that delusional contents, such as paranoia, predominantly revolve around social themes, we investigated whether the overestimation of volatility that has been associated with paranoia is particularly pronounced in social contexts.

Methods: In a laboratory experiment, we stratified 116 participants into high ($n = 57$) versus low ($n = 59$) paranoia groups. All participants completed two computerized three-option reversal learning tasks within both a social (trust game) and a non-social context (gambling game). Taking a computational modeling approach, we formalized belief updating using Hierarchical Gaussian Filters over trial-by-trial responses. We compared model-free choice switching as well as computational parameters of volatility beliefs across groups and contexts.

Results: Consistent with previous research, participants with high paranoia demonstrated higher average win-switch rates as well as higher initial volatility beliefs as compared to those with low paranoia. Moreover, we observed a main effect of context on lose-switch rates, indicating that participants were more inclined to switch choices after losses in the social as compared to the non-social context. However, there was no evidence for a significant modulation of volatility beliefs by context.

Discussion: Our results replicate previous findings supporting the notion that paranoia is linked to an overestimation of environmental volatility, emphasizing the role of aberrant belief updating in delusion etiology. While our context manipulation influenced choice switching behavior, our results suggest that heightened volatility beliefs in paranoia appear to be stable across different types of contexts within a well-controlled laboratory environment.

S273. PREFRONTAL GLUTAMATE LEVELS IN ANTIPSYCHOTIC-NAÏVE PATIENTS WITH PSYCHOSIS ARE RELATED TO BRAIN STRUCTURE AND CLINICAL OUTCOME AFTER TWO YEARS ILLNESS

Kirsten Bojesen*¹, Cecilie Lemvig², Jayachandra M. Ragahava³, Bjørn Hylsebeck Ebdrup⁴, Birte Yding Glenthøj⁵

Background: Prefrontal glutamate levels are suggested to underlie structural changes in patients with schizophrenia based on findings in animal models, but whether this translates to humans is unknown. Moreover, prefrontal glutamate levels have been related to cognition and short-term treatment response in patients with first-episode psychosis (FEP), but the association with long-term clinical outcomes remains to be elucidated.

Methods: This was a longitudinal study of 57 initially antipsychotic-naïve patients with FEP (22.6±5.0 years, 58% females) and 55 healthy controls (HCs) (22.2±4.3 years, 62% females) matched on age, sex and parental socioeconomic status that were followed-up after two years (35 patients and 44 HCs).

Glutamate levels were assessed in a 2*2*2cm³ spectroscopic voxel in dorsal Anterior Cingulate Cortex (dACC) on a 3T MR scanner with the PRESS sequence, and brain structure in dACC, hippocampus, and striatum with a T1-weighted sequence. LCMoel and Freesurfer were used for analyses of data. Clinical outcomes after two years included symptom reduction in positive symptoms, functional outcome, and performance in tests of the cognitive domains sustained attention and spatial working memory (SWM).

General linear models evaluated associations between baseline glutamate levels and structural volume as well as clinical outcomes after two years, and linear mixed models evaluated structural changes over time. Analyses were adjusted for age, sex, tobacco and cannabis smoking, and total grey matter volume.

Results: Glutamate levels at baseline: Glutamate levels in dACC were borderline significantly lower in the antipsychotic-naïve patients compared with HCs (p=0.05).

Structure in hippocampus, striatum, and dACC: The structural volumes did not differ between patients and HCs at baseline or after two years, but reductions were seen in the subcortical

areas after two years in both patients and HCs (main effect of time: left hippocampus: $p=0.002$; right hippocampus $p=0.009$; left striatum: $p=0.002$; right striatum: $p=0.003$) but not in dACC. Glutamate levels at baseline and brain structure after two years: For hippocampus, there was a significantly more positive association between prefrontal glutamate levels at baseline and hippocampal volume after two years in patients compared with HCs (group*glutamate: right hippocampus $p=0.019$; left hippocampus $p=0.04$). For striatum, a similar trend was found for right striatum (group*glutamate: right striatum $p=0.07$; left striatum $p=0.10$). In dACC, there was a trend for a more positive association in HCs between prefrontal glutamate levels at baseline and gray matter in the spectroscopic voxel after two years (group*glutamate: $p=0.06$). Glutamate levels at baseline and clinical outcome after two years: There was a significant positive association between glutamate levels at baseline in dACC and cognitive performance in the test of attention after two years in both patients and HCs ($p=0.012$) but not with SWM. Prefrontal glutamate levels at baseline were not significantly associated with reduction in positive symptoms or level of function after two years.

Discussion: The results suggest that glutamate levels in dACC are lower in antipsychotic-naïve patients with first-episode psychosis and that higher glutamate levels in the FEP patients at illness onset are related to better cognitive performance and less reductions of subcortical volumes after two years. In contrast, higher glutamate levels in HCs at baseline seem associated with greater reduction of gray matter in dACC after two years. This may suggest the existence of an optimal range of prefrontal glutamate levels for long-term structural alterations and cognitive function.

S274. META-ANALYSIS OF CEREBELLO-THALAMO-CORTICAL NETWORK DYSCONNECTIVITY IN SCHIZOPHRENIA

Orsolya Lanyi^{*1}, Dániel Zahemszky², Gábor Csukly²

¹*Semmelweis University*, ²*Semmelweis University, Department of Psychiatry and Psychotherapy*

Background: A growing body of evidence highlights the pivotal role of the thalamus and cerebellum in the pathomechanism of schizophrenia. While thalamo-cortico-cerebellar connectivity dysfunctions have been extensively investigated, existing evidence remains inconclusive regarding its reliability across illness stages and medication status. Additionally, resting-state fMRI studies suffer from limitations, such as small sample sizes and replication bias. This meta-analysis aims to comprehensively synthesize statistical evidence of thalamo-cortico-cerebellar network dysfunctions in the psychosis spectrum. Our focus spans prodromal and high-risk populations, as well as clinical cohorts, including first-episode psychosis and chronic schizophrenia, with the objective of elucidating the developmental and etiological aspects of thalamic and cerebellar dysconnectivity in the psychosis spectrum.

Methods: Adhering to the PRISMA guideline and the Cochrane Handbook, our study protocol was registered on PROSPERO (CRD42023482939). The systematic search, conducted in three databases in September 2023, included articles using seed-based resting-state fMRI in patients with schizophrenia-spectrum disorders, first-episode psychosis, clinical high-risk for psychosis, and healthy control groups. Seeds for connectivity analysis were selected within the thalamo-cortico-cerebellar network. For statistical hypothesis testing we employed Multilevel Kernel Density Analysis (MKDA), a coordinate-based meta-analytic method. Risk of Bias was

evaluated using the Newcastle-Ottawa scale and we followed the recommendations of Müller and colleagues (2018) for fMRI meta-analysis.

Results: Data extraction and analysis encompassed 100 studies. Of these, 48 focused on seed-based thalamocortical connectivity, 33 reported cerebellar connectivity, and 15 included both thalamic and cerebellar connectivity. Preliminary findings indicate a confirmatory pattern of thalamocortical hypoconnectivity between the thalamus and subregions of the prefrontal cortex, alongside hyperconnectivity between the thalamus and motor and sensory cortical areas. Moderate heterogeneity was found among the included articles concerning preprocessing methods, statistical analysis, and the conceptualization of seed ROIs. Analysis of the cerebellum is in progress as well as the analysis of thalamic and cerebellar connectivity to differentiate between high-risk and clinical disorder states. The final results of MDKA analyses will be presented at the SIRS 2024 conference.

Discussion: Thalamo-cortico-cerebellar network connectivity dysfunctions have been described as a core feature in the pathophysiology of schizophrenia. This meta-analysis aims to offer a comprehensive statistical summary of existing findings on thalamo-cortico-cerebellar dysconnectivity and evaluate the reliability and robustness of these findings. Preliminary results suggest that thalamocortical and corticocerebellar functional dysconnectivity represents a fundamental neurobiological abnormality in schizophrenia spectrum disorders. With a focus on different illness stages, we anticipate that our final results will confirm thalamo-cortico-cerebellar dysconnectivity emerging prior to the onset of psychosis, potentially serving as a predictive marker for the transition from prodromal to clinical states.

S275. CELLULAR ADHESION MOLECULES AND COGNITION IN DRUG-NAÏVE AND PREVIOUSLY MEDICATED PATIENTS WITH SCHIZOPHRENIA-SPECTRUM DISORDERS: A LONGITUDINAL STUDY

Health Centre; Norwegian University of Science and Technology, Department of Mental Health, ¹¹Division of Psychiatry, Haukeland University Hospital; Department of Clinical Medicine, University of Bergen, ¹²Division of Psychiatry, Haukeland University Hospital; Department of Clinical Medicine, University of Bergen

Background: The pathoetiology of schizophrenia seems to involve inflammation. Endothelial inflammation, disruption of the blood-brain barrier (BBB) and the pathway of the cellular adhesion molecules (CAMs) have been associated with cognitive dysfunction, which can precede psychotic symptoms in the development of schizophrenia. The aim of the current study was to investigate the relationship between levels of soluble CAMs and measures of neurocognitive function in patients with schizophrenia-spectrum disorders, monitored at baseline, 6, 26 and 52 weeks after initiation of antipsychotic treatment in a randomized drug trial.

Methods: The study population includes 138 patients with schizophrenia-spectrum disorder, of which 54 were first episode and drug-naïve, and 84 were previously medicated. A brief neuropsychological battery, including Trail Making Test A (TMT-A) and Trail Making Test B (TMT-B), the Hopkins Verbal Learning Test (HVLT-R), WAIS Letter Number Sequencing, the Delis-Kaplan Executive Function System (D-KEFS) Verbal Fluency Tests (FAS) and Symbol Coding, were used to assess cognitive function. T-scores were converted from the test scores. The average t-scores were calculated, based on the subtests, for overall cognition (all subtests), working memory (TMT-B, WAIS Letter Number Sequencing), processing speed (TMT-A, Symbol Coding) and verbal abilities (HVLT-R, FAS). Analysis of soluble CAMs included neural cadherin (N-CAD), vascular adhesion molecule (VCAM)-1, intercellular adhesion molecule (ICAM)-1, mucosal addressing cell adhesion molecule (MADCAM) and junctional adhesion molecule (JAM-A). The possible confounders age, gender, body mass index (BMI), smoking and years of education were adjusted for in the linear mixed effect models. The average effect of CAMs on cognitive outcome measures during the follow-up period were explored.

Results: Levels of N-CAD and test scores of overall cognition ($p=0.026$) and verbal abilities ($p=0.027$) were significantly positively correlated in the total patient group. Levels of VCAM-1 were significantly negatively correlated with test scores of overall cognition ($p=0.019$) and processing speed ($p=0.048$) in the drug-naïve patient group. Levels of N-CAD and test scores of overall cognition ($p=0.004$), verbal abilities ($p=0.019$), working memory ($p=0.036$) and processing speed ($p=0.040$) were significantly positively correlated in the previously medicated group.

Discussion: We found an association between levels of N-CAD and VCAM-1 and measures of neurocognitive function. This suggests that immune processes are involved in cognition and that N-CAD and VCAM-1 may have a role as future biomarkers of cognitive dysfunction.

S276. USING NEUROTRANSMITTER VULNERABILITY TO DISCRIMINATE SCHIZOPHRENIA PATIENTS FROM HEALTHY CONTROLS

Lisa Hahn^{*1}, Florian Raabe², Daniel Keeser², Moritz J. Rossner², John Fanning², Clara Vetter², Alkomiet Hasan³, Irina Papzova³, Peter Falkai², Nikolaos Koutsouleris²

¹Ludwig-Maximilian University, ²Department of Psychiatry and Psychotherapy, Ludwig-Maximilian University, ³Department of Psychiatry, Psychotherapy and Psychosomatics, Medical Faculty, University of Augsburg

Background: Aside to common psychotic symptoms such as hallucinations, delusions and disorganized thinking, schizophrenia (SCZ) is characterized by structural alterations such as volume reductions in the temporal, frontal, and parietal lobes. Here, we evaluated if the co-localization of these alterations with the distribution of specific neurotransmitter systems, i.e. an indication of neurotransmitter vulnerability) can be utilized to discriminate SCZ patients from healthy controls (HC).

Methods: Maps of grey matter volume (GMV) were derived from T1-weighted structural magnetic resonance imaging for 445 SCZ patients (mean age = 34.0 ± 11.3 , 103 females) and 416 HC (mean age = 33.5 ± 11.3 , 108 females) from the Multimodal Imaging in Chronic Schizophrenia Study (MIMICSS; part of the PsyCourse study), the Center for Biomedical Research Excellence (COBRE; part of the COIN study) cohort, Mind Clinical Imaging Consortium (MCIC; part of the COIN study) cohort, the UCLA Consortium for Neuropsychiatric Phenomics LA5c Study, and the Munich cohort (internal dataset). Two linear classifiers utilizing a leave-site-out cross-validation (CV) design (CV1: 10x5, CV2: 1x10) for the discrimination of SCZ patients and HC were created. The preprocessing steps computed within the CV framework included offset correction using the global mean, correction for age and sex using partial correlations, the model-specific feature computation, and standardization. The model-specific features either entailed whole-brain correlation coefficients between GMV and 29 nuclear-imaging derived neurotransmitter maps (e.g., receptor and transporter density) from a healthy volunteer population computed using the JuSpace toolbox or 29 eigenvariates computed using principal component analysis (PCA) as a control model.

Results: The first classifier (using whole-brain correlation coefficients) discriminated SCZ from HC with a balanced accuracy of 64.1 % and area under the curve of 0.68 (sensitivity = 64.7 %, specificity = 63.6 %). The control classifier (using PCA eigenvariates) performed similarly, discriminating SCZ from HC with a balanced accuracy of 66.4 % and area under the curve of 0.72 (sensitivity = 75.2 %, specificity = 57.5 %).

Discussion: SCZ patients were distinguishable from HC based on the association of structural alterations with specific neurotransmitter systems. These findings suggest that this indication of neurotransmitter vulnerability might serve as a diagnostic biomarker.

S277. DISENTANGLING FACIAL EXPRESSIONS DURING PANSS INTERVIEWS AND THEIR ASSOCIATIONS WITH PSYCHOPATHOLOGY IN ANTIPSYCHOTIC-NAÏVE PATIENTS WITH FIRST-EPISODE PSYCHOSIS

Karen S. Ambrosen^{*1}, Cecilie K. Lemvig¹, Mette Ø. Nielsen², Birte Y. Glenthøj², Warda Syeda³, Bjørn H. Ebdrup²

¹Center for Neuropsychiatric Schizophrenia Research (CNSR) and Center for Clinical Intervention and Neuropsychiatric Schizophrenia Research (CINS), ²Center for Neuropsychiatric Schizophrenia Research (CNSR) and Center for Clinical Intervention and Neuropsychiatric Schizophrenia Research (CINS) AND University of Copenhagen, ³The University of Melbourne

Background: Facial expressions are an important aspect of non-verbal communication. Reduced emotional expressiveness is among the negative symptoms of schizophrenia. Identification and quantification of negative symptoms can be challenging and involve a large degree of subjectivity. Thus, an objective method for assessing these symptoms would

represent an important advancement. The Facial Action Coding System (FACS), developed by Ekman and Friesen in 1978, is a comprehensive, anatomically based system for describing all visually discernible facial movements. It breaks down facial expressions into individual components of muscle movement, called Action Units (AUs). Utilizing computer vision to measure facial expressions may provide a means of adding more objectivity and reliability in non-verbal symptom assessment. In this study, we explore the associations between facial expressions and psychopathology in antipsychotic-naïve patients with first-episode psychosis. Specifically, we hypothesize that coactivations of facial AUs, constituting distinct facial expressions, capture distinct dimensions of psychopathology.

Methods: Fifty antipsychotic-naïve individuals with first-episode psychosis (mean age 25.4 (6.1); 65.2% males) from the PECANS study (ClinicalTrials.gov Identifier: NCT01154829) were included. Psychopathology was rated using the Positive and Negative Syndrome Scale (PANSS) and the interviews were video-recorded. The videos were recorded under real-world clinical conditions, i.e., varying backgrounds, recording angles, and illumination. The recordings were 22-97 minutes long with an average duration of 48.7 minutes. The sampling rate was 25 Hz. All videos were preprocessed using OpenFace 2.0 (Baltrušaitis et al., 2018). The activation intensity of seventeen AUs from FACS and confidence estimates were computed frame-wise for the entire duration of each recording. Frames with a confidence level below 80% were removed and participants with less than 90% frames remaining were excluded from the analyses, resulting in a final sample of 46 patients. For each participant, a 17x17 connectivity matrix was calculated using temporal correlations between each pair of AUs. All connectivity matrices were Fisher's transformed. A group-level connectivity matrix was obtained by averaging the absolute values of the connectivity matrices across participants. Spectral clustering was performed on the averaged connectivity matrix to identify multiple facial expressions, such that AUs within each facial network showed maximal co-activation. These distinct facial expressions were identified within each participant's connectivity matrix. To establish the clinical relevance of facial expressions, associations between the facial expressions and psychopathology were investigated using linear regression.

Results: Individual-level connectivity matrices showed medium to high temporal correlations between AUs. Three facial expressions were identified. F1 nodes: AU1, AU2, AU4, AU5, AU7, AU9; F2 nodes: AU15, AU17, AU20, AU23, AU25, AU26, AU45; F3 nodes: AU6, AU10, AU12, AU14. F1 and F2 comprised AUs associated with negative valence, while F3 comprised AUs with positive valence. Within network temporal correlations showed the strongest associations between F1 and general symptoms ($\rho=0.54$, $p < 0.001$), F2 and negative symptoms ($\rho=0.69$, $p < 0.001$), and F3 and general symptoms ($\rho=0.51$, $p < 0.001$). Further analyses, e.g., associations with treatment response, are ongoing, and results will be presented at the SIRS 2024 congress.

Discussion: In summary, associations between the identified facial expressions and psychopathology indicate the clinical relevance of facial expressions.

S278. THE CONTRIBUTION OF COGNITIVE AND SOCIAL COGNITIVE IMPAIRMENTS TO INTERNALIZED STIGMA IN FIRST-EPISODE PSYCHOSIS

Élisabeth Thibaudeau^{*1}, Libby Lassman², Delphine Raucher-Chéné¹, Martin Lepage¹

¹McGill University, Douglas Mental Health University Institute, ²McGill University

Background: First-episode psychosis (FEP) is associated with impaired cognitive and social cognitive functioning that have shown detrimental effects on daily life. These impairments

represent one of the main complaints following a FEP which is also associated with internalized stigma (i.e. process by which individuals apply negative stereotypes to themselves). The latter is often accompanied with increased distress and poorer social functioning. While the relationship between clinical symptoms and internalized stigma has been shown in previous studies, its association with cognitive and social cognitive impairments is not yet well understood. The objective was to explore the associations between cognition, social cognition, and internalized stigma in FEP, and to assess the role of negative symptoms in these relationships, given their contribution to cognitive impairments and internalized stigma.

Methods: Data from a RCT on cognitive interventions for social anxiety in FEP were used, including 88 participants with a FEP (65.2% men, mean age of 24.8 years). Internalized stigma was assessed with the Internalized Stigma of Mental Illness Inventory (ISMI). The ISMI includes a total score as well as the following scales: alienation, stereotype endorsement, perceived discrimination, social withdrawal, and stigma resistance. Cognition and social cognition were assessed using the Cogstate battery, including verbal and visual memory, working memory, attention, executive functions, speed of processing and social cognition (emotion recognition). Negative symptoms were assessed with the Scale for the Assessment of Negative Symptoms. First, stepwise linear regressions were used with the ISMI scales as dependent variables and each cognitive and social cognitive domain as independent variables, controlling for negative symptoms. Then, the significant predictors for each ISMI scale were entered into a regression to assess their relative contribution.

Results: For the ISMI social withdrawal scale, a significant effect of social cognition was observed, explaining 21% of the variance [$F(1,87)=1.612$, $p=.044$], with no significant effect of negative symptoms. Attention was also a significant predictor of social withdrawal, explaining 35% of the variance [$F(1,87)=12.200$, $p < .001$], with no significant effect of negative symptoms. When social cognition, attention and negative symptoms were entered into a regression model, only the effect of attention remained significant. A similar pattern was observed for the perceived discrimination scale of the ISMI, with a significant effect of social cognition explaining 22% of the variance [$F(1,87)=4.598$, $p=.035$] and a significant effect of attention explaining 28% of the variance [$F(1,87)=7.547$, $p=.007$]. However, when attention, social cognition and negative symptoms were all entered into a regression model, only attention remained significant. For the ISMI stigma resistance scale, the regression model including only speed of processing explained 24% of the variance [$F(1,87)=5.344$, $p=.023$], while the model including speed of processing and negative symptoms explained 33% of the variance [$F(1,86)=5.379$, $p=.006$]. Finally, for the ISMI total score, attention was a significant predictor, explaining 27% of the variance [$F(1,87)=6.828$, $p=.011$], with no significant effect of negative symptoms. No significant effect was observed for the ISMI alienation and stereotype endorsement scales.

Discussion: Cognition and social cognition contribute uniquely to specific aspects of internalized stigma in FEP. This highlights the importance of treating cognitive impairments early in the illness, but also to address them in psychosocial interventions targeting internalized stigma.

S279. THE INTERPLAY BETWEEN SOCIAL REJECTION AND INTERPERSONAL FEAR CONDITIONING AS A PLAUSIBLE CAUSAL MECHANISM EXPLAINING PARANOIA-LIKE THOUGHTS

Łukasz Gawęda^{*1}, Paulina Bagrowska², Renata Pionke-Ubych², Justyna Piwińska²

Background: Paranoia is defined as a set of erroneous beliefs that other people are a source of intentional harm. It is hypothesized that paranoia results from complex interactions between various factors and psychological processes. However, the empirical knowledge of how different risk factors interact with each other in predicting and causally explaining paranoia is limited. Importantly, the role of interpersonal processes that are at the core of paranoia has been understudied. Hence, the aim of this study is to provide empirical verification of causal relations between social rejection, interpersonal fear-conditioning, and paranoia through a combination of experimental assessment in Virtual Reality settings and gold-standard clinical assessments of paranoia proneness in non-clinical individuals.

Methods: Participants aged 18-40 without neurological diseases, intellectual disabilities, a history of psychotic or bipolar disorders and substance abuse or dependence were recruited on the basis of an initial screening of levels of paranoid thoughts ($N = 3000$) and allocated to two groups - high paranoia (HP) (top 10% scores in R-GPTS ≥ 35) and low paranoia (LP) (bottom 10% scores in R-GPTS ≤ 1). Preliminary analyses were carried out on a group of 103 individuals (LP = 79, HP = 24). Semi-structured clinical interviews (M.I.N.I and CAARMS) preceded the experimental procedure. Initially, a VR version of the Cyberball game, which involves playing ball with virtual players, was used to elicit participants' feelings of being excluded. Participants were randomly assigned to one of two conditions: social inclusion or social exclusion. This was followed by a social fear conditioning procedure using interpersonal stimuli as a social stressor (offensive words shouted from a minimum distance by agents wearing blue or green T-shirts [conditioned stimulus] in front of the subject's face). This phase consisted of habituation, fear acquisition (16 stimuli, 75% reinforcement) and fear extinction (8 stimuli, no reinforcement). Measurements of state paranoia were collected after each phase (4 time points).

Results: The results of the 2 (Group: HP x LP) x 2 (Condition: Social inclusion x Social exclusion) x 3 (Time: T0, T1, T2, T3) mixed model ANOVA revealed a significant interaction effect ($F(3, 96) = 9.476$, $p < 0.001$, $\eta^2 = 0.23$). Pairwise comparisons revealed that in the LP group there were no significant differences in the level of paranoid thoughts between any time points and the Cyberball conditions. However, in the HP group in the social inclusion condition, there were significant differences in paranoia scores between T0 and T1 (before and after Cyberball) ($p = 0.006$), between T1 and T2 (after Cyberball and after fear acquisition) ($p = 0.001$), and between T1 and T3 (after Cyberball and after fear extinction) ($p = 0.004$). In the social exclusion condition, paranoia scores differed significantly between T0 and T1 (before and after Cyberball) ($p = 0.004$), T0 and T2 (before Cyberball and after fear acquisition) ($p = 0.019$), and between T2 and T3 (after fear acquisition and after fear extinction) ($p = 0.002$).

Discussion: The preliminary findings showed that LP group did not exhibit an increase in paranoid thoughts following social rejection and did not display susceptibility to interpersonal fear conditioning. HP group, however, demonstrated a significant reduction in paranoid thoughts following social inclusion, and a notable increase in paranoid thoughts after social rejection. Moreover, HP group was susceptible to interpersonal fear conditioning, displaying heightened paranoid thoughts regardless of Cyberball condition. While these initial findings are based on limited data forming unequal groups, one could tentatively suggest a plausible causal connection between social rejection and social fear conditioning. Alternatively, these may represent distinct processes, with either the social rejection experience or the fear conditioning process contributing to the escalation of paranoid thoughts.

S280. EMOTIONAL AND NON-EMOTIONAL MENTAL IMAGERY AND AUDITORY VERBAL HALLUCINATIONS (HEARING VOICES): A SYSTEMATIC REVIEW OF IMAGERY ASSESSMENT TOOLS

Hella Janssen¹, Karin C. van den Berg², Georgie Paulik³, Katherine Newman-Taylor⁴, Christopher D.J. Taylor⁵, Craig Steel⁶, Ger P.J. Keijsers⁷, Machteld C. Marcelis⁸, Machteld Marcelis^{*9}

¹Department of of Psychiatry and Neuropsychology, MHeNs Maastricht University, the Netherlands, ²Medical Psychiatric Research Group, Geestelijke Gezondheidszorg Eindhoven (GGzE), the Netherlands, ³School of Psychological Science, University of Western Australia, ⁴University of Southampton and Southern Health NHSF Trust, ⁵University of Manchester and Pennine Care NHS FT, ⁶Oxford Centre for psychological Health and Oxford Institute of Clinical Psychology Training and Research, ⁷Behavioural Science Institute, Radboud University, Nijmegen, the Netherlands, ⁸Department of Psychiatry and Neuropsychology, School for Mental Health and Neuroscience, EURON, Maastricht University Medical Center, Maastricht, the Netherlands; Institute for Mental Health Care Eindhoven (GGzE), Eindhoven, the Netherlands, ⁹Maastricht University Medical Center

Background: It is unknown to what extent mental imagery and auditory verbal hallucinations (AVHs) are related. Trials evaluating this issue used both emotional and non-emotional mental imagery tools, thereby complicating outcomes comparisons. The present study aimed to systematically review the literature on mental imagery in individuals with AVHs to 1) inventory imagery assessment tools used in this population, 2) to collect information on the relation between emotional and non-emotional mental imagery in all sensory domains and AVHs, and 3) to integrate the outcomes of this systematic review in a model of different mental imagery domains and related assessment tools.

Methods: We conducted a systematic literature search in the PubMed Database.

Results: After full-text screening 17 papers were included. Findings showed that a variety of assessments methods have been used to assess various aspects of mental imagery in people with AVHs, suggesting that there is a lack of agreed theoretical conceptualisation of mental imagery and AVHs. In addition, the studies confirmed as was expected that non-emotional mental imagery seemed unrelated to AVHs, whereas emotional mental imagery was related to AVHs.

Discussion: AVHs are associated with emotional mental imagery. Emotional and non-emotional mental imagery measures are poorly distinguished, resulting in inaccurate research conclusions. We proposed a model of mental imagery domains and corresponding assessment methods distinguishing between emotional and non-emotional mental imagery.

S281. MULTIMODAL BRAIN IMAGING MARKERS PREDICT AUDITORY HALLUCINATION IMPROVEMENT AFTER NEUROFEEDBACK INTERVENTION

Jiahe Zhang^{*1}, Emma Tusuzian¹, Clemens Bauer², Ann Shinn³, Francesca Morfini¹, Yoonji Lee¹, Angelina Awad⁴, Lena Stone³, Margaret Niznikiewicz⁵, Susan Whitfield-Gabrieli¹

Background: Approximately 75% of patients diagnosed with schizophrenia (SZ) suffer from auditory verbal hallucinations (AVH) and about one-third of those experiencing AVH do not respond to medication. We recently developed a real-time fMRI neurofeedback (NF) approach that trains participants to voluntarily down-regulate activity in their auditory cortices in the superior temporal gyrus (STG) aided by a display of moment-to-moment changes in their STG activation. In order to further optimize this approach, it is important to identify characteristics that can help predict outcome success. Altered STG and default mode network (DMN) morphometry and functional connectivity have been observed in SZ and AVH. This study aimed to test whether multimodal neuroimaging analyses of the STG and the DMN can predict AVH improvement in patients after a single session of NF.

Methods: Twenty-five participants with medication-resistant AVH were randomly assigned to receive either active STG NF (N = 12) or sham motor cortex NF (N = 13). All participants underwent structural MRI and resting state fMRI scanning before the NF session. During NF, patients listened to prerecorded sentences spoken in their own voice or in a gender-matched stranger's voice, delivered over headphones. Blood oxygen level dependent (BOLD) activation in the active or sham brain target was displayed in the form of a thermometer. Patients were asked to reduce BOLD activation when they listened to the stranger's voice, and to increase it when they listened to their own voice. Both STG and motor cortex targets were identified using a baseline localizer scan. AVH were assessed using the Psychotic Symptom Rating Scale (PSYRATS). For cortical thickness and functional connectivity analysis, we identified bilateral a priori STG regions from the Destrieux atlas and computed subject-specific DMN using a localizer resting state scan.

Results: ANOVA test on AVH change contrasting active and sham groups across pre- and post-NF timepoints showed a significant main effect of time ($F = 8.72$, $p = .007$), but did not reveal a significant main effect of group or group-by-time interaction. Nevertheless, participants who received STG NF reported significantly decreased AVH after NF [$t(11) = 2.30$, $p = .042$, two-tailed, paired-sample t-test]. Within the STG NF group, we found that more improvement in AVH was associated with the following characteristics at baseline: (1) more severe AVH ($r = .61$, $p = .037$), (2) thicker bilateral STG ($r = .63$, $p = .027$), (3) stronger functional connectivity within the DMN (between the whole DMN and bilateral posterior cingulate cortex, PCC; $r = .87$, $p < .001$), and (4) stronger anticorrelation (i.e., more negative connectivity) between the DMN and bilateral dorsolateral prefrontal cortex (DLPFC; $r = -.95$, $p < .001$).

Discussion: In participants who were trained to reduce STG activation with help from real-time STG NF, their post-NF AVH reductions were predicted by baseline STG thickness as well as within-DMN connectivity (i.e., DMN-PCC) and DMN-executive network connectivity (i.e., DMN-DLPFC). These results suggest that participants with more severe symptoms (i.e., higher PSYRATS scores), poorer brain indices of SZ disorder (i.e., thicker STG and stronger within-DMN connectivity) but preserved cognitive capacity (i.e., stronger DMN-CEN anticorrelation) at baseline may benefit more from STG NF. Consistent with principles of precision medicine, this study provides potential brain-based biomarkers that prospectively predict symptom improvement in AVH for SZ.

S282. NEURORADIOLOGICAL ABNORMALITIES IN FIRST EPISODE OF PSYCHOSIS: AN EPIDEMIOLOGICAL COHORT OF 331 PATIENTS

Jorge Romay*¹, Paula Suarez-Pinilla¹, Javier Vazquez-Bourgon¹, Marta Drake-Perez¹, Enrique Marco de Lucas¹, Fernando Roman-Rubio¹, Pilar García-Pelayo¹, Rocío Pérez-iglesias¹

¹*Hospital Universitario Marqués de Valdecilla*

Background: An increasing number of studies and a recent meta-analysis are trying to support the use of Magnetic Resonance Imaging (MRI) in the early phases of psychosis. Identify MRI abnormalities in these early stages could demonstrate markers and potential pathways involved in the onset of psychosis, despite the lack of a clear consensus on the use of MRI as part of the clinical evaluation.

This study aimed to investigate neuroimaging patterns and brain abnormalities in Magnetic Resonance Imaging performed on patients included in a cohort of 331 patients with a first-episode of psychosis treated in the early intervention program ITPCan.

Methods: A total of 331 patients in early stages of psychosis were included in this study. All of them were offered an imaging test (MRI or CT scan) at the beginning of the follow-up. Out of this total, 253 (76.4%) patients agreed to undergo the imaging test, while 78 (23.5%) were unable to undergo the imaging test due to either incompatibility or refusal. Among these 253 patients who underwent imaging, 161 received an MRI, while 92 received a CT scan. Data was recorded between January 2020 and September 2023, covering a population area of approximately 589765 inhabitants in Santander (Spain). Inclusion criteria were established for patients aged 17 to 65 years with an untreated first episode of psychosis and subsequent diagnosis of schizophrenia, schizophrenia related disorder or manic episode with psychotic symptoms. The imaging data and the associated clinical report were described and interpreted by two neuroradiologists (M. Drake-Pérez, E. Marco de Lucas), using an MRI protocol that included T1, T2, FLAIR, and diffusion-weighted images.

Results: Of the 161 patients undergoing MRI, 45.3% (N 73) showed no significant findings in the imaging test, while 54.7% (N 88) exhibited alterations in MRI. Among this subset with abnormalities in the imaging test, 42.04% presented high degrees of heterogeneity lesions in the white matter, which can be categorized into three groups: 1) Non-specific subcortical lesions accounting for 61.84% (N 26); 2) Subcortical lesions and periventricular lesions, deeper than those indicative of chronic microangiopathic ischemic leukoaraiosis (Fazekas 1), constituting 14.2% (N 6); 3) Infratentorial millimetric lesions at 4.7% (N 2). Other abnormalities in MRI included encephalomalacia 2.6 % (N 3), malformations 14.9% (N 17), or atrophies 6.1% (N 7). Analyzing these data with age as a variable, using a cutoff point of 35 years, we observed a statistically significant Chi-square relationship ($p = 0.001$) between individuals older than 35 years and abnormalities in MRI. Among patients without MRI, 27.8% (N 92) underwent a CT scan, with 98.9% of the results being normal.

Discussion: These findings contribute valuable insights for both clinical diagnosis and future research endeavors aimed at elucidating the neural correlates of early-stage psychotic disorders. Further exploration is warranted to establish the clinical relevance of these neuroimaging patterns and the implementation of MRI as strategy in early phases of psychosis.

S283. COROLLARY DISCHARGE DYSFUNCTION AS A POTENTIAL UNDERLYING MECHANISM FOR ABNORMAL SELF-EXPERIENCES AND ITS ASSOCIATION WITH CLINICAL SYMPTOMS IN SCHIZOPHRENIA

Rosa M. Beño-Ruiz-de-la-Sierra*¹, Antonio Arjona-Valladares¹, Sabela Fondevila Estévez², Inés Fernández-Linsenbarth¹, Alejandro Roig-Herrero¹, Alvaro Díez¹, Vicente Molina³

¹University of Valladolid, ²Center UCM-ISCIII for Human Evolution and Behaviour,

³University of Valladolid. Clinical Hospital of Valladolid

Background: The accurate differentiation between self-generated stimuli and those originating from external sources is crucial for the development of an intact sense of self, with Corollary Discharge (CD) representing a key mechanism in this process.

The N1 Event-Related Potential (ERP) in Electroencephalogram (EEG) studies serves as an indicator of CD-mediated auditory cortical suppression of self-generated speech in Healthy Controls (HC), but this phenomenon seems to be altered in people with schizophrenia (Sz). Challenges in discerning the source of stimuli may contribute to the manifestation of certain clinical symptoms and the prevalence of Anomalous Self-Experiences (ASEs) within the psychosis spectrum.

Methods: A 64-channel EEG system was used to record the data from forty-three participants with Sz (18 First Episode (FE) and 25 chronic) and 43 HC. Both men and women participated and there were no significant differences between groups in sex or age. The N1 ERP was elicited by two task conditions: 1) self-pronounced vowels (talk condition) and 2) playback of the previously self-uttered vowels (listen condition). ASEs, positive and negative symptoms were assessed using the Inventory of Psychotic-Like anomalous Self Experiences (IPASE), the Positive and Negative Syndrome Scale (PANSS), and the Brief Negative Symptom Scale (BNSS) respectively.

First, to assess the occurrence of CD, a within-group analysis was conducted to measure the differences between conditions (Talk vs. Listen) using a repeated measures Student's t-test. Secondly, the amplitude difference between conditions (Talk minus Listen) was used as an indicator of CD-mediated auditory cortical suppression of self-generated speech, and a between group analysis was performed using an independent measure Student's t-test. Finally, the relationship between sensory suppression and the intensity of ASEs and symptoms was studied using linear regression analysis.

Results: The N1 suppression in the Talk condition compared to the Listen condition was lower in both Sz and HC participants. However, N1 amplitude suppression was statistically significantly higher in HC than in Sz. In addition, N1 suppression was significantly and negatively correlated with IPASE, PANSS, and BNSS scores. The same results were found for FE and chronic participants. No significant relation was found between N1 amplitude suppression and antipsychotic doses in participants with schizophrenia.

Discussion: Sensory identification of our own voice when speaking occurs at a pre-stimulus level. By activating the CD mechanism, we can predict the consequences of our own actions and differentiate the source of stimuli. This study replicates previous findings of CD impairment in schizophrenia and supports the idea that CD dysfunction may be a potential substrate of ASEs and psychotic symptoms in people with schizophrenia.

S284. CLINICAL AND FUNCTIONAL OUTCOMES FOLLOWING TREATMENT OF ACUTE PHASE OF FIRST-EPISODE PSYCHOSIS TREATED IN A REAL-WORLD SETTING

Rocio Perez-Iglesias*¹, Javier Vázquez-Bourgon², M Luz Ramírez-Bonilla¹, Deirdre Sierra-Biddle¹, Patricia Cordero-Andrés¹, M Carmen Flor-Gómez¹, Elsa Gómez-Ruiz¹, Raquel Obeso-Menéndez¹, Jorge Romay-González¹, Paula Suárez-Pinilla¹

¹University Hospital Marques de Valdecilla, ²Department of Psychiatry, University Hospital Marqués de Valdecilla, Institute of Biomedical Research Valdecilla (IDIVAL), Santander, Spain. CIBERSAM

Background: The aim of this study is to examine the clinical and functional outcomes of an epidemiological cohort of first-episode patients treated in the Early Intervention (EI) Service of Cantabria (ITPCan).

Methods: This is an audit study of all the patients admitted to the EI Service of University Hospital Marqués de Valdecilla, Spain, from January 2020 to July 2023. The catchment area has a population of 310,000 habitants. Patients were included if they were residents in the area, aged from 17 to 65 and were experiencing a first episode of psychosis (affective or non-affective).

As part of the clinical protocol, patients were offered a comprehensive assessment by an experienced psychiatrist in EI within 24 hours of referral. They were treated with a very low dose of antipsychotic medication in monotherapy and CBT for psychosis and physical health interventions started within the first two weeks of contact with services. To maintain the continuity of care, the same EI team treated the patients in the ward and in the outpatient clinic. The response to treatment was assessed at baseline, 3, 6 and 12 weeks with standardized scales such as PANSS, Calgary and Young. The side effects of antipsychotics were assessed using UKU scale and the GAF scale was used to assess functional outcome. To measure Patient Related Outcomes, we used the ISMI (Internalized Stigma of Mental Illness) and PBIQ-R (Personal Beliefs about Illness) scales.

Results:

A total of 163 were included. Forty five percent were male (n=74); sixty three percent were single (n=102). The mean age was 37 and fifty three percent of the cohort (n=87) were more than 35 years old at first contact with services, particularly women (64,1%). Twenty percent were living alone and 34% were unemployed. Eighty four percent were non-affective psychosis (33% schizophrenia; 10% TID, 44% schizophreniform disorder ; 11% Non-specified psychosis) and 16% first manic episode with psychotic symptoms. The mean duration of untreated psychosis was 13 months and the median was 2,5 months. A hundred and one patients (61%) required hospital admission and 83 (51%) were involuntary. Twenty percent of patients used cannabis on a daily basis. The GAF at initial assessment was 36,6 (SD=12); all of them below 70.

The most frequently prescribed antipsychotic treatments at baseline were aripiprazole (44%); olanzapine (31%) and risperidone (17%). The maximum mean dose was 9,1 mg/d for aripiprazole, 10,5 mg/d for olanzapine and 2,6 mg/d for risperidone. The mean maintenance dose at 12 weeks was 7,1 mg/d for aripiprazole; 8,6 mg/d for olanzapine and 2,3 mg/d for risperidone. Only 14 patients did not attend the assessment at 12 weeks.

The rate of responders using the PANSS remission criteria proposed by Andreasen was 53% at 3 weeks, 70,3% at 6 weeks and 85% at 12 weeks. The mean GAF at 12 weeks was 71, 64% of them scored 70 or more. The majority of patients rated low in the PRO on perceived stigma, alienation, discrimination and social withdrawal.

Discussion: Very low dose of antipsychotic treatment is effective to treat acute phase of first episode of psychosis, achieving a high response rate and a good functional outcome.

S285. STRESS FROM ETHNIC AND GENDER MINORITY STATUS, ADVERSITY, PARENTAL SUPPORT, AND SELF-REPORTED MENTAL HEALTH ON PSYCHOTIC EXPERIENCES: A CROSS-SECTIONAL SCHOOL-BASED SURVEY OF IRISH ADOLESCENTS

John Hoey*¹, Ronan Fleury¹, Jessica Ohland¹, Lorna Staines¹, Niamh Dooley², Emmet Power¹, Ian Kelleher³, David Cotter¹, Mary Cannon¹

¹Royal College of Surgeons in Ireland, ²King's College London, ³University of Edinburgh

Background: Psychotic experiences (PEs) in adolescence are associated with poorer long-term mental health outcomes in adulthood. It is known that early adversity is associated with an increased risk of psychotic experiences, however, less is known about the role of minority stress (defined as the stress experienced due to being in a minority group based on ethnicity or gender) and the protective role of parental support.

Methods: Cross-sectional data were drawn from the 2021 Planet Youth Project. Students from Cavan, Monaghan, and North Dublin were recruited to complete a self-report questionnaire. Participants were assessed for risk of PEs using the 7-item Adolescent Psychotic Symptom Screener (APSS). Mental health was assessed using the Strengths and Difficulties Questionnaire (SDQ). We employed multivariate logistic regression to analyse how a range of factors, specifically race, gender, feelings of safety at home and school, parental support, and self-reported mental health independently and collectively influence the risk of PEs in a general population adolescent sample.

Results: Of the students who completed the self-report questionnaire, 2168 (50.7%) identified as male, 1902 (44.5%) as female, 118 (2.7%) as transgender or non-binary, and 68 (1.6%) chose not to disclose their gender. Regarding ethnicity, 1991 (51.1%) identified as White Irish, 456 (11.7%) as other White, and 258 (6.6%) as Black, Asian or another minority. We observed differences in the risk of PEs in gender and ethnic minority groups. The prevalence of PEs was notably higher in minoritised ethnic groups, as indicated by an OR of 1.44 (95% CI [1.14, 1.82], $p = 0.002$), as opposed to their white counterparts. Non-binary or transgender individuals with SDQ scores above 16 showed a substantially increased risk of PEs, with an odds ratio (OR) of 4.15 (95% CI [2.61, 6.60], $p < 0.001$) as compared to their cisgender counterparts with SDQ scores below 16. Cisgender individuals (those who identified as male/female) with SDQ scores above 16 also demonstrated a higher risk of PEs, with an OR of 3.52 (95% CI [2.93, 4.24], $p < 0.001$), albeit lower than the gender diverse group. Adolescents perceiving safety at home and school reported lower prevalence of psychotic experiences (PEs), with ORs of 0.72 (95% CI [0.60, 0.87], $p = 0.001$) and 0.71 (95% CI [0.59, 0.86], $p < 0.001$), respectively. Participants with high adversity and lacking parental support had a significantly increased risk of PEs, with an OR of 1.79 (95% CI [1.34, 2.40], $p < 0.001$). Adolescents facing high adversity, with parental support, still

showed an elevated risk, albeit less than those without support, with an OR of 1.58 (95% CI [1.18, 2.13], $p = 0.002$).

Discussion: This study has identified potential risk and protective factors for PEs from multiple demographic and psychosocial domains emphasizing the complex interaction between mental health, a safe living environment and the presence of supportive adults. While these findings are significant, the cross-sectional nature of this study limits our ability to infer causality necessitating cautious interpretation. Nevertheless, these findings can guide clinicians in understanding the psychosocial factors influencing PE onset and inform the development of targeted interventions for adolescents, especially those in minoritised high-risk groups.

S286. DURATION OF UNTREATED PSYCHOSIS AS A MODERATOR BETWEEN SOCIAL COGNITION AND SOCIAL FUNCTIONING IN FIRST EPISODE PSYCHOSIS

Silvia Corbera^{*1}, Hadar Hazan², Fangyong Li³, Bin Zhou³, Sneha Karmani², Toni Gibbs-Dean², Sumeyra Tayfur², Cenk Tek², Vinod Srihari²

¹Central Connecticut State University, ²Yale University School of Medicine, ³Yale Centre for Analytical Sciences

Background: Despite evidence of impaired social cognition (SC) in first episode psychosis (FEP), the precise relationship between SC and social functioning (SF) remains unclear. While cross-sectional studies have established a link between SC and SF in FEP, longitudinal studies have yielded mixed results, with some demonstrating a mediating effect of SC between cognition and SF and others finding no relationship with SF. Duration of untreated psychosis (DUP), the time elapsed from psychosis onset to treatment, is a crucial predictor of SF in FEP, with reductions in DUP associated with improved SF and diminished negative symptoms. Negative symptoms have been identified as a potential mediator in the relationship between SC and SF in FEP, and are particularly susceptible to delays in DUP. However, to date no study has examined the moderating effects of DUP on the SC-SF relationship and the role of DUP between SC and negative symptoms in FEP. This longitudinal study examined them at baseline, and at 6-and 12 months after receiving specialized first-episode services.

Methods: Participants: 246 FEP participants (16-35yo) with primary non-affective psychotic disorders (DUP LESS THAN 3 year) were assessed at baseline, 6 (n=228) and 12 -months (n=211) as part of a quasi-experimental trial of early detection campaign delivered at a program for Specialized Treatment Early in Psychosis (n=171) compared to a usual detection coordinated specialty care site (n=75). Measures: Baseline: Symptoms: Structured Clinical Interview for DSM-IV; Positive and Negative Syndrome Scale (PANSS); Structured Interview for Psychosis-Risk Syndromes; Premorbid Adjustment Scale (PAS). Cognition: Premorbid IQ estimate-WRAT-4 reading; Social Cognition-MATRICES- MSCEIT Managing Emotions Branch. Social Functioning: Global Assessment of Functioning (GAF); Heinrichs Quality of Life (QOL). 6-and 12-months measures: PANSS and SF. DUP was calculated using the median split of the DUP of the sample (227.5 days; Long DUP: LDUP; Short DUP: SDUP n=123). Analyses: 1) T tests were used to compare baseline SF, SC, symptoms and cognition between DUP groups; 2) Two multivariable linear regression models were done using baseline SC as the predictor and SF as Dependent Variable(s) (GAF and QOL) at 6-and 12-months, controlling for their values at baseline, PAS, recruitment site, and DUP as a moderator; 3) Bi-variate correlations between SC and negative symptoms in both groups were performed.

Results: At baseline, QOL and PANSS negative scores differed between groups with the SDUP group having higher QOL and lower negative symptoms (QOL: SDUP M=63.47(20.41); LDUP M=58.55(19.46); $p=0.06$; PANSS Neg: SDUP M=18.57(7.26); LDUP M=20.49(7.05); $p=0.037$) yet no differences were observed in premorbid IQ estimate, SC, and GAF. Moderation analyses revealed a significant positive relationship between SC and GAF at 12-months, (95% CI: 0.016 to 0.519; $p=0.03$) in the LDUP only. Similarly, a significant differential relationship between SC and QOL at 12-months between groups was found with only the LDUP having a positive relationship (95% CI: 0.003 to 0.944, $p=0.04$). SC correlated with negative symptoms in both groups at baseline (SDUP $r = -.275$; $p=0.003$; LDUP $r = -.238$ $p=0.011$). Only in the LDUP social cognition correlated with negative symptoms at 12-months ($r = -.211$; $p=0.038$).

Discussion: Despite that groups did not differ in SC at baseline, it predicted SF at 12months only in the LDUP. Similarly, higher SC was related with lower negative symptoms at baseline in both groups, but only related at 12-months in the LDUP. These results suggest that SC is a protective factor that may buffer from detrimental effects of DUP providing evidence for early intervention in this area in FEP.

S287. TRAUMA-INFORMED PREDICTIVE MODEL OF RECOVERY IN EARLY PSYCHOSIS

Sandra Vieira^{*1}, Philippe Golay², Raoul Jenni³, Giorgio Pistis⁴, Chin B. Eap⁵, Paul Klauser⁶, Luis Alameda⁷

¹*Institute of Psychiatry, Psychology and Neuroscience, King's College London*, ²*Service of General Psychiatry, Department of Psychiatry, Lausanne University Hospital, Switzerland*, ³*Center for Psychiatric Neuroscience, Lausanne University Hospital and University of Lausanne, Switzerland*, ⁴*Department of Psychiatry, Lausanne University Hospital and University of Lausanne, Prilly, Lausanne, Switzerland*, ⁵*Department of Psychiatry, Unit of Pharmacogenetics and Clinical Psychopharmacology, Lausanne University Hospital, Prilly, Switzerland*, ⁶*Center for Psychiatric Neuroscience and Service of Child and Adolescent Psychiatry, Department of Psychiatry, Lausanne University Hospital, Lausanne, Switzerland*, ⁷*Center for Psychiatric Neuroscience, Department of Psychiatry, Lausanne University Hospital, Switzerland - Service of General Psychiatry, Department of Psychiatry, Lausanne University Hospital, Switzerland*

Background: Treatment resistance affects about a fourth of patients diagnosed with a psychotic disorder. It is now well established that different forms of traumatic experiences including abuse (sexual, physical and emotional) and neglect (physical and emotional) during childhood and/or adolescence are associated with poorer recovery rates, poorer functioning, more pronounced cognitive deficits, more substance use (mainly cannabis), and higher suicide risk. Evidence shows that the effect of trauma is mediated by several psychological and biological mechanisms such as symptom severity, cognition, oxidative stress and genetic risk for psychosis. However, findings from trauma-related studies in psychosis come primarily from traditional group level analyses. This hinders clinical translation as it does not allow to disentangle which patients are more or less likely to improve after treatment. In this study, we used a machine learning approach to develop a trauma-informed predictive model of recovery for patients with first-episode psychosis (FEP) based on a comprehensive assessment of trauma and associated mechanisms.

Methods: 77 FEP patients from the Treatment and Early Intervention in Psychosis Program (TIPP, Lausanne, Switzerland) underwent an extensive assessment of exposure to traumatic life events including: 1) type of trauma (e.g. sexual abuse, physical abuse), 2) time of occurrence in relation to psychosis stage (premorbid, prodrome or after onset), 3) age at the time of first exposure, and 4) number of times exposed. Additional trauma-associated variables were also collected namely symptom severity, neurocognition (MATRICS), peripheral blood markers (oxidative stress) and genetic vulnerability (polygenic risk score for schizophrenia). All variables were used to predict level of socio-occupational functioning 18 months after entering the TIPP programme. Each input feature was scaled independently by removing the mean and scaling to unit variance. Missing values were imputed using k-nearest neighbours and dimensionality was reduced via principal component analysis (PCA). The resulting factors were entered in a regularised logistic regression (elastinet) to predict poor/good functioning (score ≥ 60 on the Global Assessment of Functioning scale). A total of 100 models were trained and tested with cross-validation. The most informative predictors were determined by retrieving the PCA components with the highest regression coefficients and respective items with highest loadings.

Results: At 18 months, 46 and 31 patients had poor and good functioning, respectively. There were no statistically significant differences between the two groups for age, sex and ethnicity. Across all 100 iterations, the model was able to predict good level of functioning at 18 months with 71.3% (6.1) accuracy, 64.5% (6.4) sensitivity and 78.1% (7.6) specificity. The most informative predictors were 1) depressive symptoms and baseline functioning, 2) cognition, 3) psychosis symptoms and mania, followed by 4) trauma (abuse and neglect), ethnicity and migrant status.

Discussion: This study sheds light on the role of trauma in the prediction response to treatment in early psychosis at the individual level. We found that patients of ethnic minorities, migrants and who experienced neglect or abuse are less likely to recover and therefore may need additional and specialised support. We encourage future studies in precision psychiatry to include information about history of trauma.

S288. CAUSAL INFERENCE IN FIRST EPISODE PSYCHOSIS: FINDINGS FROM THE FEP-CAUSAL COLLABORATION

Alejandro Szmulewicz*¹, Miguel Hernan², Dost Ongur³, Gonzalo Martinez-Ales⁴, Maria Ferrara⁵, Celso Arango⁶, Covadonga Díaz-Caneja⁷, Lakshmi Yatham⁸, Diane Fredrikson⁹

¹Harvard School of Public Health, ²Harvard TH Chan School of Public Health, ³Mclean Hospital, ⁴Icahn School of Medicine At Mount Sinai, ⁵Institute of Psychiatry, University of Ferrara, Italy, ⁶Hospital General Universitario Gregorio Marañón, ⁷Institute of Psychiatry and Mental Health, Hospital General Universitario Gregorio Marañón, CIBERSAM, IiSGM, School of Medicine, Universidad Complutense, Madrid, Spain, ⁸The University of British Columbia, ⁹University of British Columbia

Background: Making informed decisions among several courses of action requires knowledge about their causal effects. Randomized trials are the preferred method to quantify those causal effects. When randomized trials are not available, causal effects are often estimated from sources of observational data. Causal inference from observational data can be viewed as an attempt to emulate a hypothetical randomized trial—the target trial—that would quantify the causal effect of interest. Contrary to popular belief, many well-known failures of observational

studies were the result of not adequately emulating a target trial rather than of limitations of the observational data. This talk describes those methodological failures in non-technical language and present examples that illustrate how observational data can be used to inform clinical and policy decisions when randomized trials do not exist. The example presented here is a target trial emulation on trying to determine the optimal timing of initiation of LAI antipsychotics (i.e., at presentation, after first relapse, or at second or subsequent relapse while on treatment with oral antipsychotics) in First Episode Psychosis, which remains an unanswered clinical question.

Methods: We will use data from the FEP-CAUSAL Collaboration, an international consortium of observational cohorts from USA (McLean OnTrack, STEP-Clinics at Yale and Pittsburgh, NYU Healthcare System, RAISE-ETP), Canada (UBC at Vancouver, PEPP-Montréal), and Spain (AGES-CM) to emulate a target trial of different strategies of initiation of LAI (paliperidone, aripiprazole, risperidone). Eligibility criteria were: age between 18-45, a diagnosis of a psychotic disorder, no prior use of clozapine or LAI agents in the past 6 months, no history of suicidality, and complete data on demographics. The treatment strategies that we compared were: to initiate a LAI agent or to maintain oral antipsychotic treatment at different clinical stages (before first relapse, after first relapse, after second or subsequent relapses). The primary outcome was all-cause psychiatry hospitalization after 3 years of follow-up. We adjusted for the following variables: age, race, sex, housing status, diagnosis, comorbid substance abuse, prior use of antipsychotics (including treatment failures), employment and educational status, and baseline symptomatic (Clinical Global Impression-Severity [CGI-S] score) and functional (Global Assessment of Functioning [GAF] score) statuses. We also included measures of frequency and intensity of substance use.

Results: Of the initial sample of 1420 FEP patients, a total of 803 individuals were eligible for the study. The median age (interquartile range, IQR) was 22 years (21, 27), 72% of individuals were female, 41% were White. Compared with oral users at baseline, LAI initiators had, on average, more markers of severity: higher baseline diagnoses of schizophrenia and substance use disorders, lower proportion of full-time students and workers, and a higher proportion of patients in CGI-S scores of 4-5.

The estimated observational analogue of the intention-to-treat 3-year relapse risk in LAI initiators and non-initiators was 55.1% (47.9, 68.7) and 52.9% (41.4, 58.6), respectively. The corresponding risk difference was 2.2% (-2.8, 7.6). The subgroup analysis revealed that LAI initiation before the first relapse showed no advantage as compared to oral continuation (3-year risk difference: -1.8, 95%CI: -8.1, 2.1). However, we found a strong protective effect for those initiating LAI after the first relapse (3-year risk difference -9.3, 95%CI: -22.9, 0.0).

Discussion: LAI use had no effect in preventing relapses over the study period but showed a small protective effect in preventing hospitalizations (risk difference: -4.1%, 95%CI: -9.5, 1.6). This result was consistent with the findings from the EULAST randomized trial that showed no benefit with the use of LAI in early phase psychosis. We found a strong protective effect of LAI initiation vs. oral maintenance in patients after their first relapse (with a risk difference of around 10%), suggesting that this might be the optimal timing for offering LAI in patients with early psychosis.

Our target trial emulation will pioneer the implementation of causal inference methodology to observational prospective cohorts in FEP. The superiority of this methodological approach has been demonstrated in several areas of medicine but not yet in psychiatry. We expect that our work will result in methodological advancements and case studies that will be generally applicable across many areas of research in mental health.

S289. DIAGNOSTIC TRAJECTORIES IN FIRST EPISODE PSYCHOSIS (FEP): FINDINGS FROM A RETROSPECTIVE STUDY IN THE FEP PROGRAM OF FERRARA, ITALY

Ludovica Vecchioni^{*1}, Maria Ferrara², Giulia Zaffarami², Martino Belvederi Murri², Spyridon Zotos³, Barbara Giroto³, Raffaella Bertelli³, Franca Emanuelli³, Luigi Grassi²

¹*Institute of Psychiatry, University of Ferrara*, ²*Institute of Psychiatry, University of Ferrara*,

³*Integrated Department of Mental Health and Pathological Addictions*,

Background: Diagnostic instability within First Episode Psychosis (FEP) has been the object of several studies over the last decade. Our study describes the evolution of FEP diagnosis over time, and analyzes demographic and clinical predictive factors of diagnostic changes amongst patients who were admitted to an Italian FEP program.

Methods: This retrospective study includes all the individuals admitted to the FEP program in Ferrara, Italy, from its inception (2012) to October 2023, that were diagnosed with an affective or non-affective psychosis or were considered Clinical High Risk for Psychosis (CHR), were not previously treated for psychosis more than two years, and were aged 15 to 35 years old. The FEP program excludes those who had severe intellectual disability, or were diagnosed with organic psychosis. The program guarantees an intensive clinical intervention for up to two-years, led by a multidisciplinary team, formalized within a PDTA. The PDTA has been further strengthened with its inclusion in a research project labeled the “Early Psychosis: Implementation and Care - Ferrara” (EPIC-FE), that has the goal to implement a real-time monitoring of access, process, and outcome indicators, to improve individual treatment.

This study analyzes the evolution of the initial diagnosis from admission to the time of discharge from the program and possible predictive factors, within the information collected at baseline including demographics, education, employment status, substance use, duration of untreated psychosis, referral to the program, and number and length of psychiatric hospitalizations. The severity of illness was evaluated by administering the Health of the Nation Outcomes Scale (HoNOS) at admission and every six months.

Results: Since its inception until October 2023, the FEP program has admitted 200 patients, of whom 11% were diagnosed with CHR and 89% with First Episode Psychosis (of which most had a non-affective psychosis diagnosis). The majority of the sample were male (71%), mean age was 24.2 (DS 5.2), 42% reported cannabis use, 51% had been previously admitted to the inpatient unit. Average HoNOS score at admission was 17.4 (6.8) indicative of a moderate overall clinical severity.

The preliminary analysis of a portion of the sample showed an overall diagnostic instability of 28%. Indeed, within the 120 patients discharged from the program, 10% were referred to a different PDTA (e.g.. Severe Personality Disorders). Moreover, 37.5% completed the two-years program and were discharged to the community mental health service for follow-up visits while 9% were referred to the General Practitioner and 6% to a different city’s mental health service; 18% dropped out from the program.

Further analysis on diagnostic change at the time of discharge is currently being conducted along with investigations on possible demographic and clinical predictors of diagnostic instability.

Discussion: This study, by analyzing the differences in diagnosis at discharge and their predictive factors, will provide useful insights for service planning, such as implementing

scheduled case discussion, promoting the collaboration between the First Episode Psychosis PDTA and other PDTA (e.g Severe Personality Disorders), general psychiatric services and general practitioners, aimed at implementing a tailored approach to therapeutic interventions for patients with FEP.

S290. INTERHEMISPHERIC COMMUNICATION, AUDITORY PERCEPTION AND AVH: THE ROLE OF GLUTAMATERGIC NEUROTRANSMISSION

Christoph Mulert^{*1}, Saskia Steinmann², Moritz Haaf², Gregor Leicht², Stjepan Curic³

¹*Justus-Liebig University*, ²*University Medical Center Hamburg-Eppendorf*, ³*University Medical Center Hamburg*

Background: The interhemispheric miscommunication hypothesis (IMH) of auditory verbal hallucinations (AVH) is based on findings with diffusion tensor imaging (DTI), functional magnetic resonance imaging (fMRI) and electroencephalography (EEG). Moreover, recent findings link IMH findings with excitation inhibition (E/I) balance, glutamatergic and GABAergic function and especially the NMDA receptor.

Here, we were interested whether modulation at the NMDA receptor with either antagonist ketamine or the co-agonist glycine has impact on interhemispheric communication, auditory perception and AVH.

Methods: In a double-blind, randomized, placebo-controlled crossover design, 25 healthy volunteers were measured using 64-channel-electroencephalography (EEG) during a dichotic listening task (DL). Psychopathologic changes were assessed by PANSS and the 5D-ASC questionnaire. The current study examined the effects of ketamine, a NMDAR antagonist as well as glycine, a glutamate N-Methyl-D-Aspartate receptor (NMDAR)-coagonist on mechanisms underlying interhemispheric gamma-band connectivity, conscious auditory perception and AVH. Interhemispheric connectivity analysis were performed using eLORETA source estimation and lagged phase synchronization (LPS) in the gamma-band range (30–100 Hz).

Results: Ketamine induced a schizophrenia-like change in laterality of dichotic hearing that could be reversed by glycine-modulation. In addition, interhemispheric gamma-band connectivity was found to be altered both under ketamine and glycine (higher interhemispheric gamma-band connectivity). Pretreatment with glycine normalized the ketamine-induced alterations of interhemispheric connectivity. Moreover, we found a relationship between alterations of auditory perception, interhemispheric communication and the emergence of AVH in healthy subjects.

Discussion: These findings argue for an important role of glutamatergic neurotransmission for the interhemispheric communication between bilateral auditory cortices. NMDAR-modulation could help to restore E/I-imbalance causing disturbed auditory perception in schizophrenia.

S291. RATER DRIFT: REDUCING ERRANT RATINGS AND ANOMALOUS PANSS DATA IN SCHIZOPHRENIA CLINICAL TRIALS

Jenicka Engler^{*1}, Cristian Sirbu¹, Katrina Patrick¹, Cynthia McNamara¹

¹*Cronos, an IQVIA Business*

Background: Rater “drift” is the phenomenon where raters become less reliable and consistent over time which can introduce more variability and error into study data. Despite industry attention to this issue, no solution has been adopted consistently. We examined if rater surveillance and intervention could reduce the number of data inconsistencies observed in schizophrenia trials.

Methods: Four studies with comprehensive PANSS rater surveillance and intervention programs were included for analysis. Two of the studies used a single vendor for rater training and the oversight and intervention program, while the other two studies used a second vendor for rater training. We looked at pre-programmed quality flags (representing significant data anomalies from Risk-Based Data Monitoring (RBDM)) for the first five and the last five PANSS assessments for each rater as a proxy for data quality.

Results: The PANSS raters who received the rater training, oversight, and intervention from the same vendor (N=185) demonstrated a significant reduction in flags over time [$F(1,544) = 5.52, p=.02$], with one of those studies showing a nearly 30% reduction in data flags over the course of the study (M=.489 to .200 flags; Std DevFIRST 5 ASSESSMENTS=.546, Std DevLAST 5 ASSESSMENTS=.316). The other study had a smaller reduction (M=.265 to .214 flags; Std DevFIRST 5 ASSESSMENTS=.371, Std DevLAST 5 ASSESSMENTS=.525). The PANSS raters (N=361) in the two studies who received rater training from a second vendor had comparable flag rates across the studies and maintained the number of data flags over the course of the study (M=.082 to .086 flags; Std DevFIRST 5 ASSESSMENTS=.218, Std DevLAST 5 ASSESSMENTS=.196).

Discussion: Rater oversight and intervention programs may be helpful in preventing rater drift and anomalous PANSS data in schizophrenia clinical trials. Interestingly, the consistency of the vendor used across rater training and oversight and intervention programs may be an important variable that is often not considered in the literature or by sponsors, although it is logical the consistency of instruction used in rater training and in interventions with the raters over the course of the trial would matter. Limitations include future work required to examine any moderating and confounding factors (e.g., study features, rater experience, ongoing access to training materials throughout the study).

S292. RESTING-STATE EEG GAMMA-BAND SOURCE FUNCTIONAL CONNECTIVITY IN CLINICALLY REMITTED SCHIZOPHRENIA PATIENTS WITH SHORT DURATION OF DISEASE TREATED WITH FIRST- AND SECOND-GENERATION ANTIPSYCHOTICS.

Giorgio Di Lorenzo^{*1}, Tommaso B. Jannini², Antonio Carbone³, Chiara D'Amelio⁴, Carmine Gelormini⁴, Diego Cichetti⁴, Cherubino Di Lorenzo⁵, Tommaso Cassano⁶, Stefano Seri⁷

¹Laboratory of Psychophysiology and Cognitive Neuroscience, University of Rome Tor Vergata, ²Laboratory of Psychophysiology and Cognitive Neuroscience, Department of Systems Medicine, University of Rome Tor Vergata, ³Department of Physiology and Pharmacology "V. Erspamer", Sapienza University of Rome, ⁴Laboratory of Psychophysiology and Cognitive Neuroscience, Department of Systems Medicine, University of Rome Tor Vergata, ⁵Department of Medico-Surgical Sciences and Biotechnologies, Polo Pontino, Sapienza University of Rome, ⁶Department of Clinical and Experimental Medicine, University of Foggia, ⁷College of Health and Life, Wellcome Laboratory for MEG Studies, Aston Brain Centre, Aston University

Background: Alterations of synchronization in gamma-band oscillations are implicated in dysconnectivity of cortical networks observed in people affected by schizophrenia. This work aims to investigate to what extent these functional alterations may be influenced by antipsychotic treatment in the first phases of illness course.

Methods: Resting-state EEG gamma-band source functional connectivity was computed using lagged phase synchronization in clinically remitted patients with schizophrenia and a short duration of disease treated with first-generation vs. second-generation antipsychotics (FGA vs. SGA). We implemented network-based statistics (NBS) and graph theory (GT). NBS is a method to detect

functionally interconnected (functionally integrated) nodes (sources) in a graph that cluster into a single component, and which are significantly different between two groups. GT metrics provide quantification of behavior of nodes and paths (connections or edges between nodes).

Results: NBS revealed hyperconnectivity in the gamma band in the frontal regions in FGA compared to SGA. FGA had gamma band hyperconnectivity in the frontal and frontotemporal areas compared with HV. Finally, SGA also showed hyperconnectivity compared to HV but only in the frontal cortices.

Looking at the graph theory indices, FGA had higher mean values in ROI strength than SGA, but this was not significant. FGA showed higher strength values than HV although this did not exceed the significant threshold. Conversely, SGA had significantly higher strength values than HV.

Discussion: The results of the present study demonstrate that antipsychotic treatment with FGA and SGA affects gamma-band oscillation source connectivity differently in schizophrenia and should be considered when approaching interpretations of the connectivity alterations observed in people with schizophrenia in early stages of the disease.

Furthermore, this study was able to confirm that a gamma-band hyperconnectivity, mainly located in the fronto-temporo-parietal regions, is a key feature of people with schizophrenia in the early

years of the disease, and that FGA and SGA seem to influence hyperconnectivity differently in the gamma band.

S293. INCREASED MICROGLIA-MEDIATED PRUNING OF PREFRONTAL SYNAPSES IN A MOUSE MODEL OF HUMAN ENDOGENOUS RETROVIRUS EXPRESSION

Michelle Meier*¹, Felisa Herrero¹, Urs Meyer¹

¹*University of Zurich*

Background: Endogenous retroviruses (ERVs) are remnants of germline infections that took place several million years ago and represent approximately 8% of the human genome. Accumulating evidence implicates increased expression of ERVs in the spectrum of psychotic disorders, including schizophrenia and bipolar disorder. Thus far, however, the link between increased ERV expression and psychotic disorders largely remains circumstantial. To gain more mechanistic insights into the neurobiological disease pathways affected by ERVs, we

recently developed a novel mouse model that mimics the expression of the human-specific ERV type-W envelope protein (HERV-W env). Using this mouse model, we examined whether HERV-W affects microglia-mediated synaptic pruning in the prefrontal cortex (PFC) across early adolescence to adulthood. We also subjected transgenic HERV-W env and wild-type (WT) mice to cognitive testing in adolescence and adulthood with the aim to identify age-dependent cognitive phenotypes in mice expressing HERV-W.

Methods: Mice with transgenic HERV-W env expression were generated by inserting the multiple sclerosis-derived retrovirus (MSRV)-pvl4env sequence, featuring the HERV-W envelope open reading frame (ORF) and 3' long terminal repeat (3'LTR) under the CAG promoter, into the hypoxanthine-guanine phosphoribosyl transferase (HPRT) locus. Brain samples (n = 6 per genotype and age) were collected at 4, 6 and 10 weeks of age for immunohistochemical colocalization studies using the microglial marker, Iba1, and the presynaptic marker, Bassoon. We quantified the number of Bassoon+ synaptic puncta colocalizing with prefrontal microglia, which were reconstructed and surface-rendered with Imaris software. Cognitive testing was conducted at 5 and 10 weeks of age (n = 10-12 per genotype and age) and included a test for prepulse inhibition (PPI) of the acoustic startle reflex and a novel object recognition test.

Results: Compared to age-matched WT mice, HERV-W env-expressing mice displayed a significant (p LESS THAN 0.05) increase in Bassoon+ synaptic puncta colocalizing with microglia at 6 weeks of age, but not during 4 or 10 weeks of age. At 10 weeks of age, however, HERV-W env-expressing mice demonstrated a significant (p LESS THAN 0.01) overall decrease in the Bassoon immunoreactivity in the PFC. Moreover, HERV-W env-expressing mice displayed age-dependent deficits in PPI and novel object recognition memory, which were manifest at 10 but not 5 weeks of age.

Discussion: Our data provide the first line of preclinical evidence linking the expression of HERV-W to abnormal synaptic pruning in the PFC across adolescent maturation. Furthermore, our results show that HERV-W expression leads to age-dependent deficits in sensorimotor gating and short-term declarative memory for objects. These findings add to the ongoing attempts to identify the neurobiological disease pathways affected by HERV-W in relation to schizophrenia and other psychosis-related disorders.

S294. THETA POWER DIFFERENCES DURING ASSOCIATIVE INFERENCE IN SCHIZOPHRENIA

Ingrid Martin*¹, Daniel Bush¹, Rick Adams¹, Neil Burgess¹

¹UCL

Background: Previous rodent and human studies have implicated the role of dysfunction in the hippocampal-prefrontal (HPC-PFC) network in the underlying pathophysiology of Schizophrenia (SCZ). Recent neuroimaging has shown patients display a loss of prefrontal theta power and PFC-HPC theta coupling (Adams et al, 2020). However, the link between this loss of oscillatory power/coupling and specific (psychotic) symptoms is less clear. We sought to investigate whether a loss of theta power and coupling may underlie associative inference impairments in the disorder and whether this relates to level of delusion symptoms.

Methods: We recruited 25 SCZ patients and 25 controls matched on IQ, years of education, sex, and age. Participants completed an associative inference task whilst undergoing Magnetoencephalography (MEG). During the task participants viewed pairs of images for 8s with each pair drawn from 3-stimuli 'events' comprising a Person, Place, and Object

(Encoding). After a short break, participants then completed a retrieval block. During retrieval each image was presented first individually to test for recognition memory. Then participants were asked to choose from 4 options what image it was most associated with. Importantly images could be directly (seen paired together) or indirectly (not directly viewed together) associated. Participants were then asked to rate their confidence in their choice from 1 (not at all) -3 (very confident).

Results: Hypothesised results based on previous work we will investigate differences in theta power on frontal scalp sensors during the encoding period between patients and controls. Next, we will assess across all participants the relationship between strength of theta power at encoding with associative inference performance. We hypothesise that patients will display a loss of prefrontal theta power which will correlate with poorer performance on the task. We will then look for this same differences/relation to task performance in theta power during retrieval.

Discussion: These results offer insight into the underlying pathophysiology of SCZ, translating findings from prominent rodent work.

S295. THE PARADOXICAL EFFECT OF LONG-USE OF CANNABIS ON COGNITION IN CHRONIC PSYCHOTIC DISORDERS

Fiorela Gorea¹, Martina Pelle^{*2}, Fatime Elezi³, Federico Fiori Nastro⁴, Giorgio Di Lorenzo⁴

¹*“Our Lady of Good Counsel” University of Tirana, Tirana, Albania,* ²*Tor Vergata University of Rome,* ³*University Hospital Center “Mother Teresa” of Tirana,* ⁴*Department of Systems Medicine, University of Rome Tor Vergata, Rome,*

Background: Neurocognitive deficits among patients with psychotic disorders are considered one of the core features of the disorder, relevant to its course and prognosis. The cognitive areas with the highest impairment are verbal skills, memory, attention, speed of processing, and executive functions. Cannabis is one of the most popular recreational drugs used among adolescents and young adults, particularly by youth with psychosis. Although the use of cannabis has been linked to a risk of developing psychotic spectrum symptoms, the effects on the brain and cognition remain controversial.

This study aims to investigate the association between neurocognitive deficits in subjects who suffer from psychosis, with or without cannabis use.

Methods: One-hundred-five patients (mean age, 40.3±11.84; 34 women) with psychotic disorders (n=75, 71.43%) were recruited from the University Hospital Center “Mother Teresa” of Tirana between January 2022 and January 2023. All of them were, at the time, hospitalized and had a history of more than one hospitalization. Fifty-six patients (53.33%) had a comorbid current cannabis use disorder (CUD). Socio-demographic information (such as age, sex, and marital status) and clinical data (such as use of alcohol or cannabis, years with diagnosis, number of hospitalizations, heredity for mental health problems, current therapy, as well as the use of long-acting antipsychotics) were collected. Psychopathological assessment was performed through Brief Negative Symptom Scale (BNSS), Calgary Depression Scale for Schizophrenia (CDSS), Psychotic Symptom Rating Scales (PSYRATS), and Thought Language and Communication Scale (TLC). The cognition was measured with the Montreal Cognitive Assessment (MoCA). Statistical analysis was done using JASP 0.18.3.

Results: Psychotic patients with CUD were significantly more men (p=0.003), younger (p LESS THAN 0.0001), and had earlier onset of psychosis (p=0.003) than those without CUD.

Except for the BNSS “motivation-pleasure” deficit significantly higher in psychotics without CUD than with CUD ($p=0.01$), no psychopathological difference emerged between groups. MoCA scores were significantly higher in psychotic patients with CUD than those without CUD ($p < 0.0001$). After controlling for gender, age, and psychosis onset, the difference was maintained significantly.

Discussion: Several studies have investigated the association between cannabis and cognitive deficits in psychotic disorders, revealing conflicting and paradoxical results.

Firstly, our study underscores that individuals with a history of chronic illness tend to use cannabis. Secondly, among patients with psychosis, subjects with cannabis use showed better performance in MoCA compared with patients without cannabis use.

In conclusion, our study not only contributes to the growing body of knowledge on cannabis and cognition in psychotic disorders but also underscores the importance of considering individual differences and underlying factors that may influence the complex relationship between cannabis use and cognitive outcomes in this vulnerable population to better-target interventions and treatments.

S296. NEURAL SIGNATURES OF HALLUCINATION EMERGENCE IN A CLINICAL HIGH-RISK POPULATION

Raina Vin^{*1}, William Palmer¹, Rashina Seabury¹, Scott W. Woods¹, Tyrone D. Cannon¹, Albert Powers¹

¹*Yale University*

Background: Hallucinations and delusions are prominent positive symptoms of psychosis. Although fully developed forms have been studied with some success, limited research has explored the neural basis of their emergence, development and interactions over time.

Recent research suggests that delusions may arise from overly noisy bottom-up input, causing aberrant prediction-error signaling and inappropriate learning. By contrast, hallucinations have been associated with a dominance of expectations (or priors) in perception, an abnormality that tracks with symptom severity. We hypothesize that these contradictory mechanisms may be causally related in time: top-down dominance of priors may arise to compensate for pre-existing bottom-up noise. New evidence supports this: delusions reliably emerge prior to hallucinations in psychosis. If our hypothesis holds, hallucination onset should coincide with a shift from bottom-up to top-down dominant connectivity between early sensory and higher-order processing regions in individuals with delusional ideation. We present evidence supporting this hypothesis.

Methods: We analyzed resting-state fMRI data from the Clinical High-Risk for Psychosis cohort in the North American Prodrome Longitudinal Study (NAPLS) 3. Our experimental group ($n = 26$) experienced only delusions at baseline, and developed hallucinations at follow-up. The control group ($n = 26$) was matched for time elapsed and change in symptom severity but did not develop hallucinations over that time.

Using the Human Brainnetome atlas, we identified 14 subcortical and cortical regions of interest (ROIs) that have been implicated in psychosis. The ROIs were grouped into three clusters: 1) visual/auditory cortex and thalamus (bottom-up sensory processing); 2) basal ganglia, hippocampus, insula, cingulate cortex, and superior temporal gyrus (integration of

bottom-up and top-down signals); and 3) medial and dorsolateral prefrontal cortex, and the inferior frontal gyrus (higher-order processing). We then analyzed the effective connectivity between these ROIs using regression dynamic causal modeling (rDCM) informed by the Brainnetome structural connectome. The rDCM-derived posterior parameter estimates were contrasted both within-group (across time points) and between groups.

Results: In the experimental group, there was greater bottom-up connectivity from the auditory cortex to the posterior insula and from the posterior thalamus to the basal ganglia at baseline. At follow-up, this relationship switched, with stronger top-down connectivity from the posterior insula to the auditory cortex, as well as from the basal ganglia to the supramarginal gyrus.

The control group did not exhibit large differences in effective connectivity between the time points; both were characterized by strong bottom-up connectivity from the auditory cortex to the insula (and weaker top-down connectivity from higher order regions to the auditory cortex).

Between-group contrasts of connectivity changes over time showed a strengthening of top-down connectivity from the basal ganglia to the auditory cortex and supramarginal gyrus in the experimental group compared to the control group.

Discussion: The present results are consistent with the hypothesis that early delusions are associated with bottom-up signaling, while hallucinations are characterized by top-down prior hyper-precision. We plan to conduct similar analyses to uncover network interactions during the emergence of hallucinations within specific modalities (auditory, visual, etc.), which could subsequently pave the way for novel treatment development and early therapeutic intervention.

S297. UNRAVELING THE PSYCHOSIS PRECIPICE: INFLUENCE OF THE COVID-19 PANDEMIC ON PSYCHOSIS CONVERSION RATES IN AT-RISK INDIVIDUALS

Federico Fiori Nastro^{*1}, Alice Clemente², Eleonora Esposto², Martina Pelle², Lucia Longo², Michele Ribolsi³, Alberto Siracusano², Cinzia Niolu², Giorgio Di Lorenzo²

¹*Tor Vergata University of Rome*, ²*Tor Vergata University of Rome*, ³*Psychiatry Unit, Campus Bio-Medico University*

Background: The COVID-19 pandemic has induced substantial worldwide upheaval, affecting virtually every aspect of human existence. Quarantine measures and social isolation have resulted in adolescents experiencing extended physical separation from their peers and community networks. Furthermore, economic instability and the fear surrounding the virus have led to elevated levels of stress, which promotes widespread psychological effects.

The existing literature presents mixed results on the influence of the pandemic on mental health. Although depression and anxiety seem to have worsened, the findings on schizophrenia and vulnerability to psychosis are contradictory.

This study seeks to examine how the COVID-19 pandemic has affected a group of people at clinical high risk (CHR) of psychosis presenting with Attenuated Psychotic Symptoms (APS). The research aims to analyse the incidence of transition to full-blown psychosis within this population and to investigate the related psychopathological characteristics.

Methods: We longitudinally evaluated a sample of 24 young help-seekers (12 female, 50%; age 21.79, $\pm$ 3.2 SD) with APS for one year to examine the impact of the COVID-19 pandemic

on conversion rates to psychosis. The patients were enrolled in the outpatient services of Policlinico of Tor Vergata.

Prodromal Questionnaire 16 (PQ-16) and Aberrant Salience Inventory (ASI) were administered to all participants. All patients were evaluated using the Structured Interview for Prodromal Syndromes (SIPS).

The inclusion criteria were as follows:

1. mental health help-seeking request;
2. age 16 - 30 years;
3. absence of any psychosis spectrum disorder diagnosed by the Structured Clinical Interview for DSM-5 (SCID);
4. no past or current substance dependence as defined in the DSM-5 criteria;
5. APS condition, as defined by the Scale of Prodromal Symptoms (SOPS) criteria.

Patients who did not meet the psychometric criteria for a diagnosis of a current psychotic episode but had already received treatment or were undergoing treatment with an antipsychotic were subsequently excluded from the data analysis and considered to have already converted to psychosis.

Results: After the one-year follow-up, a conversion rate to full psychosis was observed at 29.17%. Student's t-test and chi-square tests were used to investigate possible variations based on age, gender, cannabis use, and urbanicity in relation to the transition to full psychosis. However, none of the findings resulted in statistically significant differences.

Discussion: The impact of the COVID-19 pandemic and subsequent quarantine measures on psychosis is still debated. In our study, we observed a higher one-year transition rate to full psychosis among CHR patients compared to before the pandemic times. Although a small sample size represents a primary limitation of our study, this finding suggests several potential explanations. Throughout the two-year pandemic period, Italy underwent stringent phases of lockdown and social distancing, which could have contributed to increased distress and potentially served as adverse prognostic factors for the transition to psychosis. Additionally, longitudinal studies are required to expand the sample size and evaluate the true impact of the COVID-19 pandemic on the transition to psychosis.

S298. DESIGN POSTER: CHALLENGE-YOUNG-PILOT: A FEASIBILITY STUDY OF VIRTUAL-REALITY ASSISTED THERAPY FOR AUDITORY HALLUCINATIONS IN YOUTH WITH PSYCHOTIC DISORDERS

Ditte Lammers Vernal*¹, Lisbeth Joergensen², Marlene Briciet Lauritsen³, Ulla Schierup Nielsen³

¹Psychiatry, Aalborg University Hospital, Department of Clinical Medicine, Aalborg University, ²Privat Practice Psychologist, ³Research Unit for Child and Adolescent Psychiatry, Aalborg University Hospital

Background: Virtual Reality-assisted Therapy (VRT) has demonstrated efficacy in treating various mental disorders. In recent years, VRT for psychotic disorders, particularly targeting paranoia and auditory hallucinations, have shown promise.

The Danish randomized controlled trial, Challenge, inspired by the UK-Avatar Trial, commenced in 2020 and concluded recruitment in the summer of 2023. The Challenge trial focused on the treatment of auditory verbal hallucinations with VRT, using software developed by Heka VR. Although trial results are still pending, positive clinical experiences have inspired further exploration of this intervention in children and adolescents with psychotic disorders. To date, VRT studies targeting children and adolescents remain an under-researched area, especially with regards to psychotic disorders. The Challenge-YOUNG-Pilot (feasibility) study is a first steppingstone, providing valuable insights and contributing to the foundation for future research in this field.

Methods: Challenge-YOUNG-Pilot, a feasibility study, draws on the technology, insights, and experiences from the adult Challenge-trial. Twelve children and adolescents diagnosed with schizophrenia spectrum disorders from the Child and Adolescent Outpatient Clinic at Aalborg University Hospital will be recruited. All participants will receive VRT consisting of 7 sessions, using the same equipment and overall techniques as in the adult trial. To cater to the younger age group, changes were made to the assessment battery, including shortening it, and adapting scales and interviews. The revised therapy manual incorporates techniques known to foster agency and engagement in children and adolescents. Baseline and follow-up interviews, along with post-therapy qualitative interviews, will assess acceptability, adaptation needs, barriers, and engagement.

Results: Currently, the study is poised to begin recruitment but awaits approval from the Ethics Medical Committees.

The Challenge-YOUNG-Pilot results will inform the design of a large national randomized controlled trial involving approximately 250 patients, considering acceptability, adaptability, sample size justification, and barriers and enhancers of recruitment and implementation in a child and adolescent outpatient setting.

Discussion: The risk-benefit ratio for antipsychotic medication is generally less favorable for children and adolescents compared to adults, with more side-effects and reduced effectiveness. Moreover, studies indicate a worse prognosis in patients with early onset, underscoring the urgent need for evidence-based non-pharmacological interventions for this target group. While VRT is still in its infancy for treating mental disorders, studies thus far are promising, reflecting a positive outlook on integrating VR technology into psychiatry. For children and adolescents, the potential benefits may be even greater, given their expected familiarity and receptiveness to new technology. Evidence-based interventions targeting auditory hallucinations in the early course of a psychotic disorder could potentially reduce the risk of chronicity and mitigate the negative effects of the hallucinations on self-esteem and agency.

S299. ANTHROPOMETRIC AND PHYSIOLOGICAL MEASURES IN INDIVIDUALS WITH AT-RISK MENTAL STATE COMPARED WITH INDIVIDUALS WITH SCHIZOPHRENIA: FINDINGS FROM A LOWER MIDDLE-INCOME COUNTRY

Muhammad Husain^{*1}, Inti Qurashi², Nusrat Husain², George Foussias¹, Imran Chaudhry³

¹University of Toronto, ²Institute of Population and Mental Health, University of Liverpool, ³Department of Psychiatry, Ziauddin University

Background: Individuals with psychosis have reduced life expectancy and this is largely driven by cardiometabolic disease. Cardiometabolic risk increases with age and duration of psychotic illness. Anthropometric and physiologic abnormalities have been identified among individuals with at-risk mental state (ARMS) for psychosis. The prevalence of cardiometabolic disease is disproportionately higher in lower middle-income countries (LMIC); however, literature on cardiometabolic disease in individuals with psychosis spectrum disorders in LMIC is scarce.

Methods: This is a cross-sectional secondary analysis of data from two large randomised controlled trials that recruited individuals with ARMS (n=326) and schizophrenia (SCZ; n=303) from inpatient and outpatient settings in Pakistan. All participants completed anthropometric and physiological assessments.

Results: There was a statistically significant difference in BMI between groups, 21.42 (SD=4.11) in ARMS and 23.31 (SD=5.41) in the SCZ group (p=0.001). Although mean values were within the normal range, 17.8% (n=58) of ARMS individuals and 33.1% (n= 100) SCZ individuals were overweight or obese. Waist circumference was 32.75in (SD=3.13) in the ARMS group and 32.16in (SD=5.18) in SCZ. Although waist circumference was higher in ARMS, this was not statistically or clinically significant. The pulse rate and blood pressure in both groups were within normal range.

Discussion: We found evidence of abnormal anthropometric and physiological parameters that would indicate that individuals with psychotic-spectrum disorders in Pakistan are at an elevated cardiometabolic risk.

S300. PREDICTING DROPOUT IN CLINICAL HIGH-RISK FOR PSYCHOSIS STUDIES: ASSOCIATION WITH RISK OF DEVELOPING PSYCHOSIS AND PERCENT OF MISSING DATA AT BASELINE

Nora Penzel^{*1}, Daniel H. Mathalon², Robert J. Glynn³, Mark Vangel¹, Anastasia Haidar³, Pablo Polosecki⁴, Johanna Seitz-Holland³, Grace R. Jacobs³, Eduardo Castro⁴, Kang Ik Kevin Cho³, Sylvain Bouix⁵, Cheryl M. Corcoran⁶, Tina Kapur³, René Kahn⁶, Martha E. Shenton³, Guillermo A. Cecchi⁴, Ofer Pasternak³

¹Massachusetts General Hospital, Harvard Medical School, ²Department of Psychiatry, University of California, San Francisco, San Francisco, United States and Psychiatry Service, ³Brigham and Women's Hospital, Harvard Medical School, ⁴IBM, Thomas J. Watson Research Center, ⁵École de technologie supérieure, ⁶Icahn School of Medicine At Mount Sinai

Background: High dropout rates in clinical high-risk for psychosis (CHR) studies pose a challenge for research and treatment. Bias may be introduced when dropout rates are linked to the clinical outcome of interest (e.g., conversion to psychosis), leading to non-representative sample populations. Therefore, evaluating whether dropout occurs at random or is linked with an outcome of interest is important for statistical modeling approaches. Identifying predictors of dropout would also be useful for sample selection for future studies/clinical trials. Here, we test whether variables predictive of conversion to psychosis are also predictive of time to

dropout. We also test whether the percent of missing data across different domains at baseline predicts time to dropout.

Methods: We analyzed 698 CHR participants from the North American Psychosis Longitudinal Study - wave 3 (NAPLS 3). Individuals were divided into three groups: 1) 229 Dropouts: defined as dropping out of the study within one year of participation, 2) 414 Remainers: defined as remaining in the study for 1 year or more, and 3) 55 Converters: defined as those who develop psychosis within 1 year. Three independent multivariable cox regressions determined whether 1) the eight variables included in the psychosis risk predictor developed in NAPLS 2 predict time to conversion 2) the same variables predict time to dropout and 3) the percent of missing data from five different domains (4 modalities of magnetic resonance imaging [MRI], electroencephalography [EEG], cortisol measurement, cognition and interview-based variables) measured at baseline predict time to dropout.

Results: The model including the 8 psychosis risk factors did significantly predict time to conversion (Wald test=33.36, $p < .001$) but did not predict time to dropout (Wald test=12.64, $p = .100$). The model including information about percent of missing variables at baseline significantly predicted time to dropout (Wald test=59.32, $p < .001$). Higher percent of missing imaging modalities of MRI (hazard ratio=2.02, 95% confidence interval=1.50-2.72, $p < .001$) and non-participation in the EEG-domain were significantly associated with time to dropout (hazard ratio=2.38 $p < .001$, 95% confidence interval=1.62-3.48, $p < .001$).

Discussion: This study assessed whether variables associated with the development of psychosis or percent of missing variables at baseline can predict time to dropout in CHR individuals. While prediction based on variables associated with psychosis risk was not significant in predicting the time to dropout, percent of missing variables at baseline significantly predicted time to dropout. Our findings suggest that dropout might not be linked with the risk of conversion to psychosis, which is the primary clinical outcome of many CHR studies. Further, our study finds that participants who do not participate in all domains at baseline are also more likely to dropout. Future studies are encouraged to identify participants with missing assessments to apply strategies to keep these subjects in the study. However, it remains to be tested whether this pattern generalizes to other CHR studies.

S301. AUTISM DEVELOPMENTAL VULNERABILITY TO UNUSUAL EXPERIENCES AS A RESPONSE TO STRESSFUL EVENTS: THE ADVERSE STUDY

Riccardo Bortoletto^{*1}, Marco Garzitto¹, Marco Lamberti², Lorenzo Bassani², Donatella Arcangeli², Carla Comacchio¹, Matteo Balestrieri¹, Marco Colizzi¹

¹*Unit of Psychiatry, Department of Medicine (DMED), University of Udine,* ²*Department of Child and Adolescent Psychiatry, Hospital of Merano (SABES-ASDAA), Teaching Hospital of the Paracelsus Medizinischen Privatuniversität (PMU)*

Background: Accumulating research converges towards the evidence that psychosocial stressors can trigger psychotic episodes among individuals with pre-existing psychosis as well as in otherwise healthy subjects. Interestingly, autistic individuals were found to experience more childhood adversities (CAs) over the course of their lives (e.g., family poverty, sexual abuse, parental illness, parental alcoholism, and parental divorce) compared with neurotypical peers. This study aims at examining the impact of CAs on the occurrence of psychotic episodes

in adolescents with autism spectrum disorder (ASD) in-patiently admitted to a tertiary hospital Child and Adolescent Psychiatry ward.

Methods: Sixty-nine hospitalized ASD adolescents presenting with psychotic/manic symptoms (PSY) and other mental health issues (NPSY) were studied over a nine-year period (from May 2013 to May 2022). ASD diagnoses were based on International Statistical Classification of Diseases and Related Problems (ICD)-10 criteria, and psychotic/manic symptoms were assessed using the Kiddie Schedule for Affective Disorders and Schizophrenia (K-SADS). Sociodemographic and clinical data were retrospectively retrieved from electronic and paper clinical records of all consecutive autistic adolescents in-patiently admitted to the ward. CAs exposure was assessed independently during each admission and coded according to the multi-axial ICD-10 system. Initially, univariate comparisons between groups were performed. Subsequently, a binomial model was employed to explore associations with prior exposure to psychosocial stressors, with results presented in terms of change in Akaike Information Criterion (Δ AIC).

Results: PSY patients had a higher prevalence of exposure to adverse life events (30.43% vs. 6.52%, OR = 6.079 [1.209, 40.926], $p = 0.013$) and school/work difficulties (30.43% vs. 8.70%, OR = 4.478 [0.984, 23.846], $p = 0.034$) compared to NPSY patients. Admissions for psychotic/manic symptoms (PSY-h) were more likely to occur in the context of family disturbances (OR = 2.275 [1.045, 5.045], $p = 0.030$) and adverse life events (OR = 3.489 [1.194, 11.161], $p = 0.014$). The fitted binomial model was significant compared to the random effects model (Δ AIC = -1.962; $\chi^2_{10} = 21.96$, $p = 0.015$) and highlighted the significant impact of family disturbances ($z = +4.118$) and school/work difficulties ($z = +2.455$) on the risk of psychotic/manic symptoms in ASD adolescents.

Discussion: These findings underscore the importance of addressing psychosocial stressors in clinical and policy interventions for individuals with ASD. This seems of the utmost importance when autistic adolescents have experienced disability and/or psychiatric disturbances within their families and conflicts with peers, as these stressful events could potentially precipitate the developmental path from ASD to psychosis.

S302. THE ABERRANT CORTICAL FOLDING PATTERN: VERTEX-WISE ANALYSIS OF LOCAL GYRIFICATION INDEX USING T1-WEIGHTED MAGNETIC RESONANCE IMAGING

Inkyung Park^{*1}, Minah Kim², Minji Ha³, Dan Stein⁴, Odile van den Heuvel⁵, Paul Thompson⁶, Jun Soo Kwon²

¹Seoul National University College of Natural Sciences, ²Department of Psychiatry, Seoul National University College of Medicine, Department of Brain and Cognitive Sciences, Seoul National University, ³Department of Brain and Cognitive Sciences, Seoul National University College of Natural Sciences, ⁴SAMRC Unit on Risk and Resilience in Mental Disorders, Dept. of Psychiatry and Neuroscience Institute, University of Cape Town, ⁵Department of Psychiatry, VU University Medical Center, Amsterdam, The Netherlands, ⁶Imaging Genetics Center, Mark and Mary Stevens Neuroimaging and Informatics Institute, Keck School of Medicine, University of Southern California

Background: Schizophrenia and obsessive-compulsive disorder (OCD), both recognized as neurodevelopmental disorders, share numerous phenotypical and clinical characteristics. Indeed, numerous neuroimaging studies have underscored a considerable overlap in the

underlying neurobiological mechanisms of these conditions. However, it remains unclear whether there are common neurodevelopmental risks between the two disorders, underscoring the importance of investigating cortical gyrification in relation to the neurodevelopmental abnormalities shared in both schizophrenia and OCD. Cortical folding is primarily determined during the embryonic and early postnatal developmental period and maintains its pattern relatively stable over the lifespan, serving as a reliable neurobiological marker for early neurodevelopmental deficits. In this study, as part of an integrated series of research, the presence of gyrification abnormalities was examined in the OCD group.

Methods: The local Gyrification Index (LGI) was computed at each vertex to analyze whole-brain gyrification using T1-weighted magnetic resonance imaging in a total of 2611 OCD patients and 2723 HCs, collected from 32 sites (52 datasets) worldwide as part of the ENIGMA Working Group. Whole-brain LGI data were harmonized using ComBat to account for site and scanner effects within a mega-analysis framework. The vertex-wise LGI group comparisons were conducted between the patients with OCD and healthy controls (HCs) using a general linear model implemented in Freesurfer while controlling for age and sex.

Results: Both adult and pediatric patients with OCD exhibited significantly increased gyrification compared to the HCs in bilateral fronto-parietal, temporal, and cingulate regions including caudal middle frontal, precentral, postcentral, lateral orbitofrontal, superior frontal, supramarginal, inferior parietal, middle temporal, as well as posterior cingulate gyri. Furthermore, hypergyrification in the fronto-parietal clusters was significantly correlated with an earlier age of onset in pediatric OCD, even after correction for multiple comparisons.

Discussion: Our findings provided evidence that the early neurodevelopmental abnormalities exist in both adult and pediatric OCD patients. Particularly, hypergyrification observed in those pediatric cases near their illness onset, may serve as a biomarker for neurodevelopmental deficits that are present prior to the onset of the disorder. These findings may also enhance the understanding of the neurodevelopmental origins contributing to the shared etiology of schizophrenia and OCD, aligning with the existing evidence suggesting that both schizophrenia and OCD are neurodevelopmental disorders. This could further help categorize patients with psychiatric disorders into more neurodevelopmentally homogeneous subtypes.

S303. SEMANTIC SIMILARITY USING BERT MODELS AND PANSS CORRELATIONS

Mara Fennema^{*1}, Janna de Boer¹, Marieke van Vugt², Iris Sommer¹

¹University Medical Center Groningen, ²University of Groningen

Background: Natural Language Processing (NLP) techniques are increasingly used in schizophrenia research in an attempt to capture semantic similarity in language. Although these methods have been shown to be successful at separating patients with an (emerging) schizophrenia spectrum disorder from healthy controls, it is still unclear to what extent these measures reflect psychotic symptoms. Therefore, this study aims to analyse the relationship between psychotic symptoms and NLP semantic similarity measures in a large sample of Dutch speaking patients with a schizophrenia spectrum disorder.

Methods: Our data sample consists of speech recordings by 161 patients with a schizophrenia spectrum disorder. All participants took part in a 5-10 min semi-structured interview on neutral topics while their speech was recorded. Our sample consisted of 161 patients, all of whom diagnosed with schizophrenia spectrum disorder. Speech samples were cut at 120 seconds for analyses. Whisper was used for automated transcription. Vector representations per sentence

in each recording were calculated using a Dutch language sentence-based BERT model. The cosine similarity score was calculated between each sentence's vector representation and every other sentence in the transcription. The mean similarity score, the variance within the similarity scores and the minimum and maximum score present per transcription were then calculated. Associations between PANSS and semantic similarity measures were assessed using Spearman's correlation, and corrected for multiple comparisons with a False Discovery Rate.

Results: Of these 161 patients, 115 were cis-male and 46 were cis-female, and 1 patient was trans-male, with an average age of 31.2 (STD=11.7). The mean PANSS Total Score was 41.1 (STD 11.6). The total Negative subscore of the PANSS was significantly associated with the maximum similarity ($R=0.26$, adjusted $p=0.01$). Follow-up testing showed that N1, Blunted Effect, was also significantly associated with the maximum similarity ($R=0.20$, adjusted $p=0.04$), as were N3, Poor Rapport, ($R=0.19$, adjusted $p=0.02$) and N6, Lack of Spontaneity, ($R=0.30$, adjusted $p=0.0006$). None of the other tests resulted in a statistically significant correlation after correction for multiple comparisons.

Discussion: This study shows that negative psychotic symptoms are associated with the maximum cosine similarity. This implies that patients with more severe negative psychotic symptoms could be more likely to use multiple sentences to convey very similar information. Additionally, a significant positive association between the maximum similarity score and Blunted Effect, Poor Rapport and Lack of Spontaneity were found. This suggests that sentences spoken by patients that scored high on these PANSS subscores were more semantically similar than those of patients who scored lower on these PANSS subscores. Further research is needed to explore more in depth the correlation between semantic similarity in speech and psychosis symptoms.

S304. DETECTING PUTATIVE PSYCHOSIS-RISK SYMPTOMS WITH THE YOUTH EXPERIENCES AND HEALTH (YEAH) QUESTIONNAIRE

Sebastian Therman*¹, Majja Lindgren¹, Tommi Tolmunen²

¹*Finnish Institute for Health and Welfare*, ²*North Savo Welfare District*

Background: Two-stage screening with questionnaires and structured interviews has been proposed as a solution to make psychosis risk screening more effective, but current dedicated questionnaires have low accuracy, especially among adolescents.

Methods: Based on a literature review, a new 39-item Youth Experiences and Health (YEAH) questionnaire was constructed by combining individual questionnaire items proven to either predict psychosis prospectively or to be strongly associated with concurrent psychosis risk status assessed with gold-standard interviews. A seven-point frequency response scale with specific anchors (daily, weekly, etc.) was chosen to maximize measurement precision. The YEAH was filled in by 752 patients (ages 13–18) entering adolescent outpatient care and analyzed with exploratory categorical factor analysis using the WLSMV estimator and oblique Varimax rotation. Rank order correlations between factor scores and results from various established mental health self-report scales were investigated.

Results: The response category “Continuously” was very infrequently used and was therefore combined with the next category “Several times per day” in the analyses. A four-factor model had good fit (CFI .97, RMSEA .04, SRMR .03), few cross-loadings, and was clearly interpretable as consisting of Delusions, Hallucinations, Negative Symptoms, and Dissociation, with approximately equal numbers of items.

Delusions were most strongly correlated with self-reported depression (.58), mental well-being (-.50), social phobia (.47), anxiety (.47), loneliness (.40), childhood adversity (.39), internet dependency (.34), insomnia (.34), and school bullying (.33). Hallucinations were mainly associated with anxiety (.27). Negative Symptoms were most strongly correlated with depression (.66), mental well-being (-.57), insomnia (.46), anxiety (.47), social phobia (.40), resilience (-.40), and loneliness (.36). Dissociation was associated with depression (.39), loneliness (.38), mental well-being (-.35), anxiety (.34), internet dependency (.29), and childhood adversity (.27).

Discussion: The novel YEAH questionnaire was informative and well-received in adolescent psychiatric care, a setting where screening for psychotic-like and putative psychosis-risk symptoms may improve detection and help direct interviewing resources. The meaningful differential correlations with other measures supported the interpretation of the factors. The cohort will be followed in comprehensive registers to assess diagnostic test accuracy.

S305. REDUCED OFFLINE MEMORY CONSOLIDATION DURING BRIEF REST PERIODS IN SCHIZOPHRENIA

Dimitrios Mylonas¹, Bailey Driscoll¹, Martin Sjogard¹, Bryan Baxter¹, Robert Stickgold², Dara Manoach*¹

¹*Massachusetts General Hospital*, ²*Harvard Medical School, Beth Israel Deaconess Medical Center*

Background: Research on the role of the hippocampus in memory has generally focused on active learning. But to understand memory, it is at least as important to study learning that happens offline, during both wake and sleep. During active learning, hippocampal firing represents ongoing experience. During the wakeful rest and sleep that follows, the hippocampus replays this pattern of firing during sharp wave ripples, which predict memory improvement. Schizophrenia is characterized by hippocampal abnormalities, including a selective loss of inhibitory interneurons that modulate ripple generation. Abnormal ripples may give rise to the impairments of sleep-dependent memory consolidation seen in schizophrenia. Here we tested the hypothesis that a disruption of ripple-related memory replay also gives rise to impairments in offline learning during wake.

Methods: We used the finger tapping Motor Sequence Task (MST) to probe motor procedural memory. Even though a functional hippocampus is not necessary to learn the MST during training, it is necessary for its offline consolidation during both sleep (Schapiro et al., 2019) and wake (Mylonas et al., 2024). People with schizophrenia (PWS) show intact total learning during MST training but fail to show significant sleep-dependent consolidation (Manoach et al., 2004). To look for a corresponding deficit of offline learning during wake, we divided total learning during training, measured as gains in typing speed, into its Online (during task execution) and Offline (across interleaved 30 s breaks) components.

Results: As expected, PWS (n=41, age 34+/-8, 32M) and demographically matched controls (n=44, age 32+/-7, 33M) did not differ in total MST learning ($F(1,81)=0.50$, $p=.50$), but differed in the pattern of performance improvement (Group X Condition: $F(1,164)=6.54$, $p=.01$). Both groups improved primarily offline, across the rest breaks, but PWS showed reduced offline improvement and higher online gains than controls.

Discussion: Despite intact overall learning of a motor task during training, PWS learned differently than their healthy peers. They show reduced offline learning during wake, which together with their deficit in sleep-dependent memory consolidation, is consistent with the hypothesis of a disruption of hippocampal ripple-related memory replay. Further support for this hypothesis comes from magnetoencephalography findings of reduced memory replay in the context of increased hippocampal ripple power in PWS and a mouse model of schizophrenia that shows increased ripples accompanied by a breakdown of memory replay during awake rest periods. This study adds to the literature showing reduced sleep-dependent memory in schizophrenia by establishing a corollary deficit in offline learning during wake. Deficits in both types of offline learning implicate the hippocampus and can serve as outcome measures in clinical trials of interventions to improve memory in schizophrenia.

S306. EXPLORING THE IMPACT OF ONLINE YOGA ON OUTCOME AND NEGATIVE SYMPTOMS IN PEOPLE WITH PSYCHOSIS

Michael Bodnar*¹

¹*The Royal's IMHR*

Background: Psychosis impacts ~3% of Canadians at any one time. The gold standard for care includes antipsychotics along with therapeutic support. In an ever-changing world, E-mental health, composed of therapy via secure online platforms, web-based self-management and internet forums, is now an option providing support and improving mental health care via increase accessibility. But with these advances, the negative symptoms still remain an unmet need for care. Yoga is a complementary and alternative medicine (CAM) encompassing health modalities of Eastern cultures that involves breathing techniques, relaxation, and bodily postures. Yoga has been found to improve levels of depression and quality of life, and even attenuate negative symptoms. Given the extensive health care expenditures and unmet care needs for negative symptoms, there is a growing need to consider CAMs, such as yoga, and accessibility of CAMs via online methods.

Methods: This pilot study explored the effect of an 8-week (i.e., 8 session) online yoga and mindfulness program on outcome, with a focus on negative symptoms, in people with psychosis. We recruited 10 people with psychosis (yoga=4) and 12 non-clinical people (yoga=6), randomly assigned to each group. Mindfulness is yoga without the physical aspect (i.e., poses). We hypothesized that people in the yoga group would show lower total scores on the CORE10 and people with psychosis would show an attenuation of symptom severity, with a larger effect on negative symptoms. Behavioural data for the CORE10, PANSS-8, and SNS (self-report negative symptom scale) were collected at Baseline, Week 4, and at Week 8; an instructor was present for 4 of the 8 sessions. All sessions were pre-recorded and accessible to the participants at any time.

Results: People with psychosis showed a strong response to the 8-week program as indicated by a large decrease in the CORE10 (Baseline=15.7 vs. Week8=9.8) and PANSS-8 (Baseline=21.6 vs. Week8=15.8). Of note, those in the yoga group showed a significant decrease in the CORE10 (Baseline=15.0 vs. Week8=6.5), SNS (Baseline=20.5 vs. Week8=14.0), and PANSS-8 (Baseline=19.0 vs. Week8=13.0); the mindfulness group did not show the same decrease. Of note, this study was hampered by low recruitment and high drop-out.

Discussion: Online-yoga may prove to be a highly accessible and cost-effective modality for care, with an added benefit for improving negative symptoms. It may prove to be a critical care

option for both mental health care providers and for those with psychosis who cannot readily access care and for those with predominant negative symptoms.

S307. SEXUAL ORIENTATION AND ILLNESS EXPRESSION IN FIRST-EPISODE SCHIZOPHRENIA SPECTRUM DISORDERS

Hilmar Luckhoff¹, Anna Margaretha Smit¹, Elisabetta C. del Re², Sanja Kilian¹, Lebogang Phahladira¹, Robin Emsley¹, Laila Asmal*¹

¹*University of Stellenbosch*, ²*Harvard Medical School, Veterans Affairs Boston Healthcare System, Brockton Division and Psychiatry Neuroimaging Laboratory, Brigham and Women's Hospital, Harvard Medical School*

Background: Sexual minorities with schizophrenia face discrimination at the intersection of both marginalised identities. Sexual minorities are also at increased risk of psychosis which may be linked to childhood trauma, social adversities and substance use. Sexual orientation might also influence the clinical expression and severity of schizophrenia. No studies have comprehensively examined the association between sexual orientation, and illness expression in people with first episode schizophrenia (FES). Our aim was to examine the associations of sexual orientation with neurodevelopmental compromise and illness presentation in patients with FES compared to matched controls Hypothesis: Higher orientation as lesbian, gay, or bisexual is associated with more severe illness in patients with FES.

Methods: Our sample comprised 77 patients (56 males, 21 females) with FES compared to 64 matched controls. Self-reported sexual attraction and self-identified sexual orientation were measured using the Sexual Orientation and Identity Scale (SOIS). Neurodevelopmental risk markers of interest were schizophrenia family history, obstetric complications, childhood trauma, premorbid functioning, cognition, neurological soft signs, and cannabis use. Clinical measures of interest were psychopathology, depression, insight, functioning, and quality of life. Sexual orientation profiles were compared between cases and controls. Stepwise linear regression models were used to determine predictors of sexual orientation in patients.

Results: FES patients and controls were balanced for age, sex, ethnic background, and cannabis use Sexual orientation profiles were similar in FES patients compared to controls. Higher self-identified LGB orientation was associated with emotional neglect during childhood ($p=0.016$), poorer premorbid functioning during late adolescence (0.010), poorer insight into the need for treatment ($p=0.015$), and worse quality of life ($p=0.012$) Lower self-identified heterosexual orientation was associated with more severe experiential negative symptoms ($p=0.024$) and sensory integration deficits ($p=0.02$)

Discussion: Self-identified sexual orientation may influence illness expression in FES. In sexual minorities with schizophrenia, emotional neglect during childhood may contribute to poor premorbid functioning during adolescence, potentially increasing the risk for substance abuse and more severe psychopathology. Our finding of an association between lower heterosexual orientation and more severe symptoms is consistent with the theory that sexual orientation can become “less defined” in acute schizophrenia. We also propose that patients with more pronounced negative psychopathology and sensory integration deficits have diminished capacities for the self-attribution and expression of their sexuality, as part of a deficit-type presentation. Limitations include a cross-sectional design and the use of a single instrument to measure sexual orientation. Further prospective studies are needed to examine

biological and behavioural factors from childhood through adulthood to observe how these are related to the development of schizophrenia in sexual minorities.

S308. THE EXISTENCE OF A GRADIENT FOR ABERRANT SALIENCE IN SCHIZOPHRENIA

Yinan Li^{*1}, Oishi Naoya¹, Qi Dai¹, Yukako Nakagami¹, Yuko Nakamura², Shinsuke Koike², Toshiya Murai¹, Jun Miyata³

¹Kyoto University, ²University of Tokyo Institute for Diversity and Adaptation of Human Mind (UTIDAHM), ³Aichi Medical University

Background: Schizophrenia spectrum disorder, a prevalent psychiatric condition, is characterized by positive symptoms, such as hallucinations and delusions. Studies in non-human primates have demonstrated a salience gradient in the midbrain-striatum circuitry, shedding light on the role of these altered circuits and their potential contribution to the development of hallucinations or delusions. However, the precise relationship between aberrant salience and the development of delusions and/or hallucinations remains unclear, as no clear salience gradient has been identified in the human midbrain-striatum.

Methods: To address this, we conducted a study using resting-state functional magnetic resonance imaging (rsfMRI) on 124 patients with schizophrenia (SCZ) and 239 healthy controls (HC). We extracted the mean time series data from six striatal subregions and calculated their voxel-based correlations within a mask consisting of the ventral tegmental area (VTA) and substantia nigra (SN). Permutation-based non-parametric inference was performed using PALM in FSL. One-sample t-test, Group comparison, and correlation with the Aberrant Salience Inventory (ASI) were performed. Additionally, we also examined the interaction between the diagnosis and 3 factors of the ASI in the functional connectivity of midbrain-striatum circuit.

Results: Our results revealed a significant positive correlation ($p=0.03$, family-wise error [FWE] corrected) between the left ventral striatum and the ventral midbrain in terms of functional connectivity across the entire group. SCZ showed reduced connectivity between the ventral striatum and the ventromedial part of the VTA-SN mask, and increased connectivity between the right caudal striatum and the dorsolateral part of the VTA-SN, compared to HC ($p=0.02$ and $p=0.04$, FWE adjusted, respectively). While ASI scores varied significantly between groups ($p=0.04$, Welch's T-test), no potential association was found between these scores and midbrain-striatum connectivity in patients. However, an interaction was observed between diagnosis and Factor 3 (Sharpening of Senses) scores of the ASI in relation to connectivity between the midbrain and the left caudal striatum ($p=0.04$, FWE adjusted).

Discussion: These findings underscore a pattern of functional dysconnectivity within the midbrain-striatum circuit, supporting the idea that abnormal connectivity is a key feature of schizophrenia. While the interaction between the diagnosis and Factor 3 (Sharpening of Senses) of the ASI was significantly found in the midbrain-striatum connectivity, the lack of correlation between ASI scores and connectivity challenges assumptions in previous studies about their direct associations. It's crucial to consider factors such as sample size, antipsychotic use, and disease duration. In conclusion, our study elucidates midbrain-striatal dysconnectivity in schizophrenia and highlights the complexity of associations between abnormal salience and the pathophysiology of schizophrenia.

S309. MULTIMODAL NORMATIVE MODELLING IN ANTIPSYCHOTIC MEDIATION-NAÏVE FIRST EPISODE PSYCHOSIS PATIENTS

Rhea Thukral*¹, Natalie Remiszewski², Jose Maximo³, Adrienne Lahti², Saige Rutherford⁴, Andre Marquand⁴, Nina Kraguljac¹

¹The Ohio State University, ²University of Alabama at Birmingham, ³University of Alabama At Birmingham, ⁴Donders Centre for Cognitive Neuroimaging, Donders Institute for Brain, Cognition and Behavior, Radboud University

Background: Given the known clinical heterogeneity in psychosis spectrum disorders, it has become increasingly important to map these individual differences to establish a better understanding of psychosis spectrum disorders. To this end, normative modeling ('brain growth charting'), a novel analytical technique, has been established to understand variations in brain structure and function at the individual level (Rutherford et al., 2022). This method allows us to characterize the extent of the individual-level heterogeneity present in patients with psychosis.

Most research on the structural and functional distinctions among people with psychosis have been done, primarily, independently. However, if we are to understand psychosis on a more comprehensive basis, it is important to understand structural and functional abnormalities in context of each other.

Methods: We analyzed structural data from 114 antipsychotic, medication-naïve first-episode psychosis patients and 113 matched controls and resting-state functional connectivity data from 117 patients and 125 matched controls. Cortical thickness and functional network connectivity were assessed for each patient using the Destrieux and Yeo-17 parcellations, respectively. The PCN toolkit was used as a normative reference model to determine the number of deviations (± 2 standard deviations) in patients for cortical thickness and functional connectivity. Positive and negative deviations were determined for both modalities using a z-score threshold of +2 and -2, respectively. Patients were then sorted into one of 4 groups (no significant deviations, primarily positive, primarily negative, and a mix) using a false discovery rate significance threshold of 0.05.

Patients included in both analyses were then combined to compare the deviation loads between imaging modalities resulting in a total of 108 patients included in this analysis.

Results: χ^2 analysis was conducted on the combined groups ($p = 0.038$). Overall 23 out of the 108 patients included remained within the same group across modalities. A correlation was found between the three deviation load ratings across modalities when the patients who changed groups were separated from the patients who remained in the same group. In the group of patients who changed groups, the absolute, positive, and negative deviation loads across modalities were all found to be negatively correlated after Benajmini-Hochberg corrections (Absolute: $r = 0.22$, $p = 0.04$; Positive: $r = -0.28$, $p = 0.01$; Negative: $r = -0.28$, $p = 0.01$). Furthermore, the patients who stayed in the same group were also found to have significant correlations between the modalities and their deviation loads (Absolute: $r = 0.56$, $p < 0.01$; Positive: $r = 0.49$, $p = 0.02$; Negative: $r = 0.42$, $p = 0.04$).

Discussion: This data suggests that a significant degree of individual-level heterogeneity is present across modalities, and that there is a relationship between structural and functional pathology in patients suffering from a psychosis spectrum disorder.

These findings suggest that normative modeling is a promising method to relate different imaging modalities and create a holistic patient profile. This holds great promise for precision psychiatry, where inferences are made at the individual level.

S310. ELUCIDATING THE POTENTIAL ROLE OF OBSTETRIC COMPLICATIONS ON PSYCHOPATHOLOGY IN SCHIZOPHRENIA: A SYSTEMATIC REVIEW AND META-ANALYSIS

Neurosciences Institute. Hospital Clinic of Barcelona. CIBERSAM, IDIBAPS

Background: Schizophrenia (SZ) is a complex and systemic brain disorder characterized by a myriad of symptomatology, such as positive, negative and cognitive, associated with functional and neuro-structural abnormalities. Its aetiology comprehends a gene, epigenetic, plus environment interaction (1,2). Among the latter, obstetric complications (OCs) have been widely considered key contributors to psychosis risk, but how OCs relate to different clinical phenotypes still remains unclear (3,4,5).

Aims: 1) to review and describe the potential association of OCs with clinical symptomatology in SZ patients, and 2) to analyse whether SZ patients with OCs present a specific clinical profile worsening in comparison to those patients without OCs.

Methods: A systematic review and meta-analysis describing clinical psychopathology and OCs in patients with SZ and related disorders were conducted. It was registered on PROSPERO (CRD42022316655). PubMed/MEDLINE, PsychINFO, and Scopus were systematically searched to identify eligible studies up to November 8, 2023.

Meta-analyses were conducted using a random-effect model, using RStudio version 4.1.2. Standardized mean differences (SMD) with their confidence intervals (CI) were used as effect sizes and represented by Hedge's *g*. Homogeneity was assessed using the Q-statistic (χ^2).

Results: A total of 4,088 records were retrieved. After duplicate removal 2,683 studies were screened. Among these, 2,597 were excluded at the title/abstract level and 75 after the full-text evaluation. Finally, 13 studies were included, 12 of them provided enough data to perform a meta-analysis.

SZ patients with positive lifetime history of OCs presented higher total scores at psychotic symptoms scales (SMD=0.44, 95%CI=0.24, 0.64; p -value=1.45e-05) when compared to patients without history of OCs. When looking at different subscales, the first showed higher scores at positive (SMD=0.10, 95%CI=0.01, 0.20; p -value=0.03) and general (SMD=0.37, 95%CI=0.22, 0.52; p -value=1.29e-06) symptoms scales. No differences were found between the two groups in terms of negative symptoms scales (SMD=0.19, 95%CI=-0.01, 0.38; p -value=0.05). SZ patients with OCs also presented worse depressive symptoms (SMD=0.47, 95%CI=0.09, 0.84; p -value=0.01). No differences were found between the two groups in terms of functioning (SMD=-0.01, 95%CI=-0.35, 0.34; p -value=0.95).

Discussion: OCs appear to have an impact on specific clinical profiles in SZ patients. Specifically, in comparison to patients without OCs, those with OCs presented greater severity in positive, depressive, and general symptomatology, but not in the negative and functional outcomes. Our findings suggest the sociosanitary need to detect OCs in SZ samples and in early stages of the illness, such as first-episode psychoses.

Future studies should have into consideration the timing and type of the obstetric complication during the perinatal period in order to better understand its potential impact on the clinical presentation in the early stages of schizophrenia. This could help to better understand its association on long-term clinical and functional outcomes, reflecting the need for earlier and personalised interventions.

S311. SEX-SPECIFIC IMPACT OF PERIPUBERTAL STRESSORS ON THE ACTIVITY OF THE THALAMIC RETICULAR AND REUNIENS NUCLEUS IN RATS

Daniela Uliana^{*1}, Anthony Grace¹

¹*University of Pittsburgh Dept. of Neuroscience*

Background: Stress is a socio-environmental risk factor for schizophrenia with the age of exposure potentially determining the outcome. Early life adversity has a significant impact on the development of neuropathological states with males and females having different vulnerability periods. Males rats are sensitive to peripuberty stress (PeriP; postnatal days, PD31-40) and females to postpubertal stress (PostP; PD41-50) in inducing adult hyperdopaminergic state and deficits in cognition. The neurobiological mechanisms contributing to sex-specific stress susceptibility remain understudied. We explore the

involvement of the nucleus reuniens of thalamus (RE) and thalamic reticular nucleus (TRN) in the observed differences, as these regions are linked to dopaminergic activity and cognitive regulation. TRN has extensive expression of parvalbumin (PV) interneurons and their perineuronal nets (PNN) which is implicated in thalamic relay neuron inhibition. Here we investigated the impact of PeriP and PostP stress on adult RE activity, TRN gamma oscillations, and PV/PNN staining.

Methods: Male and female Sprague-Dawley rats were subjected to footshock/restraint stress during PeriP (PD31-40) and PostP (PD41-50). The rats were tested for single-unit extracellular electrophysiology recording of RE neurons 5-6 weeks after stress (PeriP, PD75-82; PostP, PD85-92). Independent groups of animals were subjected or not to stress and recorded in the TRN for local field potentials at PD31, PD41, PD51, and PD75 for PeriP stress and at PD41, PD51, PD61, and PD85 for PostP stress. Low (30-50Hz) and high (60-120Hz) gamma were analyzed. Posterior immunohistochemistry assessed PV/PNN content one week after PostP stress (PD61). All procedures were conducted in compliance with the NIH Guide for the Care and Use of Laboratory Animals and were approved by the Institutional Animal Care and Use Committee at the University of Pittsburgh.

Results: Sex differences were observed with males having more active RE neurons at baseline (PeriP, $F_{1,20}=21.56$, $p < 0.05$; PostP, $F_{1,36}=5.28$, $p < 0.05$; ANOVA). PostP stress increased the number of active RE neurons only in females after 5-6 weeks of stress ($n=6$; Sex-Stress, $F_{1,36}=16.74$, $p < 0.05$, ANOVA) with no effect of PeriP stress on either sex ($n=8-12$). PeriP stress increased low gamma power only in females ($n=5-9$) at PD51 ($F_{1,35}=5.48$, $p < 0.05$, ANOVA) and PostP stress ($n=3-8$) increased low gamma at PD51 (Stress-age interaction, $F_{2,29}=6.10$, $p < 0.05$, ANOVA). High gamma was not changed in females after PeriP and PostP stress. No effect was observed in males for all time points (PeriP, $n=6-7$; PostP, $n=3-7$). For PV/PNN staining, PostP stress decreased the number of PV in the TRN at PD61 only in females ($n=2-9$; sex-stress interaction, $F_{1,16}=7.53$, $p < 0.05$, ANOVA). Females were found to have more PV+ interneurons than males (sex, $F_{1,16}=5.94$, $p < 0.05$, ANOVA).

Discussion: Females exhibit sensitivity to PostP stress, potentially mediated by RE and TRN activity. PostP stress increased the adult RE activity, increased low and high gamma immediately after stress, and decreased PV+ cells one week after stress. Stress affects PV-TRN transmission during PostP stress, leading to impaired PV content and disrupted inhibitory drive to RE, resulting in increased RE activity. TRN gamma oscillations and RE activity were unaffected by PeriP or PostP stress, suggesting that they do not underlie male vulnerability. Therefore, TRN and RE seem to be involved in the sex-dependent neurobiological circuit disruption underlying early-life stress vulnerability, especially in females.

S312. A SYSTEMATIC REVIEW AND META-ANALYSIS OF THE IMPACT OF COMMUNITY-BASED INTERVENTIONS FOR IMPROVING MENTAL HEALTH OUTCOMES IN DEPRIVED NEIGHBOURHOODS

Sheri Oduola*¹, Charlottee Humphreys¹

¹*University of East Anglia*

Background: Residents of deprived areas face inequalities in their mental health and access to treatment. Many of the stressors these residents face often lie outside the remit of mental health services. Health policy in England, UK has highlighted the importance of community engagement to ensure sustainable gains in health at the population level, e.g., community-based

interventions which attempt to situate treatment in a person's social context. Previous reviews examined the impact of community-based interventions on marginalized groups facing similar challenges to deprived area residents. This review considers the impact of community-based interventions on mental health specifically in deprived areas.

Methods: This review included a narrative synthesis of 26 studies and meta-analyses of six eligible studies. A harvest plot approach to narrative synthesis based on the direction of change and not statistical significance was taken as this is suited to combining research with different study designs and outcomes. Two meta-analyses were completed - one on eligible papers with all mental health outcomes and another on interventions using postnatal depression measures.

Results: 7 categories of community-based interventions were identified in this review, with mixed findings found for their impact. Meta-analysis showed a significant difference in mental health outcomes, favouring the control group (Hedge's $g = 0.12$, 95% CI 0.04 to 0.19, $p < 0.005$). Training-based interventions (e.g. exercise consultation and parenting training courses), shorter interventions, and those with fewer components appeared most promising. Interventions targeting post-natal depression showed more promise than general mental health interventions in new mothers. No interventions focused on the mental health outcomes of residents with severe mental illness were identified.

Discussion: More high-quality randomised trials are needed to build confidence in community-based interventions. Shorter, skills-based, single-component interventions seem most promising for residents who can participate. However, interventions must be accessible to deprived areas, where engagement barriers may be higher.

S313. AN EXPLORATORY STUDY OF THE RELATIONSHIP BETWEEN PREMATURE TERMINATION OF MENTAL HEALTH SERVICES IN EARLY PSYCHOSIS CLINICS AND SELF-REPORTED FAMILY FUNCTIONING AND SUPPORT, AND SHARED DECISION MAKING WITH A DOCTOR

Susie Xiong^{*1}, Yen-Ling Chen², Tzuahzia Lee³, Kathleen Nye⁴, Valerie Tryon⁵, Laura M. Tully⁶, Stephanie Hayes⁶, Mark Savill³, Sabrina Ereshefsky³, Katherine Pierce⁷, Madison Miles⁵, Merissa Kado-Walton⁸, Katherine Nguyen⁶, Nitasha Sharma⁶, Amanda McNamara⁸, Christopher Hakusui⁶, Maliha Safdar⁸, Rachel Loewy⁹, Daniel I. Shapiro³, Khalima A. Bolden³, Karina Muro³, Yi Zhang¹⁰, Leigh Smith³, Adam B Wilcox¹¹, Rebecca Grattan³, Tara A. Niendam³, Cameron S. Carter³, Joy Melnikow¹², Daniel Tancredi¹³, For the EPI-CAL Group For the EPI-CAL Group¹⁴

¹University of California, Davis, ²UC Davis Dept. Psychiatry and Behavioral Sciences; Early Psychosis Programs, ³Department of Psychiatry and Behavioral Sciences, University of California Davis, ⁴Department of Psychiatry, University of California, Davis, ⁵Department of Psychiatry and Behavioral Sciences, University of California, Davis, School of Medicine, ⁶Department of Psychiatry and Behavioral Sciences, University of California-Davis, ⁷Department of Psychiatry and Behavioral Sciences, University of California, Davis, ⁸Herbert Wertheim School of Public Health and Human Longevity Science, University of California San Diego, ⁹Department of Psychiatry, University of California San Francisco, ¹⁰Center for Healthcare Policy and Research, University of California-Davis, ¹¹Washington University St. Louis, ¹²University of California, Davis, ¹³University of California Davis, ¹⁴For the EPI-CAL Group

Background: Research shows Asian Americans (AA) are 50% less likely than other ethnic groups to employ mental health services and have a higher percentage of unmet mental health treatment needs. Those connected to services have been reported as challenging, complex, or difficult to connect with, by their therapists. To add, American Psychological Association (APA) reported high premature termination of mental health services for AA. Some reasons for premature termination include discomfort with emotional display and personal disclosures that may be perceived as disloyal to the family, filial piety, lack of cultural understanding and communication and discussion by the therapist, and language barriers. Also, the family is an integral role within AA values and cultural systems and may impact individual's mental health service utilization. This pilot study aims to explore whether family functioning/support, and perceived shared treatment decision-making with a provider were related to AA premature termination in early psychosis (EP) clinics.

Methods: The pilot sample is from the EPI-CAL project and data was collected with Beehive. The sample included 8 individuals who were enrolled and discharged in EP clinics. Of the sample, 75% were female ($M = 19$ years old, $SD = 3.46$ years old). Additionally, 25% identified as AA only and 75% identified as biracial/multiracial. Premature termination of service was clinician-reported with Beehive. Family functioning/support was captured through self-report on beehive and with

The Systemic Clinical Outcome and Routine Evaluation (SCORE-15), which is 15-item on a 5-point Likert Scale (1=describes us very well, 5=describes us not well at all). Items that assessed self-reported shared decision-making were scored on a 6-point Likert scale (1=completely disagree, 6=completely agree). Descriptive statistics were reported for demographic and study variables. The active EPI-CAL project is continuously collecting data and anticipates an increase in sample size for additional analysis to examine the relationship between family functioning/family support, shared decision-making, and premature termination of services.

Results: The pilot sample indicated 25% did not complete the program. The SCORE-15 sum resulted a $M = 2.79$, $SD = 1.18$. Self-report of family support, "I feel like at least one of my parents/guardians understands or tried to understand my mental health" scored a $M = 3.85$, $SD = 1.34$. Among the shared decision-making items, the item "my doctor and I selected a treatment option together" yielded the highest score ($M = 5.4$; $SD = .89$); while participants scored lowest on the item "my doctor and I thoroughly weighed the different treatment options" ($M = 4.0$, $SD = 1.87$). The other shared decision-making items have the following scores: "my doctor told me that there are different options for treating my medical condition" $M = 4.80$, $SD = 1.30$, and "my doctor asked me which treatment option I prefer" $M = 4.6$, $SD = 1.67$.

Discussion: Participants mostly completed EP clinic services and 25% prematurely terminated. Participants reported they neither agree or disagree that they felt supported by at least one of their guardian and their family functioned well. Also, participants scored lower on thoroughly weighing in different treatment options with their doctor ("somewhat agree") when compared to selecting a treatment option together with their doctor ("completely agree"). This deserves further investigation to understand why participants felt that they selected a treatment with their doctor while they only somewhat agree that they engaged in a conversation with their doctor about different treatment options. Results produced show a trend shift in AA mental health data. Future directions include increasing the sample size to better understand the data results for a historically underserved population. Additionally, results emphasized the need for quality outreach within the AANHPI community given a significantly small sample size within the EPI-CAL project data.

S314. INTERPERSONAL DISTANCE IN SCHIZOPHRENIA

Natália Čavojská^{*1}, Vladimír Ivančík¹, Alexandra Straková¹, Jakub Januška¹, Jakub Kraus¹, Hana Hollá Kutlíková¹, Vanda Valkučáková¹, Anton Heretik¹, Ján Pečeňák¹, Michal Hajdúk¹

¹*Comenius University in Bratislava*

Background: Interpersonal distance (ID) refers to the physical space surrounding an individual during social interactions, describing the boundaries of intimacy. Research indicates that individuals with schizophrenia tend to prefer greater ID than those in the control group and the relationship between ID and severity of positive and negative symptoms was found. The present study aims to evaluate preferred ID in individuals with schizophrenia and its association with symptomatology.

Methods: The sample consisted of 40 patients (55 % females; age $M = 41.63$) diagnosed with schizophrenia spectrum disorders and 31 healthy controls (68 % females; age $M = 32.42$). Participants engaged with a same-sex researcher in two versions (approach and avoidance) of the Behavioral Approach Task. In the approach condition, participants were instructed to approach the researcher positioned 5 meters away and stop at a distance they found comfortable. Conversely, in the avoidance condition, the researcher approached the participant, who was asked to signal them to stop at a comfortable distance. Subsequently, participants rated the perceived pleasantness of each condition on the Visual analog scale. Psychopathological symptoms were assessed using the Brief Psychiatric Rating Scale and Community Assessment of Psychic Experiences. Group differences (HC vs SCH) across conditions (approach vs avoidance) for distance and pleasantness were evaluated using mixed repeated measures ANOVA. Associations with symptoms were assessed using Spearman Rank correlations.

Results: Repeated measures ANOVA for distances revealed a significant effect of condition ($F=17.05$, $p < .001$) and group ($F=15.31$, $p < .001$), while their interaction was nonsignificant ($F=1.04$, $p=.31$). Results from the subjective evaluation of pleasantness indicated a significant effect of condition ($F=14.74$, $p < .001$), a nonsignificant effect of group ($F=2.88$, $p=.09$), and a non-significant effect of the interaction ($F=.52$, $p=.47$). Participants demonstrated a preference for a lower ID when initiating contact ($1.02 \text{ m} \pm .54$) compared to being approached ($1.19 \text{ m} \pm .71$, $p < .001$). Additionally, they rated the approach condition as more pleasant (77.73 ± 20.28) than when the researcher was approaching them (72.09 ± 23.36 ; $p < .001$). Patients with SCH favored a larger ID than HC ($p=.001$). Notably, subjective assessments of pleasantness and interpersonal distances exhibited no significant correlations across groups. In individuals with SCH, ratings of pleasantness negatively correlated with self-reported positive ($r=-.35$; $p=.03$), negative ($r=-.36$; $p=.03$), and depressive symptoms ($r=-.35$; $p=.03$), as well as clinician-rated negative symptoms ($r=-.38$; $p=.02$). No significant associations between symptoms and measured ID were found.

Discussion: The present findings underline a preference for smaller interpersonal distances when initiating contact, aligning with the protective function traditionally associated with maintaining personal space. However, the perceived level of pleasantness did not directly influence individuals' preferred interpersonal distances. Patients with schizophrenia favored

larger interpersonal distances compared to healthy controls. Contrary to previous research, our study did not reveal a significant relationship between symptomatology and the actual preferred interpersonal distance across the groups. A possible explanation is that symptoms, such as social anhedonia and paranoia, may independently contribute to higher discomfort experienced during social situations and therefore the perception of interaction might be more important than the objective distance.

S315. INVESTIGATION OF SELF-DISTURBANCES WITH THE BODY DISTURBANCE INVENTORY (B-BODI) IN BRAZIL; A FEASIBILITY STUDY OF CULTURAL ADAPTATION.

Mariana da Silva¹, Renan Moreira Biokino², André Fernandes², Tatiana Baxter³, Sohee Park³, Ary Gadelha², Ary Gadelha de Alencar Araripe Neto*⁴

¹*Federal University of Sao Paulo/Univ. of Sao Paulo Medical School*, ²*Federal University of São Paulo*, ³*Vanderbilt University*, ⁴*PROESQ - EPM/UNIFESP*

Background: A central feature of schizophrenia is the alteration of the perception of boundaries between the body and the external environment, marked by symptoms of somatic passivity and opposition between "self and the world." Difficulties in integrating bodily sensations in individuals with schizophrenia (SZ) could lead to the emergence of anomalous affect, dissociated from cognitive contexts, and a disconnection of the self from the social world. However, there is a lack of culturally-valid methods to assess body disturbances. The goal of this pilot study was to translate and validate the B-BODI (Benson et al. Body Disturbances Inventory) into Brazilian Portuguese to investigate bodily disturbances including loss of self-other boundaries, agency and related impairments. We also examined the feasibility and acceptability of B-BODI in the context of culture.

Methods: This pilot study was part of the project for the translation and validation of the B-BODI Protocol in Brazil. The final version of the Brazilian version of the B-BODI protocol consisted of 7 images (6 depicting bodily disturbances and 1 control image). SZ outpatients with a stable dose of medication during the previous 4 week were recruited (mean age, 37.8 years; 80% male). Content analysis was conducted with 10 individuals regarding the B-BODI. They were asked about their personal impressions while answering B-BODI. B-BODI generated specific scores for frequency, vividness, distress, and positivity per each picture.

Results: Respondents reported having a good understanding of the images and captions. All participants completed the entire protocol and reported at least one anomalous bodily self-experiences. When asked further, SZ participants presented an adequate understanding of the experience depicted in the B-BODI image. Each item was endorsed by at least one respondent. Frequency and vividness of these experiences were mostly endorsed. Positivity was the least endorsed.

Discussion: The Brazilian version of the B-BODI was well tolerated and was completed by all participants. The B-BODI pictures were understood and evoked recognizable sensations by the Brazilian patient sample. Thus, there was no further need for a specific cultural adaptation. The next step is conduct a large-scale study to investigate dissociations body in schizophrenia in relation to symptoms, functional outcome and neural correlates.

S316. IMPLEMENTATION OF A COMMUNITY INTENSIVE TREATMENT TEAM: FLEXIBILITY IS THE ANSWER

Fernando Vílchez Español*¹, Rafael José Carrillo Molina¹, Sheila Cruz Bailén², Mirta Olga Solís³, Mercedes Valverde Barea¹

¹*Complejo Hospitalario de Jaén*, ²*Hospital San Agustín, Linares*, ³*Unidad de Salud Mental Comunitaria Baza*

Background: The Community Intensive Treatment Team (in spanish, ETIC) is an innovative model, based on flexible assertive community treatment (FACT), which seeks to provide a multidisciplinary service to achieve comprehensive care in people with serious mental illness at risk of abandonment of treatment or follow-up by Mental Health. The efficacy of people in treatment and follow-up by the ETIC of Jaen Sur is evaluated from its implantation until the first five months.

Methods: 27 patients were evaluated. Their diagnoses are described and a comparison is made of both adherence to treatment and follow-up from device implantation up to five months later, using the McNemar test to evaluate the relationship between the two variables.

Results: Of the 27 patients treated, 14 (52%) were diagnosed with schizophrenia spectrum disorders. 6 (22%) of bipolar disorder. 3 (11%) of affective psychosis. 2 (7%) of personality disorder. 1 (4%) of obsessive-compulsive disorder and 1 (4%) of anxiety disorder with agoraphobia. As regards adherence to treatment, 16 of the patients treated were not receiving treatment. 4 of them took it wrong and 7 took it right. At five months, only 4 people did not take treatment and 23 took it properly.

In terms of follow-up, 19 of them did not perform. 5 were attended only by nurses and 3 performed adequate follow-up. After five months, 3 patients did not follow up, 1 was attended only by nursing and 23 performed adequate follow-up. The results were statistically significant for both follow-up and treatment.

Discussion: Our experience in these first five months at the ETIC is that this model can address unmet needs in people with severe mental disorder.

S317. WHAT THE NOSE KNOWS: THE RELATIONSHIP OF OLFACTORY HEDONIC CAPACITY TO NEGATIVE SYMPTOMS AND INDICES OF REWARD IN SCHIZOPHRENIA

Seo Yeon Lee¹, Tabinda Khan¹, Gautami Shashidhar¹, Youjin Jang¹, Diane Beckman¹, Deanna Barch², Kathryn Lewandowski³, Diego Pizzagalli³, Bruce Turetsky⁴, Matthew Killam¹, Russell Schutt⁵, Matcheri Keshavan⁵, Raquelle Mesholam-Gately⁵, Matcheri Keshavan*⁶

¹*Beth Israel Deaconess Medical Center*, ²*Washington University*, ³*Harvard Medical School/McLean Hospital*, ⁴*University of Pennsylvania*, ⁵*Beth Israel Deaconess Medical Center/Harvard Medical School*, ⁶*Harvard University*

Background: The relationship between reward circuitry and the cognitive, emotional and behavioral deficits of schizophrenia (SZ) has garnered increasing attention in recent years, particularly given the vital role of reward in learning and social interactions and the considerable public health importance of its potential association with better cognitive and

social outcomes. Although various measures assess reward system processes, an increasing number of studies leverage the olfactory system to assess hedonic capacity across the psychosis spectrum. Amongst other benefits, standardized olfactory probes are reliable and easy to administer, and olfactory hedonic ratings often correlate with negative symptoms. In these analyses, we further explore the relationship between olfactory hedonic judgments and specific components of negative symptoms and other indices of reward.

Methods: Seventy-six participants (aged 19 - 74) diagnosed with SZ-spectrum disorders provided baseline data for these analyses as part of an ongoing clinical trial examining olfactory hedonic capacity (OHC) as a moderator of psychosocial intervention effectiveness. The NIH Toolbox Odor Identification Test was administered to examine olfactory identification abilities. Data from two participants with scores in the anosmic range were excluded from analyses, resulting in a final N of 74. Participants rated the hedonic valence of each odor by indicating specific values on a visual analog scale. Negative symptoms were evaluated with the Clinical Assessment Interview for Negative Symptoms (CAINS) and Positive and Negative Symptom Scale-6 (PANSS-6). Additional reward-related processes were assessed with the Temporal Experience of Pleasure Scale (TEPS), the Snaith-Hamilton Pleasure Scale, and the Behavioral Inhibition/Behavioral Activation System Scale (BIS/BAS). Associations between olfactory hedonic ratings and scores on symptom/reward indices were measured with Spearman's correlations.

Results: The results showed that the highest hedonic valence rating, lowest hedonic valence rating, and the average hedonic valence rating correlated significantly with negative symptomology and other indices of reward, namely anticipatory and consummatory pleasure. Several significant correlations were observed between olfactory hedonic ratings and measures of negative symptoms and reward processes. Most notably, average hedonic valence was inversely correlated with total negative symptoms from the PANSS-6 ($r_s = -.26$, $p < .05$), largely driven by the N1 item of blunted affect ($r_s = -.24$, $p < .05$) and N4 item of social withdrawal ($r_s = -.27$, $p < .05$). Additionally, average hedonic valence positively correlated with anticipatory pleasure ($r_s = .39$, $p < .001$) and consummatory pleasure ($r_s = .34$, $p < .01$) from the TEPS.

Discussion: The results showcased the relationship between OHC, negative symptoms and other indices of reward, providing further support for the use of olfactory hedonic probes as translational correlates of reward circuitry dysfunction. These preliminary data are expected to inform a highly promising line of research, including examining the predictive utility of OHC measurement for targeted psychosocial rehabilitation, that is critical for advancing the treatment of functional impairment in schizophrenia.

S318. READMISSIONS OF PSYCHOTIC DISORDERS IN A BRIEF HOSPITALIZATION PSYCHIATRIC UNIT FROM 2019 TO 2022: THE ROLE OF ADHERENCE TO SERVICES AND LONG ACTING INJECTABLES FOR PREVENTIVE APPROACHES

Sara Vega-García^{*1}, José María Pelayo-Terán², María Camino Fernández-Borregán², Mario Manuel Martínez-Pérez², Marcos Gómez-Revuelta³, Ruth Landera-Rodríguez², María Estrella García-Llamas², Zaida Gutierrez-Hervás², Raquel Martín-Gutierrez², Elena Martín-Gil², Nicolás Martín-Navarro², Flora María Vega-Fernández², Eva María Romero-Gómez², Yolanda Zapico-Merayo²

¹Hospital el bierzo, ²Servicio de Psiquiatría y Salud Mental. Hospital el Bierzo. GASBI. SACYL, ³Servicio de Psiquiatría y Salud Mental. Hospital Universitario Marqués de Valdecilla

Background: Psychosis causing great disability to the patients' normal function and burden to families, particularly during admissions.

One challenge is to improve adherence to treatments and to prevent rehospitalizations.

This study evaluates patients with psychotic disorders admitted to treatment in a hospital inpatient unit for a 4 year period to evaluate the risk of rehospitalizations and the clinical factors associated.

Methods: We evaluated the hospitalizations in the acute psychiatric Unit of Hospital El Bierzo (Spain, Catchment area of 131646 hab) with an ICD-10 Psychotic disorder diagnosis (F20-29) between 2019 and 2022.

Time to rehospitalization was evaluated with a Kaplan-Meier survival analysis. Predictors were included in a cox regression analysis with a backward-Wald model. Finally, we analyzed the factors that predict the use of LAI antipsychotics, with a logistic regression analysis (backward-Wald model).

Results: 1322 subjects were admitted from 2019 to 2022. 491 (37.1%) had a diagnosis of psychosis, the most frequent diagnosis. 57.8% were males, mean age: 45.87 ± 14.69 years. The rates increased from 115 in 2019 (8.73/10000hab) to 116 in 2020 (rate: 9.85), 126 in 2021 (9.82) and 134 in 2022 (10.50). The differences were not significant ($p=0.670$).

208 (42.4%) rehospitalized. Hospitalizations during pandemics (2020-2021) had a higher probability of rehospitalization within the year (41.3%) compared to post pandemic year (25.42; χ^2 : 9.617; $p=0.008$). The survival analysis showed a mean survival of 817.42 days (IC95% 755.11-874.74) and a median survival of 1037 days (IC95% 676.03-1397.97). Those patients with a partial adherence showed a inferior mean survival of 645 days and a median of 335 days (Log Rank of Mantel-Cox χ^2 : 6.247; p is 0.044).

Rehospitalized subjects were younger (43.8 years vs 47.4; T :-2.702; $p=0.008$), have more previous hospitalizations (54.1% vs 33%; χ^2 : 22.230; p LESS THAN 0.001), were more frequently from prepandemic period (p LESS THAN 0.001), less adherent (40.9% vs 59.6%; χ^2 : 9.334; $p=0.009$), had more suicide behavior (52.9% vs 40.7%; χ^2 : 3.618; $p=0.057$). The Cox regression model included age (ExpB: 0.987; $p=0.013$), previous hospitalization (ExpB: 0.551; p LESS THAN 0.001), substances (ExpB: 1.397; $p=0.043$, adherence (ExpB: 0.729; $p=0.038$) and suicide behavior (ExpB: 0.716; $p=0.077$) in the model (χ^2 : 35.667; p LESS THAN 0.001)

The logistic regression used to predict the indication of LAIs to improve the adherence at discharge was significant; χ^2 : 47.273; p LESS THAN 0.001 χ^2 : 47.273; p LESS THAN 0.001 and classified correctly 62.7% of the subjects.

The factors included by the model were involuntary hospitalization, tobacco abuse, substance use, length of hospitalization and the concomitant use of antidepressants.

Discussion: Maintaining adherence appears to be the one of the keys in preventing relapse. LAI may be a useful treatment to patients with psychotic disorders that may help to improve adherence taking into consideration other relevant factors.

S319. SCHIZOPHRENIA AND AUTISM: NOT THE SAME

Rafael Rodriguez-Garcia*¹, Nuria Planet Nielsen², Montse Roquer³, Maria Teresa Burguete⁴, Eva Faure³, Sira Diaz Moran³

¹CAS Delta, ²CAS Delta, badalona, ³CAS Delta, Badalona, ⁴CAS Delta Badalona

Background: Autism spectrum disorder (ASD) and schizophrenia are distinct psychiatric conditions with different features and diagnostic criteria. We present a clinical case with a new diagnostic approach after not meeting criteria for schizophrenia.

Methods: 45-year-old patient referred for alterations in thought content and cocaine use. This is a woman, transsexual since adolescence, with a single psychotic episode in 2012. Born in Brazil, resident in Spain since she was 18 years old. He presents alterations in sociability since childhood, he presented selective mutism until the age of 7, repetitive and stereotyped behaviors. Parental rejection due to sex change in a religious family. Oriented as schizophrenia after a psychotic episode in 2012 after cocaine consumption. Subsequent remission ad integrum of the symptoms. Maintains unusual beliefs during adulthood secondary to alterations in sociability, perception of the world, and social rejection. Schizophrenia is ruled out because there are no positive or negative symptoms during the course and the diagnosis is oriented toward autism spectrum disorder.

Results: ASD is a neurodevelopmental disorder that typically manifests in early childhood. It is characterized by challenges in social communication and interaction, as well as restricted and repetitive behaviors. Individuals with ASD may have difficulties in socializing, forming relationships, and communicating effectively. Core symptoms of ASD include challenges in social communication and the presence of repetitive behaviors or interests. Signs of ASD are typically present in early childhood, often before the age of three. The symptoms may become more apparent as a child grows and interacts with others. Individuals with ASD may exhibit variations in cognitive abilities, with some having intellectual disabilities and others having average or above-average intelligence. Schizophrenia is a psychotic disorder that usually emerges in late adolescence or early adulthood. It involves a range of symptoms, such as hallucinations, delusions, disorganized thinking, and impaired emotional regulation. People with schizophrenia may experience a disconnect from reality, affecting their perception of the world. Symptoms of schizophrenia include positive symptoms (hallucinations, delusions), negative symptoms (diminished emotional expression, reduced motivation), and cognitive symptoms (impaired executive function, memory deficits). Onset usually occurs in late adolescence or early adulthood. The symptoms of schizophrenia may develop gradually or suddenly, and the course of the disorder can vary widely among individuals. Cognitive impairments are often observed in individuals with schizophrenia, affecting memory, attention, and problem-solving skills.

Discussion: It's important to note that while these conditions are distinct, comorbidity (the presence of both conditions in the same individual) can occur. Additionally, advances in research may lead to updates in our understanding of these disorders over time. Seeking professional advice and evaluation is crucial for accurate diagnosis and appropriate intervention.

S320. HYPOTHALAMIC-PITUITARY-ADRENAL AXIS GENES AND COGNITION IN SCHIZOPHRENIA SPECTRUM DISORDERS: A SYSTEMATIC REVIEW

Alex Ferrer*¹, Anna Barnes¹, Ariadna Pelegrí¹, Victor Del Rio¹, Siddarta Acebillo¹, Javier Labad², Diego Palao¹, Virginia Soria¹

Background: Schizophrenia (SCZ) and other psychotic disorders are highly heritable, however results from genetic association studies are highly inconsistent. For this reason, the endophenotype approach has been increasingly used, in which association between genetic factors and quantitative traits associated to core elements of genetically complex diseases has been studied. Two well characterized endophenotypes in patients suffering from psychotic disorders are dysregulations in hypothalamic-pituitary-adrenal (HPA) axis activity and cognitive impairment, which is considered one of the core features of the disease. We hypothesized that genetic variations in HPA related genes would have an influence on cognition in patients with SCZ spectrum disorders. Our objective was to perform a systematic review dealing with the involvement of genetic and epigenetic variations in HPA axis related genes on cognitive performance in patients with SCZ and other psychotic disorders.

Methods: A systematic search was performed using PubMed, PsychInfo and Scopus databases. Studies were included only if they obtained data on genes related to the HPA axis including CRH, CRHR1, CRHR2, CRHBP, NR3C1, NR3C2 or FKBP5, assessed the association between genetic data with measured neurocognitive variables and the sample included patients with diagnosed SCZ spectrum disorders.

Results: Seven studies were identified focusing in the association between variations in HPA axis related genes and cognition in patients with psychotic disorders.

Five of the identified publications were centered on single nucleotide polymorphisms (SNPs) in the FKBP5 gene. Among them, only one study analyzed measures of “hot” cognition and found an association between rs1360780 and attention bias for threat and hippocampal morphology. The other four works pointed out measures of “cold” cognition and some positive and negative findings were found. Two studies found significant associations between FKBP5 SNPs and several cognitive measures including global cognitive performance, attentional capacity, language ability and global IQ estimates. The remaining two studies could not identify any significant associations.

The last two studies analyzed methylation levels in the FKBP5 and NR3C1 promoter regions respectively. The first work showed that in patients with first episode psychosis and relapsed schizophrenia, lower FKBP5 methylation might be associated with better cognitive performance. The second study demonstrated that higher NR3C1 methylation was associated to worse delayed memory, attention and general functioning in patients with psychosis and not in other groups.

Discussion: This review supports the hypothesis that both genetic and epigenetic variations within HPA axis related genes might influence cognition in patients suffering from psychotic disorders. The influence of FKBP5 and NR3C1 variants on cognition has also been reported in samples of healthy individuals and individuals suffering from different mental disorders. However, available data is scarce, future research in samples including SCZ spectrum disorders and HPA axis variants would be of great interest to help generate a genetic profile associated to increased cognitive dysfunction, which could be used to select subjects whom might benefit from specific interventions targeting cognition.

S321. LONELINESS IN CHILDHOOD AND FIRST-EPISODE PSYCHOSIS

Background: Loneliness or perceived social isolation refers to the subjective feeling of distress associated with a lack of meaningful relationships, irrespective of the quantity of social contact. This is in contrast to objective social isolation, which is defined as an actual lack of social connections, including interactions, contacts, or relationships. Evidence from observational and genetic studies suggests a bidirectional relationship between loneliness and psychosis. Loneliness in childhood is associated with increased odds of anxiety and depressive disorders in young adults, thus suggesting its potential as an early risk marker for mental disorders. To our knowledge, no previous study has examined the association between loneliness in childhood and first-episode psychosis (FEP).

In this study, we aimed to assess the association between loneliness in childhood and the odds of FEP and to explore gender differences in this association.

Methods: This was an observational, cross-sectional, case-control study, based on the AGES-CM cohort, a longitudinal prospective study including patients with FEP ages 7-40 and an age- and sex-matched sample of controls in seven university hospitals in the region of Madrid, Spain.

We assessed loneliness in childhood with the question "Have you ever felt lonely for more than 6 months before the age of 12" and objective social isolation with the peer relationships item from the childhood subscale of the Premorbid Adjustment Scale.

We conducted logistic and linear regression analyses to assess the association between childhood loneliness and i) the odds of presenting a FEP and ii) clinical variables of interest,

including diagnosis and scores on positive, negative, and general symptoms measured by the Positive and Negative Syndrome Scale, as well as global functioning measured by the Global Assessment of Functioning Scale. These analyses were adjusted for demographic variables.

Results: The study sample comprised 285 patients with FEP (32.6% female, age 24.50 ± 6.2 years) and 261 controls (48.7% female, age 25.93 ± 5.5 years). Objective social isolation and loneliness in childhood were associated with increased odds of FEP (adjusted odds ratio; aOR: 2.87, 95% CI [1.16-7.09], $p=.022$ and aOR: 2.17, 95% CI [1.40-3.51], $p=.002$, respectively). The association between loneliness in childhood and FEP remained significant after controlling for objective social isolation in childhood (aOR: 2.70, 95% CI [1.58-4.62], p LESS THAN .001). We found opposite effects of childhood loneliness in participants not presenting objective social isolation during childhood (aOR: 2.68, 95% CI [1.56-4.60], p LESS THAN .001) relative to those presenting objective social isolation (aOR: 0.33, 95% CI [0.08-1.45], $p=.142$).

The effect of the association between loneliness in childhood and FEP was stronger in females (aOR: 4.74, 95% CI [2.23-10.05], p LESS THAN .001) than in males (aOR: 1.17, 95% CI [0.63-2.19], $p=.623$). In females with FEP, loneliness in childhood was significantly associated with reduced odds of receiving a schizophrenia spectrum disorder diagnosis relative to other diagnoses (aOR: 0.155, 95% CI [0.048-0.506], $p=.002$). In the FEP sample, loneliness in childhood was associated with greater severity of positive and general symptoms, as well as poorer global functioning.

Discussion: Loneliness in childhood is associated with increased odds of first-episode psychosis and clinical variables of interest. This association appears to extend beyond the effects of objective social isolation and is particularly pronounced in females. These findings suggest the potential of this phenotype as an early risk marker for psychosis that could help guide targeted interventions.

S322. ILLNESS-RELATED VARIABLES AND ABNORMALITIES OF RESTING-STATE BRAIN ACTIVITY IN SCHIZOPHRENIA

Giulia Giordano*¹, Pasquale Pezzella², Luigi Giuliani², Leonardo Fazio³, Armida Mucci², Andrea Perrottelli², Giuseppe Blasi⁴, Mario Amore⁵, Paola Rocca⁶, Alessandro Rossi⁷, Alessandro Bertolino⁴, Silvana Galderisi²

¹University of Campania "Luigi Vanvitelli", ²Department of Psychiatry, University of Campania "Luigi Vanvitelli", ³Department of Medicine and Surgery, LUM University, ⁴Department of Basic Medical Science, Neuroscience and Sense Organs, University of Bari 'Aldo Moro', ⁵Department of Neurosciences, Rehabilitation, Ophthalmology, Genetics and Maternal and Child Health, Section of Psychiatry, University of Genoa, ⁶Department of Neuroscience, Section of Psychiatry, University of Turin, ⁷Department of Biotechnological and Applied Clinical Sciences, Section of Psychiatry, University of L'Aquila

Background: Schizophrenia is a complex mental disorder characterized by a large heterogeneity in terms of risk factors, pathophysiology, clinical presentation, and functional outcome. A huge number of illness-related variables, such as positive symptoms, disorganization, depression, negative symptoms and cognitive impairment has a great impact on functioning of people affected from this disorder. Among these variables, cognitive deficits and negative symptoms seem to be the most important predictors of a poor functional outcome.

In order to disentangle the pathophysiological heterogeneity of schizophrenia, the aim of the present study was to investigate the relationships between clinical features and abnormalities in resting-state brain activity in people with schizophrenia.

Methods: Resting-state (rs) functional MRI data were analyzed in 62 subjects with schizophrenia (SZs) and 46 healthy controls (HCs), as part of the add-on brain imaging study of the Italian Network for Research on Psychoses. The selected ROIs were the dorsolateral prefrontal cortex (DLPFC), the ventrolateral prefrontal cortex (VLPFC), the orbitofrontal cortex (OFC), the precuneus (PCun), the inferior parietal lobule (IPL), the temporo-parietal junction (TPJ), the superior temporal gyrus (STG), the ventral anterior insula (vaIC), the dorsal anterior insula (daIC), the posterior insula (pIC), the lateral occipital cortex (LOC), the dorsal anterior cingulate cortex (dACC), the amygdala (Amy), the nucleus accumbens (NaC), the ventral caudate (vCa), the dorsal caudate (dCa), and the putamen (Pu).

The Positive and Negative Syndrome scale was used to measure positive symptoms and disorganization, the Calgary Depression Scale for Schizophrenia to assess depression, the Brief Negative Symptom Scale for negative symptoms and the MATRICS Consensus Cognitive Battery to assess six neurocognitive domains.

Between-group comparisons were performed with χ^2 and one-way analysis of variance (ANOVA) tests, according to the type of variable. In addition, we performed regression analyses using the cognitive performance and the psychopathology as predictors, and the resting-state data as the explained variable.

Results: The SZs, compared to the HCs, showed higher rs functional activity of the right IPL and right TPJ junction, and lower rs activity of the right DLPFC, the bilateral dACC, and the ventral and dorsal caudate. Furthermore, deficits in the attention and vigilance (AV) and in reasoning and problem solving together with conceptual disorganization were associated with the rs activity of the right IPL and right TPJ. Deficits in AV together with depression were associated with the rs functional activity of the right DLPFC while, independently from psychopathology and other cognitive functions, these deficits in AV predicted the rs activity of the right and left dACC. The Expressive Deficit domain of negative symptoms was associated with the rs activity of the left vCa, while the Motivational Deficit with that of the right and left dCa.

Discussion: Our results suggested that neurocognitive functions (in particular attention and vigilance) and the two negative symptom domains were independently associated with the rs activity of different brain regions. Furthermore, in line with the literature, we demonstrated how the two domains of negative symptoms are subtended by different pathophysiological mechanisms. A better understanding of the neurobiology of cognitive deficits and negative symptoms could foster the development of innovative treatment strategies targeting these aspects that still represent an unmet need in the care of schizophrenia.

Disclosure of Interest: None Declared

S323. HOW DO AFFECT AND MEMORY FOR SOCIAL APPROVAL IN SCHIZOPHRENIA RELATE TO DAILY SOCIALIZATION: LINKING EVIDENCE FROM A NOVEL BEHAVIORAL TASK TO REAL-WORLD REPORTS OF SOCIAL BEHAVIOR

Jaisal Merchant^{*1}, Erin Moran¹, Deanna Barch¹

¹Washington University in St. Louis

Background: Despite evidence that individuals with schizophrenia (SZ) and healthy individuals (HC) have a similar desire for social relationships and experience similar momentary pleasure from socialization, SZ report smaller social networks and may have reduced motivation for daily social goals. Literature on reward and motivation suggests that SZ have a disruption in the ability to translate intact momentary pleasure to motivated behavior for positive outcomes. This could stem, in part, from difficulty maintaining emotional memory of positive experiences, which may inhibit SZ from predicting that certain behaviors could lead to similar pleasurable outcomes. It is important to further explore this link and examine whether this process extends to the social domain of reward and motivation in SZ. The current project examines the relationship between affective responses to positive vs. negative social experiences, implicit memory for these experiences, and real-world social behavior in SZ vs. HC.

Methods: SZ (n=32) and HC (n=44) completed a novel Prediction of Social Liking Task (PoSLiT) (developed by the presenter) and one week of ecological momentary assessment (EMA). In the PoSLiT participants are shown photos of “peers” who are said to be other study participants who have previously seen their photo (taking of said photo was mimicked at a prior session) and determined whether they thought they would like them. For the first half of the task, participants are presented with a peer photo, asked to indicate whether they think they would like the person pictured, and then presented with that peer’s positive or negative opinion of them: “This person thought they would like you” (social approval- 50% of opinions) vs. “This person thought they would not like you” (social disapproval- 50% of opinions). Participants then indicate their momentary affective response to that opinion on a 5-point Likert scale (“extremely upset” - “extremely happy”). In the second half, the same peer photos are presented in randomized order and participants are asked whether they think the person pictured would like them. Accuracy on this response indicates implicit social memory. The EMA portion of the study involves answering questions about current and planned activities in real-time in participants’ daily lives.

Results: SZ and HC did not differ in their affective responses to peers’ reported positive or negative opinions of them on the PoSLiT ($\beta = 0.11$, $p = .17$). Implicit memory for these opinions showed a trend-level group X opinion interaction with follow-up analyses demonstrating that HC were significantly more accurate in their memory for social approval than disapproval (OR= 5.91, $p = .00$), while this positive vs. negative nature of peer opinions did not differentially relate to implicit memory in SZ (OR= 1.76, $p = .31$). Though not significant, SZ were marginally worse than HC at remembering social approval (63% vs. 73%, $p = .06$), while HC were numerically less likely than SZ to remember social disapproval (46% vs. 55%, $p = .17$). Across participants, EMA reports of frequency of real-world current and planned socialization were positively related to memory for social approval (current: OR= 1.02, $p = .02$, planned: OR= 1.01, $p = .04$), but not to memory for social disapproval, nor to affective response to social approval or disapproval. The main effect of current socialization on memory for social approval was modified by a group X current socialization interaction, with follow-up analyses indicating that frequency of current socialization was related to memory for social approval in HC (OR= 1.10, $p = 0.01$) but not in SZ. Groups did not significantly differ in the relationship between planned socialization and memory for social approval.

Discussion: Results from the PoSLiT indicate that SZ and HC had similar momentary affect in response to positive and negative social experiences (i.e., social approval vs. disapproval). However, unlike SZ, HC demonstrated differentially better memory for social approval than disapproval. Thus, SZ may be specifically impaired in their memory for positive social outcomes. Unlike momentary affect, increased memory for positive (but not negative) peer opinions was related to more real-world plans for socialization across groups, and to more

experienced socialization in HC. This aligns with suggestions that maintenance of emotional memory for positive outcomes may play a role in driving motivated behavior for these experiences. It could also indicate that the positively biased memory for peer opinions in HC could be protective for the pursuit of social activities.

S324. THE EVOLUTION OF CONTROL OVER VOICE HEARING EXPERIENCES

Silmilly Toribio*¹, Catalina Mourgues-Codern¹, Albert Powers III²

¹*Yale University*, ²*Yale University School of Medicine*

Background: Auditory verbal hallucinations are a common symptom of psychosis, often debilitating and interfering significantly with daily life. Nevertheless, some individuals can exert voluntary control over these voices. Qualitative studies have revealed that this control is cultivated over time, with individuals adopting a variety of strategies to manage their voices. The specific factors that may facilitate the development of such control remain uncertain. This study investigates the potential roles of intrusive thoughts, a predisposition towards hallucinations and delusions, diagnoses within the psychosis spectrum, depression, and beliefs about the voices as factors that could influence the acquisition of control over time.

In this study, we investigated the evolution of control over auditory hallucinations over time, using a self-report questionnaire to assess changes from the onset of the voices to the current level of control.

Methods: We selected 632 participants from the Yale Control Over Perceptual Experiences (COPE) study who experienced auditory hallucinations at least once a week for the past month. A stepwise regression analysis was performed, with the change in the degree of control over the hallucinations as the dependent variable, and as independent variables, sex and gender were included as well as the presence of psychosis spectrum diagnosis, then the self-report questionnaires were included, White Bear Suppression Inventory (WBSI), Launay-Slade Hallucination Scale (LSHS), Auditory Hallucinations Rating Scale (AHRS), COPE scale, Patient Health Questionnaire (PHQ) and Peters et al. Delusions Inventory (PDI) to understand the dynamics of this control over time.

Results: The final model explained 25% of the change of control over the voices. These preliminary findings suggest that contrary to expectations, neither a diagnosis within the psychosis spectrum ($B = -.021$) nor symptom-related measures such as the PDI ($B = -.028$), LSHS ($B = .064$), WBSI ($B = -.048$) significantly predicted changes in control over time. Instead, individuals' beliefs about their voices emerged as significant predictors of change in control (Malevolent voices $B = .210$, benevolent voices, $B = .358$ and Omnipotence, $B = -.403$, $P < .05$), along with levels of depression (PHQ, $B = -.126$, $P = .029$) and severity of verbal hallucinations ($B = .101$, $P = .026$). Specifically, the belief in the omnipotence of voices was associated with less change in control, while perceptions of malevolent or benevolent voices correlated with increased control.

Discussion: Understanding the connection between one's beliefs regarding the content and significance of auditory hallucinations and the level of control over these experiences is crucial. A higher level of power associated with the voices seems to correspond with a diminished ability to control them over time, implying a potential decline in the individual's sense of agency.

An exploration of the perceptions surrounding the content of auditory hallucinations emerges as a promising avenue for developing control. Notably, the content of the voices is linked to a

heightened degree of control, whether perceived as malevolent or benevolent. Moreover, this implies that the affective responses elicited by the auditory hallucination content may exert a limited influence on the individual's ability to regulate the voice-hearing experience.

Examining therapeutic interventions targeting these beliefs is crucial. Shaping early beliefs about voices may enhance the likelihood of engaging with them and developing control. A longitudinal study in the same cohort is ongoing, offering a chance for a comprehensive analysis of psychosis symptom management dynamics, potentially identifying more effective treatments.

S325. METABOLIC SYNDROME AND NEUROCOGNITIVE IMPAIRMENT IN FIRST-EPISODE SCHIZOPHRENIA SPECTRUM DISORDERS

Lebogang Phahladira*¹, Hilmar Luckhoff¹, Leigh Van Den Heuvel¹, Retha Smit¹, Bröcker Erine¹, Laila Asmal¹, Robin Emsley¹, Soraya Seedat¹

¹*Stellenbosch University*

Background: First-episode schizophrenia spectrum disorders (FES) are associated with subclinical metabolic abnormalities. The relationship between metabolic features and cognitive impairments is not clear cut.

Methods: We examined the associations between metabolic syndrome (MetS) and neurocognitive function in patients with first-episode schizophrenia spectrum disorders (FES) compared to controls assessed using the Repeatable Battery for the Assessment of Neuropsychological Status. In patients, psychopathology was assessed using the Positive and Negative Syndrome Scale and Calgary Depression Scale for Schizophrenia.

Results: First, we found illness- and domain-specific associations between the individual MetS features and neurocognitive performance in patients, but not in controls. Second, body mass index and total cholesterol levels were lower in patients than controls, which in turn correlated with increased global psychopathology severity and cognitive deficits. Third, negative symptoms moderated the association between low HDL cholesterol and poorer immediate verbal memory performance in patients.

Discussion: Our findings suggest that distinct lipid profile alterations are associated with cognitive performance and psychopathology severity in patients with FES. Further studies are needed to explore the associations of MetS with neurocognition over time, as well as how these relationships are affected by socio-demographic and clinical factors, including depression, anxiety, and related psychopathology.

S326. AN EVALUATION OF MEDICATION PRESCRIBING PRACTICES IN EARLY PSYCHOSIS PROGRAMS IN CALIFORNIA, USA

Apurva Bhatt*¹, Mark Savill², Katherine Pierce³, Briana Sepulveda², Kate Hardy⁴, Regina Graham², Kathleen E. Nye⁵, Valerie Tryon⁶, Lindsay Banks⁷, Kristin LaCross⁸, Christopher Blay⁸, Stephania Hayes⁹, Sabrina Ereshefsky⁹, Adrian F. Asbun⁹, Daniel Shapiro¹⁰, Katherine Eisen⁴, Misha Carlson⁸, Tara Niendam⁹

¹Stanford University School of Medicine, ²University of California Davis, ³Department of Psychiatry and Behavioral Sciences, University of California, Davis⁴Stanford University, ⁵University of California, Davis, School of Medicine, ⁶UC Davis Medical Center, ⁷Case Western Reserve University, ⁸University of California San Francisco, ⁹University of California, Davis, ¹⁰UC Davis Dept. Psychiatry and Behavioral Sciences; Early Psychosis Programs

Background: Coordinated Specialty care programs for early psychosis are multidisciplinary teams that include psychiatric providers (psychiatrists and nurse practitioners) who participate in assessment, offer physical health services and medication management. These programs work with individuals experiencing a first episode of psychosis (FEP) and/or clinical high risk psychosis syndrome (CHRP). EPI-CAL is a statewide effort in California, USA to support a learning healthcare network approach to early psychosis care. The objective of this study was to evaluate prescribing patterns in early psychosis programs across EPI-CAL.

Methods: We evaluated data from the EPI-CAL Fidelity Assessment. Each fidelity assessment was conducted using the First Episode Psychosis Services - Fidelity Scale, which involved interviewing key providers, program administrative data, and health record data from a randomized sample of 10 service users. We evaluated data regarding prescribing practices by licensure type, and assessed antipsychotic medication prescribing patterns (polypharmacy, use of clozapine for treatment-resistant psychosis, adherence to evidence-based dosing guidelines for first episode psychosis, and use of antipsychotic medication for CHRP).

Results: Of the 22 participating early psychosis programs, 9 programs had psychiatrists in the psychiatric provider role, 6 had nurse practitioners, 6 had both psychiatrists and nurse practitioners, and one program had an unknown psychiatric provider. Of the 43 service users served just by nurse practitioners, 20.9% received more than one antipsychotic, as compared to 9.7% amongst who were served just by psychiatrists (3/31 service users). 10 programs had prescribing practices where GREATER THAN 60% of service users assessed received antipsychotic doses within recommended guidelines, while 4 programs had prescribing practices with LESS THAN 59% of individuals receiving medication within recommended guidelines. Only 9/16 (56.3%) programs prescribed Clozapine, presumably for treatment-resistant psychosis. Of 15 programs assessed that provided services to individuals with CHRP, 9 were prescribing antipsychotics to GREATER THAN 20% of clients diagnosed with CHRP, contrary to best practice guidelines.

Discussion: Antipsychotic polypharmacy amongst individuals with FEP, and the prescription of antipsychotics to individuals with CHRP was found to be relatively common across the EPI-CAL network. This is concerning, as both practices are inconsistent with current best practices guidelines. Nurse practitioners, who as of 2023 in California can prescribe independently, demonstrated greater polypharmacy prescribing patterns compared to psychiatrists. Almost half of programs assessed were found not to be prescribing Clozapine, which is indicated after a service user does not experience a favorable response to two prior adequate trials of antipsychotic medication. These findings highlight the need for increased support and education around best practices for medication management of early psychosis in community programs.
